W. Crookes, and A. Lamy observed that **thallous oxide,** Tl_2O, is formed when thallium oxidizes in air ; if the oxidation occurs about dull redness, the higher oxide is formed. A. Lamy obtained it by heating to 100° thallous hydroxide out of contact with air. Thallous oxide is a black powder. A. Lamy found that thallous oxide melts at about 300°, forming a dark yellow liquid which rapidly attacks glass, producing a silicate. W. O. Rabe said that thallous oxide is yellow at ordinary temp., and becomes dark red when heated ; it is not melted at 870°. J. Thomsen gave for the heat of formation, (2Tl, O)=42·24 Cals. W. Crookes, and A. Lamy found that thallous oxide is slowly reduced when heated to redness in hydrogen ; H. Flemming said that the reduction proceeds more rapidly in a stream of carbon monoxide. According to G. Wyrouboff, thallous oxide is slowly oxidized to thallic oxide by air at ordinary temp., and rapidly, when heated. A. Lamy found that thallous oxide rapidly absorbs moisture from the air, forming yellow thallous hydroxide ; the oxide is also soluble in water, and in alcohol, forming, in the latter case, alcoholates. Thus, with absolute ethyl alcohol, *thallous ethoxide,* $C_2H_5.OTl$, is formed as a very refracting liquid of sp. gr. 3·5, which is decomposed by water into ethyl alcohol and thallous hydroxide. Thallous oxide is readily attacked by chlorine, bromine, or iodine, forming thallous halide and oxygen. Acids convert thallous oxide into thallous salts. G. Rauter found that when thallous oxide and silicon tetrachloride are heated to 360°–370°, thallous chloride and silica are formed ; similarly with silicon tetrafluoride. C. Winkler found thallous oxide is completely reduced when heated with magnesium.

R. Bottger found that if thallium is kept under water which contains air in soln., **thallous hydroxide,** TlOH, is formed, and F. Bahr made the hydroxide by passing oxygen through cold water and thallium turnings. The liquid is kept agitated during the passage of the gas. When the sat. soln. is further shaken, yellow crystals of thallous hydroxide separate, and further crystals are obtained by evaporation in a vacuum desiccator over potassium hydroxide. The crystals are then collected by means of a special filter in an atm. of hydrogen, washed with ice-cold water and alcohol, and dried in hydrogen. The product is free from lead. A. Lamy made the hydroxide by the action of water on thallous oxide ; by the action of an eq. quantity of barium hydroxide on a soln. of thallous sulphate ; and by the action of calcium hydroxide on thallium oxalate. R. de Forcrand obtained a good yield of the hydroxide, as a yellow crystalline powder, by adding to thallous ethoxide in the cold an equal vol. of water, and drying the precipitate on porous plates out of contact with air. J. E. Willm made a conc. soln. of the hydroxide by repeatedly heating thallium to 100° and dipping it in water ; and G. Bredig made a **colloidal solution** of thallous hydroxide by making an arc between thallium electrodes under water.

A. Lamy stated that thallous hydroxide crystallizes from its aq. soln. in long yellow needles. According to A. Lamy, the dried hydroxide at 100°, or at ordinary temp. in vacuo, is transformed into black thallous oxide. F. Bahr measured the vap. press., *p* mm., of the hydroxide and found :

	46·3°	79·1°	83·2°	91·8°	101·6°	110·6°	122·2°	135·7°	140·0°
p . .	13	42	73	110	163	279	364	673	770

The results are represented by $\log p = -Q/2{\cdot}3RT + 1{\cdot}75 \log T + 3{\cdot}6$, where T denotes °K., and Q the heat of the reaction, $2TlOH = Tl_2O + H_2O$, which, from the equation $d(\log p)/dT = -Q/RT^2$, is 14·1 Cals., and from W. Nernst's equation $Q = 4{\cdot}57T(7{\cdot}15 \log T + 3{\cdot}6 - \log p)$ is 15·2 Cals—J. Thomsen gave $(Tl_2O, H_2O_{liq}) = 3{\cdot}23$ Cals., and allowing 9·65 Cals. for the vaporization of water at 100°, the heat of the reaction $2TlOH = Tl_2O + H_2O$ becomes 12·88 Cals., which is rather low. The dissociation temp. at 760 mm. press. is 139°. J. Thomsen gave for the heats of formation $(2Tl, O, H_2O) = 85{\cdot}4$ Cals., and $(Tl, O, H) = 56{\cdot}9$ Cals. ; and for the heat of soln. of a mol in 235 mols of water, −3·15 Cals. R. de Forcrand gave for the heat of soln. of the oxide and hydroxide in dil. hydrofluoric acid 3·117 Cals., J. Thomsen gave 3·231 Cals., hence, added the former, the heat of hydration is far removed from that of the alkali metals, but thallous hydroxide is nevertheless an equally powerful base; and towards the feeble acids, phenols, etc., it shows even stronger basic properties than the alkali hydroxides. E. Petersen gave for the heat of neutralization, $\mathrm{TlOH_{aq.}+HCl_{aq.}=TlCl+13{\cdot}74}$ Cals., and J. Thomsen, 13·84 Cals. The latter also gave $\mathrm{2TlOH_{aq.}+H_2SO_{4aq.}=Tl_2SO_{4aq.}+31{\cdot}13}$ Cals.; and $\mathrm{TlOH_{aq.}+HNO_{3aq.}=TlNO_{3aq.}+13{\cdot}69}$ Cals. F. Bahr showed that thallous hydroxide in vacuo is darkened by light, but he was unable to determine the nature of the reaction. He also measured the solubility, *S*, of the hydroxide in water and found in grams per litre

	0°	18·5°	29°	32·1°	40°	54·1°	78·5°	99·2°
S . .	25·44	34·34	39·85	41·12	49·5	64·97	103·3	148·3
Sp. gr. .	1·231	1·317	1·342	1·377	1·446	—	—	—

where the sp. gr. are at 15°/4°. The curve is continuous and shows no change of sign in the solid phase The hydroxide is soluble in alcohol. J. E. Willm *accidentellment* obtained rhombic crystals of a monohydrate, $\mathrm{Tl(OH).H_2O}$, free from carbon dioxide. A. Lamy found the aq. soln. to be colourless and strongly alkaline. Both G. Werther, and O. L. Erdmann found that thallous hydroxide turns turmeric brown, and the coloration vanishes after it has stood for some time. From the effect of thallium hydroxide on the speed of hydrolysis of ethyl acetate, W. Ostwald inferred that it is a strong base of the same order as potassium, sodium, and lithium hydroxides. F. M. Raoult gave 33·1 for the mol. lowering of the f.p. W. Ostwald found the eq. conductivity, λ, of soln. containing a mol of the hydroxide in *v* litres of water, at 20°:

v . . .	4	8	16	32	64	128	256	512
λ	182	200	217	230	238	244	248	248

A soln. of thallous hydroxide precipitates metal hydroxides from metal salt soln.—copper, zinc, aluminium, etc. According to F. Bahr, the aq. soln. readily absorbs oxygen and carbon dioxide from the atm., and, consequently, care is necessary in its preparation; for, as A. Lamy, G. Werther, and T. Carnelley and J. Walker showed, it is nearly always contaminated with carbonate. According to A. Lamy, a soln. of thallous hydroxide is oxidized to brown thallic hydroxide by chlorine, hydrogen peroxide, or other oxidizing agents; and paper soaked in thallous hydroxide soln. was used by C. F. Schönbein, E. Schöne, H. Schröder, C. Arnold and C. Mentzel, etc., as a test for ozone, which colours the paper or soln. brown. A. Lamy and F. Bahr found soln. of thallous hydroxide rapidly attack glass. L. F. Hawley found that a cold soln. of thallium hydroxide reacts with aluminium, forming *thallous aluminate* (*q.v.*). V. Cuttica and co-workers found that with nitrosyl chloride, *thallosic trinitrosyl chloride*, $\mathrm{TlCl_2.3NOCl}$, is formed, and with vanadyl chloride, *thallous vanadyl oxychloride*, $\mathrm{Tl_2O.VOCl_3}$, is formed.

Some ill-defined intermediate oxides—**thallosic oxides**—have been described. In the electrolysis of soln. of thallous hydroxide with a thallium cathode, and an anode of the oxide, L. Jones obtained a deposit, containing $\mathrm{Tl_2O_3:Tl_2O=17:1}$. G. Wyrouboff obtained $\mathrm{2Tl_2O_3.3Tl_2O}$ by keeping thallium under water for a long time. C. F. Schonbein obtained small quantities of an insoluble yellow oxide by the simultaneous reduction of hydrogen peroxide and thallic oxide, or by oxidizing thallium with hydrogen peroxide. W. O. Rabe prepared what he regarded as $\mathrm{Tl_2O_3.Tl_2O}$, or $(\mathrm{TlO})_n$, by mixing 15 grms. of a 10 per cent. aq. soln. of thallous sulphate with 175–200 grms. of 20 per cent. potassium hydroxide. The clear filtered soln. was cooled to −15°, and 3·5 grms. of a 3 per cent. soln. of hydrogen peroxide added with constant shaking. A red precipitate was formed, which rapidly gave place to the new bluish-black, lustrous oxide; the latter was separated by filtration, and washed with cooled, anhydrous alcohol and ether. Even cold water decomposes the oxide into a mixture of thallic oxide and thallous hydroxide, and dil. sulphuric and nitric acids act in an analogous way; neither free oxygen nor hydrogen peroxide is produced. On being kept in the air, the oxide absorbs carbon dioxide according to the equation: $\mathrm{Tl_2O_3.Tl_2O+CO_2=Tl_2O_3+Tl_2CO_3}$; it becomes slowly oxidized at the ordinary temp. in air free from carbon dioxide. When a current of oxygen is passed over it at the ordinary temp., it is oxidized completely to thallic oxide, which is remarkable, inasmuch as thallous salts are acted on only by powerful oxidizing agents.

According to A. Lamy,[2] molten thallium unites with oxygen with incandescence, forming **thallic oxide,** Tl_2O_3 ; below a red heat, thallic oxide is formed, at a red heat, a mixture of thallous and thallic oxides, and at a bright red heat, thallous oxide. He also made it by dehydrating thallic hydroxide at 300° ; A. Strecker, and K. Birnbaum, at 100° ; and T. Carnelley and J. Walker, at 230°–450° ; J. E. Willm treated thallic triamminochloride with water : $2TlCl_3.3NH_3+3H_2O=6NH_4Cl+Tl_2O_3$. According to W. O. Rabe, when an alkaline soln. of a thallium salt is treated with a 3–5 per cent. soln. of hydrogen peroxide, anhydrous thallic oxide, Tl_2O_3, separates as a dark brown, flocculent precipitate which slowly changes to small, lustrous crystals of chocolate-brown colour. If precautions are taken to keep the temp. low and the peroxide is used in excess, the yield is almost quantitative—the excess of hydrogen peroxide undergoes decomposition in a catalytic manner without affecting the thallic oxide. When, on the other hand, the experiment is carried out at 80°–100° in strongly alkaline soln. (10–35 per cent. of potassium hydroxide), a black modification of the same oxide is obtained as a heavy, sandy, practically anhydrous powder. W. Crookes, R. Böttger, H. Flemming, R. Lorenz, F. Wöhler, M. E. Heiberg, and M. Bose obtained thallic oxide by electrolysis. This oxide is deposited on the anode when a neutral soln. of thallous sulphate or nitrate is electrolyzed between platinum electrodes when the difference of potential between anode and electrolyte exceeds 1·43 volts ; if the anodic difference of potential exceeds 1·81 volts, with thallous nitrate, or 2·27 volts with thallous sulphate, thallic hydroxide is deposited.

Thallic oxide usually appears as a black or brown powder ; C. Lepierre obtained it in hexagonal plates. The black and brown oxides prepared by W. O. Rabe contained a little (occluded) water—the former 0·23 per cent., the latter 0·73 per cent.—this water was lost after heating a few hours at 500°. M. Lachaud and C. Lepierre gave 5·56 for the sp. gr. at 0°—this is far too low ; V. Thomas found 9·95–9·99 ; and W. O. Rabe gave 9·65 for the brown oxide at 21°, and 10·19 for the black oxide at 22°. T. Carnelley and L. T. O'Shea gave 759° for the m.p. ; and W. O. Rabe, 725° ± 10° ; the last-named added that the m.p. has not been unequivocally determined, since no containing vessel has been found to resist attack by the molten oxide. Thallic oxide begins to give off oxygen at 800°, and decomposes rapidly at 1000°. According to T. Carnelley and J. Walker, thallic metahydroxide slowly loses its water at 230° ; the weight remains constant at 360°, and it slowly gives off oxygen up to 440° ; the weight remains constant between 440° and 565 , and the composition then corresponds with $3Tl_2O_3.Tl_2O$; between 565° and 585°, oxygen is quickly evolved and thallous oxide remains. At 815°, oxygen is absorbed, forming thallic oxide and thallous oxide is volatilized. G. Werther and M. E. Heiberg observed that when thallic oxide is kept at 100°, or even at 60°–70°, in an ordinary drying oven heated by a Bunsen burner, it continues to gain in weight, and simultaneously undergoes reduction to the thallous state. They were of opinion that the increase of weight is due to the formation of thallous carbonate and sulphate, the sulphur coming from the gases given off by the burner. W. O. Rabe found that with the ordinary oxide and the black oxide, no carbonate is formed, but a mixture of normal and acid thallous sulphates. The reduction is comparatively slow at 65°, but at 115° the brown oxide is completely transformed into a mixture of the two sulphates in 468 hrs. The black is similarly, but much more slowly, converted. When the oxides are heated under such conditions that the gases from the burner cannot reach them, the weight remains constant.

G. Werther found that at a red heat thallic oxide is reduced by **hydrogen** to thallous oxide and the metal ; H. Flemming observed that **carbon monoxide** acts similarly. W. O. Rabe said that the brown oxide is partially reduced when boiled with **water,** but the black oxide is scarcely affected ; the brown oxide is easily, and the black oxide is with difficulty, dissolved by dil. mineral acids. According to

A. Lamy, **sulphuric acid** does not act in the cold on thallic oxide, but when heated, thallous sulphate and oxygen are produced; with cold **hydrochloric acid**, thallic chloride is formed without the development of gas, although there may be a partial reduction. E. Carstanjen found that when dry **hydrogen sulphide** is passed over dry thallic oxide, inflammation occurs, may be with a feeble explosion. R. Bottger noted that a mixture of thallic oxide and **sulphur** or **antimony sulphide** explodes when triturated in a mortar. G. Wyrouboff found that thallic oxide does not absorb **carbon dioxide** either at ordinary temp. or when heated. E. Carstanjen dissolved in hydrochloric acid the precipitate obtained by adding ammonia to a soln. of thallium salt; again added ammonia, and again dissolved the precipitate in hydrochloric acid; on once more adding ammonia, a white granular precipitate was formed which was completely decomposed by water into thallic hydroxide. The precipitate is assumed to be thallic hexamminoxide, $Tl_2(NH_3)_6O_3$; it can be washed with alcohol, and dried at 100° without decomposition. C. Winkler found thallic oxide is reduced when heated with **magnesium,** forming thallous oxide and the metal.

A. Lamy found that by treating thallosic chloride with alkali hydroxide: $2Tl_4Cl_6+6KOH=6KCl+6TlCl+Tl_2O_3.H_2O+2H_2O$, the product $Tl_2O_3.H_2O$, or $TlO(OH)$, is **thallic metahydroxide**—the trihydroxide, $Tl(OH)_3$, is thallic orthohydroxide. J. E. Willm found the precipitate is difficult to wash, and he made it by the action of alkali-lye or aq. ammonia on a hot soln. of thallic chloride; and by passing chlorine through a mixture of a thallous salt with alkali carbonate or hydroxide—A. Strecker used sodium hypochlorite in place of chloride. C. F. Schönbein made the hydroxide by the action of moist ozone on thallium; by passing ozonized air into a soln. of thallous hydroxide; by exposing thallium amalgam in contact with water to oxygen or air; by the action of permanganic acid, or permanganates on thallium, thallous oxide, or thallous salts; by the action of hydrogen peroxide on thallium but not on thallous hydroxide—C. Weltzien gave $4Tl+4H_2O_2=2TlOH+2H_2O+Tl_2O_3.H_2O$. W. Crookes, G. Werther, R. Bottger, H. Flemming, R. Lorenz, and M. Bose made the hydroxide as a pulverulent powder which collected at the platinum anode during the electrolysis of neutral, ammoniacal, or alkaline soln. of thallous sulphate or nitrate.

Thallic metahydroxide is a reddish-brown powder, which, according to W. Crookes, and A. Lamy, contains a mol—*i.e.* 3·8 per cent.—of water, $Tl_2O_3.H_2O$, when dried at 100°; A. Strecker said that 0·37 per cent. of water is present; while K. Birnbaum said that the oxide dried at 100°, and G. Werther the oxide dried at 115°, is free from water. T. Carnelley and J. Walker said that the oxide is dehydrated completely at 230°; W. O. Rabe, at 500°. G. Werther added that even at 60° to 70° the hydroxide is partially reduced to thallous hydroxide, and it then readily absorbs carbon dioxide from the air. R. J. Meyer found that the freshly precipitated hydroxide is partially dehydrated when boiled with the mother liquid; the product is darker in colour, settles rapidly, and contains 1 per cent. of water. According to J. Thomsen, the heat of formation is $(2Tl, 3O, 3H_2O)=86·34$ Cals.; $(Tl_2O, O_2, 3H_2O)=44·1$ Cals.; and $(TlOH, O, H_2O)=20·4$ Cals. Metathallic hydroxide is but sparingly soluble in water; the solubility product was found by R. Abegg and J. F. Spencer to be 10^{-53} at 25°. C. F. Schönbein found hydrogen peroxide is reduced by the metahydroxide, provided, said C. Weltzien, and J. E. Willm, hydrochloric acid be present. A. Lamy found that precipitated metathallic hydroxide dissolves in hydrochloric, sulphuric, and other acids; while the dried product dissolves in hydrochloric acid with the evolution of chlorine, and in sulphuric acid with the evolution of oxygen; J. E. Willm, and A. Strecker found that sulphur dioxide converts it into thallous sulphate; arsenious oxide, into thallous arsenate, Tl_3AsO_4; oxalic acid does not reduce the hydroxide in the cold, but when heated reduction is complete; and tartaric acid reduces it with the evolution of carbon dioxide and the formation of thallous tartrate and formate. According to G. Werther, metathallic hydroxide does not dissolve in alkali-lye, nor is it decomposed by that liquid. J. E. Willm found that the hydroxide is soluble in a hot conc. soln. of ammonium chloride, and ammonia is at the same time evolved.

According to D. Carnegie, molten potassium hydroxide dissolves small quantities of thallic oxide, and the resulting yellow mass when treated with water yields a reddish-brown precipitate of the hydrated thallic oxide. If, however, the fusion is continued for some time, a mass of very light, glistening, microscopic, hexagonal plates of **thallic hydroxide,** $Tl(OH)_3$, or $Tl_2O_3.3H_2O$, is produced. The crystals are brown in colour but transmit yellow light; they are not changed at 340°, and are readily soluble in dil. hydrochloric and sulphuric acids, but generally a slight reduction to thallous salt takes place. The formula was based on a determination of the contained thallium. H. Marshall stated that the brown precipitate obtained by the hydrolysis of thallic sulphate is thallic hydroxide, $Tl(OH)_3$.

According to E. Carstanjen, when chlorine is passed into a conc. soln. of potassium hydroxide in which metathallic hydroxide is suspended, an intense violet-red coloration appears and which is assumed to be due to the formation of **potassium thallate.** The soln. can be evaporated without decomposition, diluted, and filtered. Acids convert it into thallous salt with the evolution of oxygen; with hydrochloric acid, chlorine is evolved. A. Piccini found that a similar liquid is formed when thallium hydroxide is submitted to electrolysis, using a plate of thallium as an electrode, as also on adding potassium hypochlorite to a quarter of its weight of caustic potash to which the thallium sulphate is subsequently added. On digesting the whole and adding barium nitrate, a violet precipitate is finally obtained. The results of analyses made to determine the relation between thallium and barium in this precipitate led to discordant results, but sufficient evidence was afforded to point to a formula, TlO_2, for the oxide of thallium. The isolation of this oxide brings out a further point of analogy of the thallium compounds to those of lead. B. Lepsius stated that the violet coloration is not due to the formation of a higher oxide of thallium, but rather due to the presence of a small amount of manganese, as impurity in the reagents employed. G. Gallo and G. Cenni found that when a soln. of thallous sulphate, slightly acidified with sulphuric acid, is electrolyzed, the whole of the thallium is deposited on the anode in the form of an oxide, which is not the sesquioxide as is generally supposed, but which, when dried at 160°-200°, has a composition corresponding with Tl_3O_5, a complex of **thallium dioxide,** $Tl_2O_3.TlO_2$, possibly

$$O:Tl.O.\underset{\overset{..}{O}}{Tl}.O.Tl:O$$

With hydrochloric acid, chlorine is evolved and $TlCl_3.3TlCl$ is formed; presumably the oxide decomposes: $8Tl_3O_5=3Tl_2O_3+9Tl_2O+11O_2$. From the position of thallium between mercury and lead in the periodic system, the existence of a peroxide of thallium is not surprising—both lead and mercury peroxides have been reported.

§ 7. Thallium Fluorides

F. Kuhlmann[1] found that metallic thallium is slowly attacked by hydrofluoric acid, forming thallous fluoride, but the reaction is far too slow to be useful in the preparation of this compound. J. Gewecke, however, used this process and he heated the metal with 40 per cent. hydrofluoric acid in a platinum dish. E. H. Büchner prepared **thallous fluoride,** TlF, by dissolving thallous carbonate in dil. hydrofluoric acid; E. Petersen neutralized thallous hydroxide with hydrofluoric acid; and J. Gewecke, and F. Ephraim and P. Barteczko dissolved thallium sulphide in the same acid.

Metallic thallium was dissolved in dil. sulphuric acid, and the soln. treated with hydrogen sulphide. The soln. was filtered from the precipitated lead sulphide, made alkaline with ammonia, and again treated with hydrogen sulphide so as to precipitate thallous sulphide. The sulphide was filtered off, thoroughly washed, and treated with hydrofluoric acid. A brown residue may appear but this also dissolves in the acid on warming—excepting a little insoluble sulphur. The conc. of the soln. by evaporation furnishes white crystals of thallous fluoride.

H. L. Wells and H. W. Foote treated a soln. of thallous sulphate with an excess of hydrofluoric acid. The aq. soln. of thallous fluoride on cooling furnished F. Kuhlmann, and J. E. Willm with deliquescent rhombic or hexagonal plates which rapidly attack glass, and which melt and volatilize when heated. These crystals are said to be either **monohydrated thallous fluoride,** $TlF.H_2O$, or hemihydrated thallous fluoride, $TlF.\frac{1}{2}H_2O$.

The evaporation of the soln. of thallous fluoride on a water-bath, or at ordinary temp., furnishes colourless octahedral crystals of the anhydrous salt. E. H. Büchner found that 100 parts of water at 15° dissolve 80 parts of the salt; the solubility increases with a rise of temp. The aq. soln. has an acid reaction. K. Ja[illegible]h found the sp. ht. of soln. with N eq. of thallous fluoride per litre to be

N . . .	0·5	1·0	2·0	3·0	4·0
Sp. ht. . .	0·9485	0·8881	0·8021	0·7312	0·6712

E. Franke, and F. Kohlrausch and H. von Steinwehr have measured the electrical conductivity of aq. soln. of thallous fluoride. The equivalent conductivity in reciprocal ohms at 25°, is, according to E. Franke, 115·9 when $v=32$; 120·6 for $v=64$; 123·7 for $v=128$; 126·2 for $v=256$; 128·1 for $v=512$; and 130·1 for $v=1024$. A. Heydweiller gave the sp. gr. and conductivity of soln. of thallous fluoride. A. A. Noyes and K. G. Falk found the percentage ionization of soln.

with 5, 10, 20, and 50 millieq. of the salt per litre to be respectively 96·1, 93·6, 90·8, and 86·5. The salt is sparingly soluble in alcohol; and, according to G. Gore, insoluble in liquid ammonia. Thallous fluoride melts and partially volatilizes when heated, and a colourless crystalline mass remains when the molten salt is cooled; it can be distilled in a current of steam. H. von Wartenberg and O. Bosse found the vap. press. of thallous fluoride to be 431 mm. at 282°, 587 mm. at 292°, and 753 mm. at 298°. The b.p. is therefore near 298°. The vap. press., *p*, at *T*° K. is represented by $\log p=-25152/4{\cdot}571T+9{\cdot}639$. E. Petersen gave for the heat of formation: $TlOH+HF-TlF+H_2O+16{\cdot}44$ Cals. When the salt is exposed to sunlight it is coloured violet or black; but it can be kept exposed to the air in darkness without change.

E. H. Büchner evaporated over sulphuric acid a soln. of thallous fluoride in an excess of hydrofluoric acid, and obtained octahedral crystals of **thallous hydrofluoride,** TlF.HF. The crystals are stable in air, up to 100°, but above this temp. they decompose into hydrogen and thallous fluorides. E. Petersen gave $TlF_{aq.}+HF_{aq.}=TlF.HF_{aq.}-0{\cdot}583$ Cal. The crystals dissolve in an equal weight of water, forming a soln. with an acid reaction. Thallous fluoride forms double salts with a number of metal fluorides. For example, P. Barteczko prepared **thallous enneafluoaluminate,** $3TlF.2AlF_3$, by dropping a conc. soln. of thallous fluoride into a soln. of aluminium fluoride. The double salt separates out as a white crystalline precipitate. He also stated that no other double fluoride of thallium can be prepared by precipitation. The salt is slowly decomposed by sodium carbonate, and this is taken to indicate the presence of a complex compound. J. Barlot evaporated to dryness a soln. of thallium in hot dil. hydrofluoric acid, and obtained **thallium dihydrofluoride,** H_2TlF_3, which crystallizes from water in white elongated prisms; when heated, hydrogen fluoride is given off; the aq. soln. reacts acid, but does not attack glass since the fluorine is masked. It is regarded as a complex acid, **hydrotrifluothallous acid,** which forms two types of salts. **potassium hydrotrifluothallite,** $KHTlF_3$, and **potassium trifluothallite,** K_2TlF_3.

H. Moissan found that fluorine acts on metallic thallium, forming what has been stated to be **thallic fluoride,** TlF_3, the reaction proceeds so vigorously that the metal melts and becomes red hot, but it is open to doubt if thallic fluoride has been isolated. According to J. E. Willm, when conc. hydrofluoric acid acts on freshly precipitated thallous hydroxide, a dark olive-green substance insoluble in water and in cold hydrochloric acid is formed, and similarly, when thallic nitrate is treated with hydrofluoric acid. When the product is warmed, it turns brown and melts to an orange liquid, which solidifies on cooling to a white mass; if heated still more, thallous fluoride sublimes. J. E. Willm's product, said J. Gewecke, is not thallic fluoride, but rather **thallic oxyfluoride,** TlOF, and for the preparation of this compound he recommended a process similar to that employed by J. E. Willm. Thallium sesquioxide is scarcely affected by standing for a long time in contact with hydrofluoric acid, and the product of the action has not a uniform composition; thallic chloride is almost insoluble in hydrofluoric acid, and it forms a white powder the composition of which has not been investigated; thallic chloride with silver fluoride in aq. soln. forms silver chloride and thallic hydroxide; if a 40 per cent. soln. of hydrofluoric acid be used, thallic oxyfluoride is formed. When dried thallium sesquioxide is heated with potassium hydrogen fluoride, and extracted with anhydrous hydrofluoric acid, white **potassium heptafluodithallate,** $KF.2TlF_3$, is formed, which is extremely sensitive to the presence of moisture; for it is immediately decomposed by water becoming brown, giving off hydrogen fluoride, and forming thallic hydroxide.

§ 8. Thallium Chlorides

Thallium forms at least four chlorides with the empirical composition—$TlCl$, Tl_2Cl_3, $TlCl_2$, and $TlCl_3$. A. Lamy [1] prepared **thallium monochloride, or thallous chloride,** $TlCl$, by adding hydrochloric acid or a soluble chloride to a soln. of a thallous salt. M. Hebberling made it by reducing a hydrochloric acid soln. of a thallic salt with sulphur dioxide ; and E. Carstanjen used stannous chloride as reducing agent. J. Hausmann also prepared the salt suspended in gelatine jelly. F. Ephraim and P. Barteczko precipitated thallous chloride by the addition of hydrochloric acid to a soln. of thallium sulphate.

Precipitated thallous chloride is a white curdy mass which becomes more compact on standing ; it crystallizes from hot soln. in cubes and octahedra. W. P. Davey found the X-radiogram of thallous chloride shows the crystal unit is a body-centred cube with side 3·85 A., and the closest approach of the atoms is 3·34 A. B. Gossner [2] obtained crystal skeletons from hot potassium hydroxide and sodium sulphate soln. ; and E. Carstanjen, cubic crystals from hot sodium carbonate soln. The crystals, said W. Stortenbeker, are isomorphous with potassium chloride. W. P. Davey and F. G. Wick found the X-radiogram of thallous chloride, like that of cæsium chloride, corresponds with a simple cube lattice of side 3·85 A. According to M. Hebberling, the white chloride soon becomes violet when exposed to light ; the effect is said to occur only when impurities—lead or silver chlorides—are present, for the purified salt remains white after a prolonged exposure to light. H. Stolzenberg and M. E. Huth found that molten thallium chloride, m.p. 407°, becomes anisotropic on cooling, but C. Tubandt and E. Lorenz's work make it probable that the effect is due to the presence of impurities. R. Lorenz and W. Eitel did not get optically clear crystals of thallous chloride free from "fog" —*vide* lead chloride. J. E. Willm gives the sp. gr. of the solid after fusion as 7·00 ; and A. Lamy as 7·02. F. A. Henglein studied the mol. vol. of thallous halides. W. Biltz found the lattice energy of thallous chloride to be 193 Cals. per mol. T. W. Richards and G. Jones gave the coeff. of compressibility as $4·7 \times 10^{-6}$ per atm. S. Motylewsky found the drop-weight is $w=149$ (referred to water at $0°=100$), the capillary constant $\sigma=0·076w$; and sp. cohesion $a^2=2/D$, where D is the sp. gr. at the m.p.

The reported numbers for the m.p. of thallous chloride vary from E. Korreng's [3] 435° to T. Carnelley and W. C. Williams' 451°. C. Sandonnini gave 429° ; H. von Wartenberg and O. Bosse, 430° ; W. Hampe, 427° ; and K. Mönkemeyer, 426°. The best representative value may be taken as 430°. F. A. Henglein found that the mol. vols. of the chlorides of thallium, copper, and silver gave a straight line when plotted against numbers corresponding with anions or cations. E. Carstanjen said the yellow molten chloride solidifies, on cooling, to a translucent white mass which can be cut with difficulty with a knife ; and M. Hebberling, to a brown crystalline mass which soon became white. The b.p. of thallous chloride, according to T. Carnelley and W. C. Williams, lies between 708° and 719° when measured with the pyrometer in the vap. and 719° to 731° when in the liquid. H. von Wartenberg and O. Bosse found the vap. press., p, at 665° to be 129·6 mm. ; at 713°, 253·8 mm. ; at 760°, 4425 mm. ; at 791°, 653·6 mm. ; and at 807°, 767·4 mm. ; the results at the absolute temp., T, are represented by $\log p=-25108/4·571T+5·093$

and the b.p. is 806°. The vap. density between 837° and 1026° was found by H. E. Roscoe to agree with that calculated for the formula TlCl, and E. Beckmann obtained the same mol. formula from its effect on the f.p. of mercuric chloride. G. D. Roos gave 16·5 cals. per gram for the heat of fusion. According to J. Thomsen, the heat of formation is $\mathrm{Tl}+\mathrm{Cl}=\mathrm{TlCl}+48{\cdot}6$ Cals.—M. de K. Thompson calculated 43·7 Cals from the solubility. J. O. Perrine observed no fluorescence with thallous chloride in X-rays. The fused salt was found by W. Hampe to be a good electrolyte. The photochemistry of thallous chloride has been studied by C. Renz, from which it appears that under water, hydrochloric acid, ammonia, ethylamine, ethyl alcohol, glycerol, toluene, xylene, or pyridine, a darkening occurs, and the thallous chloride passes through various shades of greyish-brown to blackish-brown. This is attributed to the formation of *thallous photochloride*, and thallosothallic chloride. A. Benrath found thallous chloride, whether dry or under water, is changed by light to a brown substance, possibly $\mathrm{TlCl_3.3TlCl}$. W. W. Coblentz and J. F. Eckford measured the photoelectric sensitivity of thallous chloride. C. Sandonnini gives the electrical conductivity of fused thallium chloride at 429° as 1·224 reciprocal ohms. The eq. conductivity of soln. at 25° with a gram-molecule of the salt in v litres of water was found by E. Franke to be 139·6 reciprocal ohms for $v=128$; 143·1 for $v=256$; and 145·1 for $v=512$. G. Jones and W. C. Schumb measured the conductivity of soln. of thallous chloride. A. A. Noyes and G. Abbot calculated the degree of ionization of thallous chloride in aq. soln. at 29·75° to be 86·5 to 86·6 per cent. Lord Berkeley found the ratio of the osmotic press., P atm., and the mol. conc., C, to be 57·0 when the value calculated from the dil. soln. law is about 31. The electrical conductivity of aq. soln. has been also investigated by F. Kohlrausch and M. E. Maltby. F. Kohlrausch's value for the sp. conductivity of a sat. aq. soln. at 18° is 1511×10^{-6} reciprocal ohms per cm. cube; and at 25°, 2176×10^{-6} reciprocal ohms. J. C. Ghosh measured the sp. conductivity, μ, of fused thallous chloride and found 0·00005 at 523° K.; 0·00024 at 573° K.; 0·00090 at 623° K.; 0·00370 at 673° K.; and 0·00610 at 694° K. A. A. Noyes and K. G. Falk found the percentage ionization of soln. with 1, 5, and 10 millieq. per litre to be respectively 97·6, 94·2, and 91·5. A. A. Noyes has measured the effect of cadmium sulphate on the conductivity of aq. soln. of thallous chloride; G. N. Lewis and M. Randall measured the activity coeff.; and K. Klemensiewicz, the conductivity of soln. of thallous chloride in antimony trichloride. G. von Hevesy found the ratio of the conductivities above and below the m.p. to be 160, and he calculated that the gain of energy required to render the ions of the crystal neutral is 44 cals. The greater this energy the smaller the tendency of the lattice to be loosened with rise of temp. W. Schmidt gave 30 for the dielectric constant. G. Tammann measured the potential of fused thallous chloride with magnesium, manganese, or aluminium.

The solubility of thallous chloride in cold water is relatively small, but it rapidly increases as the temp. rises. The thallous halides, like the silver halides, are precipitated by the halogen acids, but, like the lead halides, they are appreciably soluble in water. Isolated observations on the solubility have been made by W. Crookes,[4] A. Lamy, A. E. Hill, G. N. Lewis and C. L. von Ende, G. Jones and W. C. Schumb, M. Hebberling, A. A. Noyes and G. Abbot, W. Böttger, G. Geffcken, and F. Kohlrausch; series of measurements have been made by A. A. Noyes, and the Earl of Berkeley; while A. A. Noyes and G. Abbot, and G. Geffcken have measured the influence of other salts on the solubility of thallous chloride. The best representative values by interpolation of all but the Earl of Berkeley's data give for the solubility S of thallous chloride in grams per 100 c.c. are:

	0°	10°	20°	25°	30°	40°	50°	60°	80°	100°
S . .	0·21	0·25	0·33	0·39	0·42	0·52	0·63	0·80	1·20	1·80

The Earl of Berkeley's values are:

S . .	0·17	0·24	0·34	0·40	0·46	0·60	0·80	1·02	1·60	2·41

the last value refers to 99·3°. The solid phase through the whole range is the anhydrous chloride. A. Lamy, and A. Ditte found that the solubility is depressed by the presence of *hydrochloric acid*, and this the more the greater the conc. of the acid; consequently, as M. Hebberling noted, the salt is precipitated from aq. soln. by the addition of hydrochloric acid; and, as A. Ditte noted, the salt is virtually insoluble in the conc. acid. A. A. Noyes found at 25°, the solubility of thallous chloride fell from 3·861 grms. per litre to 2·002 grms. when 1·032 grms. of hydrochloric acid, HCl, were present, and to 1·353 and 0·757 grms. when respectively 2·043 and 5·357 grms. of HCl were present. A. E. Hill and J. P. Simmons measured the solubility and sp. gr. of soln. of thallous chloride in *nitric acid*. Expressing the results, *S*, in grams per litre at 25°:

N-HNO_3 .	0	0·4977	1·0046	2·0452	4·0170
S . .	3·951	5·937	6·882	8·143	9·925
Sp. gr. .	0·996	1·0184	1·0359	1·0705	1·1362

For *acetic acid*, A. E. Hill gave:

N-CH_3COOH .	0	0·0501	0·0958	0·263	0·524
S . . .	3·8515	3·8375	3·8326	3·7503	3·6539

A. Lamy reported that thallous chloride is insoluble in *alcohol*; A. Naumann, that it is sparingly soluble in *acetone*; and A. Naumann and J. Schröder, that it is insoluble in *pyridine*.

Remembering that a litre of water dissolves *S*=0·01612 mol of thallous chloride at 25°, and expressing solubilities and proportions of salt in mols per litre at 25°, and selecting extreme terms of particular series of measurements, G. Geffeken found that with 0·5 and 2·0 mols of *ammonium nitrate* per litre the solubility, *S*, changed to 0·0258 and to 0·03966 respectively; with 0·5 and 3·0 mols of *lithium nitrate*, *S* changed to 0·0242 and 0·04438; with 0·5 mol of *potassium chloride*, *S* changed to 0·0237; with 0·5 and 2·0 mols of *potassium nitrate*, *S* changed to 0·0257 and 0·0390; with 0·5 and 4·0 mols of *sodium nitrate*, *S* changed to 0·02564 and 0·05128; and with 0·5 and 4·0 mols of *sodium chloride*, *S* changed to 0·02320 and 0·03850. A. A. Noyes found with 0·0283 and 0·1468 mol of *barium chloride*, *S* changed to 0·00857 and 0·00323; with 0·030 and 0·1574 mol of *cadmium sulphate*, *S* changed to 0·0206 and 0·0309; with 0·015 and 0·1574 mol of *sodium acetate*, *S* changed to 0·0168 and 0·0196; with 0·0283 and 0·1468 mol of *thallous nitrate*, *S* changed to 0·0083 and 0·00332; with 0·0283 and 0·0560 mol of *thallous sulphate*, *S* changed to 0·00886 and 0·00624; with a sat. soln. of *thallous thiocyanate*, *S* changed to 0·0119; with 0·025 and 0·2 mol of *ammonium or hydrogen chloride*, *S* changed to 0·00873 and to 0·00262; with 0·025 and 0·20 mol of *cupric or calcium chloride*, *S* changed to 0·00902 and 0·00287; with 0·025 and 0·20 mol of *manganous or magnesium chloride*, *S* changed to 0·00901 and 0·00278; with 0·025 and 0·20 mol of *potassium or sodium chloride*, *S* changed to 0·00871 and 0·00268; with 0·025 and 0·10 mol of *thallous chlorate or nitrate*, *S* changed to 0·00889 and 0·00423, with 0·25 and 0·20 mol of *zinc chloride*, *S* changed to 0·00899 and 0·00281; and with 0·025 and 0·20 mol of *cadmium chloride*, *S* changed to 0·0104 and 0·00427 respectively. A. A. Noyes and G. Abbot, working at 39·75°, found that with 0·01567 mol of *thallous bromate*, *S* changed to 0·01959; and with 0·02149 mol of *thallous thiocyanate*, *S* changed to 0·01807. W. C. Bray and W. J. Winninghoff found that with 20 and 300 millieq. of *potassium sulphate* per litre, the solubility rose from 0·01607 for water to 0·01779 and to 0·02600 respectively. J. F. Spencer and M. le Pla found that the presence of *potassium carbonate* also augmented the solubility of thallous chloride at 25° water alone dissolves 3·86 grms. of thallous chloride per litre, but with a 5*N*-soln. of potassium carbonate, 21·84 grms. of thallous chloride are dissolved.

According to V. Thomas,[5] dried liquid chlorine has virtually no action on dry thallous chloride; but if this salt be heated in a stream of dry chlorine, A. Lamy found that Tl_2Cl_4, or $TlCl_2$, is formed; and if the thallous chloride be suspended in water, Tl_2Cl_3 is first formed, and later $TlCl_3$ is produced. G. Werther found that aqua regia converts thallous chloride into Tl_2Cl_3, or Tl_2Cl_4, but J. E. Willm added that with a very prolonged action, thallium trichloride is formed. According to J. E. Willm, a hydrochloric acid soln. of thallous chloride is oxidized to thallic chloride by potassium permanganate. V. Thomas also found that bromine converts thallous chloride into a series of bromochlorides. A. Lamy found that hot sulphuric acid converts thallous chloride into thallous sulphate, and fused sodium hydrosulphate effects the same conversion very readily, and J. Krause made the same remarks concerning a boiling soln. of sodium sulphate of sp. gr. 1·02 to 1·04, but R. Nietzki contested the accuracy of J. Krause's statement. A. Lamy says thallous chloride is virtually insoluble in aq. ammonia, and that hot potash-lye partially decomposes thallous chloride, but on cooling, the salt is for the most part re-formed. Thallous chloride does not absorb ammonia at ordinary temp., but in liquid ammonia, W. Biltz and W. Stollenwerk found that **thallous triamminochloride,** $TlCl.3NH_3$, is formed. Similarly also with thallous bromide and iodide. The vap. press. of all three salts are very near that of ammonia itself. The solubility of the triammines in liquid ammonia increases with rise of temp., and with the at. wt. of the halogen. The heat of formation for the ammine is about 7·1 Cals. for each mol of ammonia; and it dissociates at −63° under 100 mm. press. No lower ammine was observed. W. Biltz, and J. Clark made some observations on this subject.

A. Cossa found aluminium precipitates metallic thallium from soln. of thallous chloride at 90°; magnesium acts similarly, and a mixture of dry thallous chloride with magnesium powder at a red heat was found by K. Seubert and A. Schmidt to form magnesium chloride, and metallic thallium without becoming incandescent. A. G. Page, and V. Thomas used the thallium chlorides as catalytic agents for stimulating the chlorination of organic compounds. C. Benrath found that thallous chloride is reduced to metal by oxalic, tartaric, and citric acids; more easily than the bromide, and still more easily than the iodide. Thallic halides are more easily reduced than thallous salts.

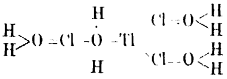
Thallous chloride forms a number of double salts with other metal chlorides,[6] but no definite compounds of thallous chloride and the alkali chlorides have been prepared. C. Sandonnini and P. C. Aureggi found that *lithium and thallous chlorides* are completely miscible when fused; there is a eutectic at 342° corresponding with 62 molar per cent of thallous chloride and no mixed crystals are formed. There is a eutectic at 412° in the system: *sodium and thallium chlorides*, corresponding with about 85 molar per cent. of the latter component. The two chlorides are probably not miscible in the solid state. *Potassium and thallous chlorides* are miscible in all proportions in the solid and liquid states; and *rubidium and thallous chlorides* are completely miscible within very wide limits; *cæsium and thallous chlorides* behave similarly. E. H. Ducloux said that a double salt is formed with cæsium chloride.

E. Korreng found that the f.p. curve of the binary system $CuCl—TlCl$ gave indications of the formation of a double salt of **thallous cuprous chloride.** According to C. Sandonnini and P. C. Aureggi, the f.p. curve of thallous and silver chlorides indicates the existence of **silver thallous chloride,** $2AgCl.TlCl$, which is shown by a break in the curve at 252°—the compound decomposes on melting and there is a eutectic at 210° corresponding with 41 molar per cent. of thallous chloride. C. Sandonnini has studied the electrical conductivities of solidified mixtures of these two salts, and he found the isotherm at 200° gives a maximum corresponding with the eutectic mixture. E. Carstanjen, and W. Crookes obtained lustrous yellow crystals of **thallous chloroaurate,** $TlAuCl_4$, by adding gold chloride to a hot aq. soln. of thallous chloride. The crystals are but slightly soluble in water, and when calcined give an alloy of thallium and gold.

In the thermal study of the binary system–*barium and thallous chlorides*—T. Liebisch and E. Korreng found no sign of the formation of a compound; while with the systems $TlCl—CaCl_2$ and $TlCl—SrCl_2$, E. Korreng found that double salts were formed, namely, **thallous calcium chloride,** $TlCl.CaCl_2$, melting at 683°; and **thallous strontium chloride,** $TlCl.SrCl_2$ melting at 569°. Similarly, with magnesium, zinc, and cadmium chlorides, T. Liebisch and E. Korreng found that thallous chloride formed compounds: **thallous magnesium chloride,** $TlCl.MgCl_2$, melting at 499°; **thallous zinc chlorides,** $2TlCl.ZnCl_2$, melting at 352°, and $TlCl.2ZnCl_2$, melting at 226°; and **thallous cadmium chloride,** $TlCl.CdCl_2$, melting at 436°—C. Sandonnini gives 426°—there are here eutectics at 259° and 400° with respectively 27 and 66 *molar per cent. of cadmium chloride. He also studied the electrical conductiviti of the mixed salts at different temp.* C. Sandonnini found that binary mixtures of thallous and mercuric chlorides gave a f.p. curve indicating the formation of two **thallous mercuric chlorides,** namely, $TlCl.HgCl_2$, melting at 224°, and $4TlCl.HgCl_2$, which probably decomposes when fused, and is formed at about 250°. Both compounds form solid soln. with each other and with the simple salts between wide limits. The eutectics at 183° and 205° correspond respectively with 64 and 32 molar per cent. of mercuric chloride. The first-named mercuric compound, $TlCl.HgCl_2$, was obtained by E. Carstanjen in long needles by cooling a hot soln of thallous and mercuric chlorides. The compound is volatilized more easily than thallous chloride, and it colours the flame intensely green. The air-dried salt was found by S. M. Jörgensen to be anhydrous, and it loses traces of mercuric chloride at 120°-130°, and within two days, at 200°, all the mercury salt is lost. When boiled with water and zinc all the thallium and mercury are precipitated. J. Kendall and co-workers made **thallous tetrachloroaluminate,** $TlCl.AlCl_3$, melting at 297°, and **thallous heptachloroaluminate,** $TlCl.2AlCl_3$.

According to J. E. Willm,[7] an aq. soln. of **thallic chloride** or **thallium trichloride,** $TlCl_3$, can be prepared by treating an aq. soln. of thallous chloride with chlorine. G. Werther treated thallous chloride suspended in water with chlorine until all had dissolved. A soln. of thallic chloride is also made by treating thallous chloride with aqua regia; or by dissolving in water the product of the action of chlorine on heated thallous chloride and precipitating thallic hydroxide by the addition of potassium hydroxide. The washed precipitate is then dissolved in cold hydrochloric acid. C. Renz obtained thallic hydroxide by warming thallous hydroxide or carbonate with sodium hypochlorite, and also dissolved the washed product in cold hydrochloric acid.

G. Werther passed chlorine into water with thallium or thallous chloride in suspension until the soln. no longer gave a turbidity with hydrochloroplatinic acid; the excess of chlorine was removed by a current of carbon dioxide; and the soln. evaporated in vacuo. Colourless prisms of **monohydrated thallic chloride,** $TlCl_3.H_2O$, were formed. A. S. Cushman could not establish R. J. Meyer's and G. Werther's claims to have made monohydrated thallic chloride. A. S. Cushman, however, does agree that one of the four mols. of water in tetrahydrated thallic chloride is differently related to thallic chloride from the other three, and he expresses his hypothesis by the symbols:



$$\begin{matrix}H\\H\end{matrix}{>}O = Cl - \underset{H}{\overset{H}{\dot{O}}} - Tl\begin{matrix} Cl = O{<}\begin{matrix}H\\H\end{matrix} \\ Cl - O{<}\begin{matrix}H\\H\end{matrix}\end{matrix}$$

The full saturation value of mols. of the type MCl_3 for water is six, as exemplified by aluminium, iron, etc. No thallic chloride with six mols. of water has been isolated. G. Werther also reported $TlCl_3.7\frac{1}{2}H_2O$, but this has not been confirmed. According to R. J. Meyer, the monohydrated salt is obtained only when the soln., not too conc., is evaporated in the desiccator; if the soln. be in the least supersaturated or undercooled the tetrahydrated salt is formed. The monohydrated salt is also formed by the hydration of the tetrahydrated salt at 55°. If the tetrahydrated salt be confined in a desiccator over potassium hydroxide, sulphuric acid, or phosphoric oxide, it loses water and liquefies; the liquid deposits long hexagonal crystals of the monohydrated salt, and finally the anhydrous chloride. According to R. J. Meyer and A. S. Cushman, **tetrahydrated thallic chloride,** $TlCl_3.4H_2O$, is prepared in the following manner:

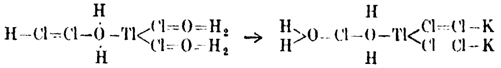
> Thallous chloride suspended in a little water is treated with chlorine while slowly heated up to its b.p.; the action is continued until all is in soln. The liquid is evaporated between 60° and 80° and repeatedly sat. with chlorine, until it has a syrupy consistency. On cooling the syrupy liquid slowly by a freezing mixture, prismatic crystals separate out; but on cooling rapidly, white needles appear The crystals belong to the rhombic system.

Tetrahydrated thallic chloride is hygroscopic, according to R. J. Meyer, and not hygroscopic, according to A. S. Cushman, while V. Thomas showed that at 17° in air, the salt deliquesces only when the moisture content of the air exceeds 63 per cent. corresponding with a dissociation press. of about 23 mm. of mercury, so that the tetrahydrated chloride is stable in air sat. with water vapour. A. S. Cushman gives the vapour tension of the tetrahydrated chloride as 9·5 mm. at 17°, and he adds that if this salt be fitted to an instrument for recording variations in weight, the curve is a record of the hygroscopic state of the atmosphere. According to R. J. Meyer, the tetrahydrated salt melts at 45° and freezes at 33°. V. Thomas gives the m.p. between 36° and 37°. Thallic chloride, anhydrous or hydrated, is very soluble in water; according to V. Thomas, 100 parts of water at 17° dissolve 86·2 parts of the tetrahydrated salt, and the sp. gr. of the soln. is 1·85 and the heat of the soln. of the tetrahydrated salt in water is $-2\cdot12$ Cals. The aq. soln. reacts acid, and the hydrolysis is emphasized by the rise in the eq. conductivity, λ, which occurs on dilution as determined by R. J. Meyer, with soln. containing a gram-eq. of the salt in v litres of water, $\lambda=34\cdot8$ when $v=2$; $\lambda=40\cdot8$ when $v=4$; $\lambda=48\cdot2$ when $v=8$; $\lambda=58\cdot6$ when $v=16$; $\lambda=74\cdot2$ when $v=32$; $\lambda=102\cdot7$ when $v=64$; and $\lambda=145\cdot7$ when $v=128$. With dilution, a stage is reached when the soln. becomes turbid through the separation of the brown hydroxide, $Tl(OH)_3$. Thallic chloride, however, is stable in dil. soln. if sufficient hydrochloric acid be present. A. Voigt and W. Biltz made some measurements of the electrical conductivity of the fused salt.

Silver nitrate precipitates the chlorine quantitatively as silver chloride from a soln. of thallic chloride acidified with nitric acid; but from a neutral soln., in addition to silver chloride, a brown precipitate of thallic hydroxide is formed. R. J. Meyer stated that silver nitrate precipitated only two-thirds of the chlorine from soln. of thallium trichloride, but after A. S. Cushman had shown that this statement is inaccurate, R. J. Meyer showed that the precipitation of silver chloride is hindered by the solubility of silver chloride in the thallium nitrate which is formed. The constitutional formula for thallic chloride, $TlCl\,Cl_2$, based on the different properties possessed by one of the three chlorine atoms in thallic chloride is therefore invalidated. One of the peculiarities of thallic chloride and its water complex is the ease with which they dissolve in most solvents including ether and alcohol. J. Nicklès passed chlorine into a suspension of thallous chloride in dry ether, $(C_2H_5)_2O$, and obtained what he thought to be $(C_2H_5)_2O.TlCl_3\,HCl.H_2O$, but R. J. Meyer could not verify this. R. J. Meyer did prepare the compound $(C_2H_5)_2O.TlCl_3$ by the action of ether on tetrahydrated thallic chloride; A. S. Cushman questioned the existence of R. J. Meyer's compound, but the objection could not be maintained, for if the ethereal soln. be evaporated in vacuo, crystals of the compound melting at 30° are produced. R. J. Meyer also prepared an analogous compound with alcohol, $TlCl_3.C_2H_5(OH)$. Several other compounds of thallic chloride with organic bases—pyridine, aniline, etc.—have been prepared.

According to F. M. McClenahan, tetrahydrated thallic chloride loses all its water when heated for an hour at 100° and there is very little loss of chlorine, and he traces the loss of water through the following stages: $TlCl_3.4H_2O\rightarrow TlCl_3\,2H_2O\rightarrow TlCl_3.H_2O\rightarrow TlCl_3$. The evidence for the existence of *dihydrated thallic chloride*, $TlCl_3.2H_2O$, has not yet been established. If the dehydration be conducted in a stream of hydrogen chloride, a hydrochloride is formed: $TlCl_3.4H_2O\rightarrow TlCl_3.3H_2O.HCl\rightarrow TlCl_3.H_2O\rightarrow TlCl_3$. According to A. S. Cushman, if the tetrahydrated salt be confined over phosphorus pentoxide in a desiccator, the anhydrous chloride is formed, but if certain impurities are present, the chloride is reduced to the dichloride with the evolution of hydrogen chloride or chlorine; but even under the best conditions, A. S. Cushman found that the hydrated salt cannot be freed from water without undergoing a slight reduction. R. J. Meyer prepared anhydrous thallic chloride by dehydrating the tetrahydrated salt at 55°. R. J. Meyer also prepared anhydrous thallic chloride by keeping the hydrate with ether, $TlCl_3(C_2H_5)_2O$, for about 10 days in vacuo, when the ether is all removed. The preparation of anhydrous thallic chloride by heating one of the lower chlorides in a stream of chlorine is not satisfactory, because a mixture with a variable amount of chlorine is formed; but V. Thomas made it by sealing some liquid chlorine in one leg of a Λ-tube, with thallous chloride in the other leg. The tube was surrounded by a metal cloth, and the leg with the solid heated by a Bunsen's burner. In about 48 hrs. a small quantity of white crystals of thallic chloride was found to have sublimed in the atm. of chlorine. V. Thomas found the product melted at 60° to 70° while confined in the sealed tube at 7–8 atm. press. The small six-sided crystalline plates, obtained by dehydrating the tetrahydrated salt, melt at 24°, but, according to W. Hampe, they cannot be melted without decomposition under atm. press. According to V. Thomas, the decomposition is slow at 40° and rapid at 100°—the lower chlorides are simultaneously formed. The anhydrous chloride is very hygroscopic, and soluble in water; and, according to R. J. Meyer, in ether and alcohol; and, according to C. Renz, in acetone. It is also soluble in other organic solvents. According to V. Thomas, the heat of formation is $Tl+3Cl_{gas}=80\cdot82$ Cals.; or $TlCl_{solid}+2Cl_{gas}=32\cdot2$ Cals.; and $TlCl_{3solid}+4H_2O_{liquid}=TlCl_34H_2O_{solid}+10\cdot55$ Cals.; and the heat of soln. of the tetrahydrated chloride in water is $-2\cdot12$ Cals.; and the heat of soln. of the anhydrous chloride is 8·43 Cals. According to J. Nicklès, colourless thallic chloride is changed by exposure to sunlight, forming brown thallium sesquioxide. Soln. of ammonia, alkali hydroxides, alkali or alkaline earth carbonates, form brown thallium sesquioxide. Ammonia does not react in this way in the presence of an excess of ammonium chloride, for the soln. remains clear and colourless; it, however, turns brown if water be added, but the original colour is restored if more ammonium chloride be added. Thallic salts in general were shown by A. J. Berry to be quantitatively reduced by ferrous sulphate: $Tl_2(SO_4)_3+4FeSO_4=Tl_2SO_4+2Fe_2(SO_4)_3$, and by sodium arsenite: $Tl_2O_3+As_2O_3=Tl_2O+As_2O_5$; he also examined the reducing effect of copper, and hydroxylamine: $Tl_2O_3+2NH_2OH=Tl_2O+3H_2O+N_2O$. Bismuth nitrate gives a white precipitate—nearly quantitative; the precipitate is soluble in a soln. of ammonium chloride.

Thallium trichloride combines with ammonia producing white crystals of **thallium triamminotrichloride,** $TlCl_3.3NH_3$, which was prepared by J. E. Willm by mixing an alcoholic soln. of the chloride with an alcoholic soln. of ammonia; by mixing a conc. aq. soln. of thallic chloride with ammonia; by boiling thallic hydroxide with a conc. aq. soln. of ammonium chloride until it begins to give off ammonia, and then treating the colourless soln. with ammonia. The white crystalline precipitate is washed with aqua ammonia, then with alcohol made feebly ammoniacal; then with absolute alcohol; and finally dried in vacuo. J. E. Willm also said that thallium triamminotrichloride is formed by the action of dry ammonia on anhydrous thallic chloride, but D. Gauthier found that **thallium pentamminotrichloride,** $TlCl_3.5NH_3$, is produced by the action of an excess of ammonia on the anhydrous trichloride at ordinary temp. W. Biltz measured the vap. press. of the triamminotrichloride at −50°, −60°, and −79°, and obtained the values 39 (38) mm., 156 (165) mm., and 290 (307) mm. respectively. The numbers in brackets refer to the vap. press. of liquid ammonia at these temp. J. E. Willm found that thallic triamminochloride is decomposed by water with the separation of bluish-black thallium sesquioxide; it dissolves in hydrochloric acid, forming ammonium chlorothallate, and when heated it gives off ammonia, and ammonium chloride, and leaves behind a residue of thallous chloride. R. J. Meyer found that tetrahydrated thallium chloride readily absorbs one molar proportion of hydrogen chloride, forming a liquid which, on standing over phosphorous pentoxide, furnishes needle-like crystals of **hydrotetrachlorothallic acid,** $HTlCl_4.3H_2O$, or $TlCl_3.HCl.3H_2O$; the same compound was obtained by evaporating a soln. of thallic chloride in conc. hydrochloric acid; and by evaporating on a water-bath a soln. of thallous chloride sat. with chlorine, and maintained sat. during the evaporation. The evaporation is completed over sulphuric acid, and potassium hydroxide contained in a desiccator. The crystals rapidly deliquesce in air, and chlorine and hydrogen chloride are evolved simultaneously with the reduction of some of the thallic salt. The crystals are stable in dry air. V. Thomas gives the heat of formation: $TlCl_{3soln.}+HCl_{soln.}=TlCl_3.HCl-0·2$ Cal. When a soln. of the salt is neutralized with potassium hydroxide, R. J. Meyer found that the salt $2KCl.TlCl_3.2H_2O$ is obtained, and not, as anticipated, $KTlCl_4.nH_2O$; the reaction is represented by: $2HTlCl_4+2KOH=K_2TlCl_5+TlCl_3+2H_2O$; and A. S. Cushman represents the transformation by the symbols:



$$H-Cl=Cl-\overset{H}{\underset{H}{\dot{O}}}-Tl<\begin{matrix}Cl=O=H_2\\Cl=O=H_2\end{matrix} \rightarrow \begin{matrix}H\\H\end{matrix}>O-Cl-\overset{H}{\underset{H}{O}}-Tl<\begin{matrix}Cl=Cl-K\\Cl\quad Cl-K\end{matrix}$$

where the linkage of H—Cl= to the complex is not strong enough to attach the heavier and more basic K—Cl=; in consequence, a redistribution of the atoms in the mol. occurs so as to produce the most stable configuration which is possible under the circumstances. R. J. Meyer drew attention to the analogy between hydrochlorothallic acid, $HTlCl_4.3H_2O$, and hydrochloroauric acid, $HAuCl_4.3H_2O$.

Three types of double salts with thallic chloride and alkali or ammonium chloride are known: $2TlCl_3.3MCl.nH_2O$; $TlCl_3.3MCl\,nH_2O$; and $3TlCl_3.MCl.nH_2O$. Thallic and ammonium chlorides can be fused and crystallized together in all proportions, the thallic salt suffers reduction during fusion, and this prevents the construction of f.p. curves like those obtained with thallous chloride. **Ammonium hexachlorothallate,** $3NH_4Cl.TlCl_3$, or $(NH_4)_3TlCl_6$, is formed, according to J E. Willm,[8] when a soln. of thallic triamminotrichloride in hydrochloric acid is evaporated to the point of crystallization; and G. Neumann prepared it by treating a soln. of thallic chloride in conc. hydrochloric acid with a conc. soln. of ammonium chloride. According to R. J. Meyer, the hexagonal plates so formed gradually become yellow owing to the reduction of the salt. J. Nicklès obtained **dihydrated ammonium hexachlorothallate,** $3NH_4Cl.TlCl_3.2H_2O$, by treating the ether or alcohol compound of thallic chloride with ammonium chloride; C. F. Rammelsberg obtained the same product by evaporating a mixture of ammonium chloride with a soln. of thallic hydroxide in hydrochloric acid; and G. Neumann, by saturating with chlorine a warm soln. of thallium sesquioxide and potassium chloride in conc. hydrochloric acid. The liquid, filtered through glass-wool, is evaporated either in a desiccator or on a water-bath while chlorine is being passed through the soln. According to C. F. Rammelsberg, the tetragonal bipyramidal crystals have the axial ratio $a:c=1:0·7954$. J. Nicklès noted that the crystals gradually become yellow with red spots due to the formation of thallic hydroxide. The salt is soluble in water and in alcohol, and it loses all its water at 100°. When a soln. of the salt is treated with alkali hydroxide, carbonate, or with water containing calcium hydrocarbonate in soln., thallic hydroxide is precipitated.

J. H. Pratt prepared sparingly-soluble, deliquescent crystals of **octohydrated lithium hexachlorothallate,** $3LiCl.TlCl_3.8H_2O$, or $Li_3TlCl_6.8H_2O$, from mixtures of soln. of the component salts; and likewise also, **dodecahydrated sodium hexachlorothallate,** $3NaCl.TlCl_3.12H_2O$, or $Na_3TlCl_6.12H_2O$. C. F. Rammelsberg, and G. Neumann prepared **dihydrated potassium hexachlorothallate,** $3KCl.TlCl_3.2H_2O$, or $K_3TlCl_6.2H_2O$, by methods similar to those which they respectively employed for the corresponding ammonium salt. R. J. Meyer made it from a mixed soln. of the component salts containing three or more mols of potassium chloride for one of thallium trichloride. J. Nicklès also investigated this salt. According to A. Fock, the tetragonal bipyramidal plates have the axial ratio $a:c=1·017913$, and they are feebly double-refracting. According to A. Fock, and R. C. Wallace, the salts $K_3TlCl_6.2H_2O$, $(NH_4)_3TlCl_6.2H_2O$, $K_3InCl_6.2H_2O$, are isomorphous with one another and with the corresponding bromides. The crystals can be kept in air for some time, but they gradually become matte and turbid; and between 50° or 60°, or in vacuo, they lose their water of crystallization. At higher temp., they decompose with reduction A soln. of the salt in hydrochloric acid becomes brown on exposure to light. A. Fock found that the salts $3KCl.InCl_3.1\frac{1}{2}H_2O$ and $3KCl.TlCl_3.1\frac{1}{2}H_2O$ form isomorphous mixtures. The salt **potassium pentachlorothallate,** $2KCl.TlCl_3.2(\text{or } 3)H_2O$, is formed by methods analogous to those employed for the *hexachlorothallate*, from soln. with less than three mols of potassium chloride to one of thallic chloride. G. Neumann failed in his attempt to make the salt. According to R. J. Meyer, this salt is formed by neutralizing hydrochlorothallic acid. According to C. F. Rammelsberg, it forms transparent, colourless, monoclinic, prismatic crystals with axial ratios $a:b:c=0·7050:1:0·9576$, and $\beta=98°\ 18'$. According to R. J. Meyer, when dried in vacuo, or when heated between 50° and 60°, a mol of water is lost. According to C. F. Rammelsberg, two mols of water are lost over sulphuric acid. It is decomposed when heated above 60°, and is partially reduced. J. H. Pratt prepared rhombic crystals of **monohydrated rubidium pentachlorothallate,** $2RbCl.TlCl_3.H_2O$, by adding between 1·25 and 18 grms. of rubidium chloride to a conc. soln. of 30 grms. of thallic chloride. The axial ratios are $a:b:c$ 0·6792 : 1 : 0·7002; R. C. Wallace gives for the axial ratios $a:b:c$ 0·9770 : 1 : 1·4388, and the sp. gr. 3·513 at 20°. The crystals are not decomposed by recrystallization. G. Neumann made **rubidium hexachlorothallate,** $3RbCl.TlCl_3$, by dissolving thallium sesquioxide and rubidium chloride in conc. hydrochloric acid, and oxidizing the hot soln. with chlorine. The hot filtered soln. deposits thin rhombic plates which are readily soluble in water with decomposition, and gradually become matte and turbid in air. J. H. Pratt prepared monoclinic crystals of **monohydrated rubidium hexachlorothallate,** $3RbCl.TlCl_3.H_2O$, from a soln. containing 1·5 to 25 grms. of thallic chloride to 40 grms. of rubidium chloride. F. Godeffroy obtained colourless, quadratic crystals of **dihydrated rubidium hexachlorothallate,** $3RbCl.TlCl_3.2H_2O$, by evaporating a mixed soln. of the component salts, and he says that 100 parts of water at 18° dissolve 13·3 parts of the salt and at 100°, 62 parts of salt. J. H. Pratt obtained pale green crystals of **cæsium pentachlorothallate,** $2CsCl.TlCl_3$, from soln. with 5 to 8 grms of thallic chloride and 50 grms. of cæsium chloride. He also prepared rhombic crystals of **monohydrated cæsium pentachlorothallate,** $2CsCl.TlCl_3.H_2O$, from dil. soln. of 8 to 15 grms. of thallic chloride and 100 grms. of cæsium chloride. The axial ratios are $a:b:c$ 0·6762 : 1 : 0·6951; R. C. Wallace gives for the axial ratios $a:b:c$ 0·9690 : 1 : 1·4321, and the sp. gr. 3·879 at 20°. The salt is isomorphous with the corresponding rubidium salt, with the corresponding indium chlorides and bromides, and with $K_2FeCl_5.H_2O$ and $(NH_4)_2FeCl_5.H_2O$. When the pentachlorothallate is recrystallized from water, or when soln. of 10 grms. of thallic chloride and 0·5 to 20 grms. of cæsium chloride are mixed, crystals of **cæsium enneachlorodithallate,** $3CsCl.2TlCl_3$, are formed. If the soln. contains 50·30 grms. of cæsium chloride to 0·5 grm. of thallic chloride, the crystals are hexagonal plates; if crystallized from water, hexagonal prisms. The axial ratios are $a:c$ 1 : 0·8257. The crystals have a feeble negative double refraction; and the indices of refraction for the Li-, Na-, and Tl-lines are respectively ω 1·772, 1·781, and 1·792, and ϵ =1·762, 1·774, and 1·786. J. H. Pratt prepared a mass of hair-like crystals of **monohydrated cæsium hexachlorothallate,** $3CsCl.TlCl_3.H_2O$, by adding a soln. of 0·25 grm. of thallic chloride to one with 50 grms. of cæsium chloride. F. Godeffroy claimed to have made *dihydrated cæsium hexachlorothallate*, $3CsCl.TlCl_3.2H_2O$, from a mixture of the component salts; and he says 100 grms. of water at 17° dissolve 2·747 grms. of the salt, and at 100°, 33·3 grms. E. H. Ducloux recommended cæsium chloride as a microchemical test for thallium. C. Sandonnini and P. C. Aureggi found that binary mixtures of silver and thallous chlorides form a compound $Ag_2Tl_3Cl_5$, **silver pentachlorotrithallate,** which decomposes on melting, and is revealed by an arrest at 252°. There is a eutectic at 210° with 41 molar per cent. of thallous chloride.

J. Gewecke prepared double salts of many of the bivalent metal chlorides of the type $MCl_2.2TlCl_3.6H_2O$, by allowing a soln. of the component salts in water acidified with hydrochloric acid to evaporate in vacuo over sulphuric acid. For example, **hexahydrated calcium octochlorodithallate,** $CaCl_2.2TlCl_3.5H_2O$, forms large, colourless, transparent crystals; **hexahydrated strontium octochlorodithallate,** $SrCl_2.2TlCl_3.6H_2O$, was also prepared; the corresponding **hexahydrated barium octochlorodithallate** could not be obtained in the pure state, since the needle-like crystals were so hygroscopic they could not be analyzed. G. Neumann prepared thin rhombic plates of **beryllium dodecachlorodithallate,** $3BeCl_2.2TlCl_3$, a method similar to that he used for the potassium salt. The crystals are dissolved by water, but are simultaneously decomposed; and they are not stable in air. J. Gewecke obtained transparent, colourless, hygroscopic crystals of **hexahydrated magnesium octochlorodithallate,** $MgCl_2.2TlCl_3.6H_2O$; colourless prisms of **hexahydrated zinc octochlorodithallate,** $ZnCl_2.2TlCl_3.6H_2O$; and large pale blue crystals of **hexahydrated cupric octochlorodithallate,** $CuCl_2.2TlCl_3.6H_2O$, from neutral aq. soln. J. E. Willm also prepared green matte crystals of **cupric octochlorodithallate,** $CuCl_2.2TlCl_3$, by evaporating mixed soln. of the component salts.

Colourless, hygroscopic, needle-like crystals of **trihydrated thallic fluodichloride,** $TlFCl_2.3H_2O$, were made by J. Gewecke by the action of chlorine upon a soln. of 30 grms. of thallous fluoride in 120 c.c. of 40 per cent. hydrofluoric acid, at 30° to 40°, until the white precipitate first formed is redissolved. Without stopping the current of chlorine, the soln. is evaporated at as low a temp. as possible. The crystals are pressed between filter-paper and dried for two hours in a desiccator over phosphorus pentoxide and potassium hydroxide. The salt becomes anhydrous **thallic fluodichloride,** $TlFCl_2$, if it be allowed to stand some time in a desiccator over phosphorus pentoxide and potassium hydroxide. The salt is very hygroscopic, and is rapidly decomposed by moist air; it is soluble in absolute alcohol, forming a pale yellow soln.; aqueous alcohol gives a deep yellow soln. and soon deposits thallic hydroxide. Thoroughly dried ammonia is absorbed by anhydrous and dry thallic fluochloride, cooled by a freezing mixture, forming white **thallic tetramminofluodichloride,** $TlFCl_2.4NH_3$. It is immediately decomposed by water. Thallic fluochloride forms white needles of a double salt with pyridine, $TlFCl_2.2C_5H_5N$. J. Gewecke also prepared colourless crystals of **potassium difluopentachlorodithallate,** $KCl.2TlFCl_2$, or $KTl_2F_2Cl_5$, by evaporating a mixed soln. of 4 grms. of potassium chloride and 24 grms. of thallic fluochloride in dilute hydrofluoric acid, recrystallizing from dil. hydrofluoric acid, and drying the product in a desiccator.

In 1863, W. Crookes and A. H. Church reported the formation of **thallium sesquichloride,** Tl_2Cl_3, **thallosic chloride,** or **thallous chlorothallate,** $3TlCl.TlCl_3$, by the evaporation of a soln. of thallous chloride in aqua regia until the evolution of chlorine has ceased. A. Lamy[9] used metallic thallium in place of thallous chloride—the product can be recrystallized from water acidified with nitric or hydrochloric acid. G. Werther says that the product of this reaction has not a constant composition since his analyses gave numbers ranging from Tl : Cl = 2 : 3 to nearly 1 : 3. A. Lamy also prepared this compound by the action of chlorine on heated thallium. Thallous chloride is scarcely attacked by dry liquid chlorine at −15°, and no method of chlorinating dry thallous chloride to thallium sesquichloride is known which does not at the same time form still higher chlorides. Gaseous chlorine converts dry thallous chloride into Tl_2Cl_3, Tl_2Cl_4, and Tl_2Cl_6. According to R. J. Meyer, there is a continuous series of mixtures of thallous and thallic chlorides. The so-called compound Tl_2Cl_3—that is, $3TlCl.TlCl_3$—corresponds with a sat. soln. of thallous chloride in thallic chloride because no complex with a higher proportion of thallous chloride has been prepared. The colour of the complex deepens with increasing proportions of thallous chloride, and the solubility also decreases in the same proportion. A. S. Cushman passed chlorine into water with thallous chloride in suspension until the latter has all acquired a lemon-yellow colour. If the current of chlorine be continued, the yellow colour disappears and soluble thallic chloride is formed. According to A. S. Cushman, the low solubility of thallium sesquichloride in cold water enables a definite stage in the chlorination to be reached before the thallium trichloride is formed. Although G. Neumann has stated that the dichloride, as well as the sesquichloride, is formed in the action of chlorine on thallous chloride suspended in water, J. E. Willm, A. Lamy, and A. S. Cushman never succeeded in preparing thallium dichloride in the presence of water. Analyses of the yellow products agree closely with the theoretical values for the sesquichloride. G. Neumann prepared thallium sesquichloride by dissolving thallium sesquioxide in hydrochloric acid; R. J. Meyer, by reducing thallic chloride by oxalic acid or hydrogen peroxide; *and J. E. Willm, by precipitating a mixture of thallous and thallic chlorides with hydrogen chloride. According to R. J. Meyer,* the best way of *making* Tl_2Cl_3—that is, $3TlCl.TlCl_3$—is to saturate with freshly precipitated thallous chloride a boiling soln. of thallic chloride in dil. nitric acid. The required salt separates out on cooling.

On cooling a soln. in hot water, thallium sesquichloride crystallizes in yellow six-sided plates—W. Crookes and A. H. Church compared the colour with that of lead iodide. The crystals are stable in air; and, according to A. Lamy, the salt melts between 400° and 500° to a dark brown liquid which contracts during solidification, forming a yellowish-brown solid of sp. gr. 5·9. The solubility in water is low; the data are somewhat divergent; according to W. Crookes, 100 grms. of water at 15° dissolve 0·26 grm. of the salt. According to M. Hebberling, 0·29 grm. at 17°; according to R. Abegg and J. F. Spencer, 0·00333 mols or 0·343 grm. at 25°; according to A. Lamy, 4 to 5 grms. at 100°; and, according to W. Crookes, 1·9 grms. of salt at the same temp. The aq. soln. is colourless; according to A. Lamy, there is a small decomposition of the salt in aq. soln., and this is prevented by a few drops of hydrochloric or nitric acid; and R. J. Meyer showed that by recrystallization from dil. soln. a mixture of Tl_2Cl_3 and $TlCl$ first forms, succeeding fractions are paler and richer in chlorine, until finally thallic chloride remains in soln. M. Hebberling emphasized the fact that aq. soln. give reactions characteristic of both thallic and thallous salts. W. Crookes and A. H. Church found that when exposed to dry ammonia, the colour is deepened, and when heated, ammonium chloride and nitrogen are evolved while thallous chloride remains: $6Tl_2Cl_3+8NH_3=12TlCl+6NH_4Cl+N_2$. The aq. soln. gives with alkali hydroxides a precipitate of thallic hydroxide, while potassium and thallous chlorides remain in soln. A. S. Cushman states that the prolonged action of chlorine in the presence of water converts the salt into thallous chloride, and J. F. Spencer and R. Abegg explain this by the small dissociation press. of chlorine in the complex $3TlCl.TlCl_3$.

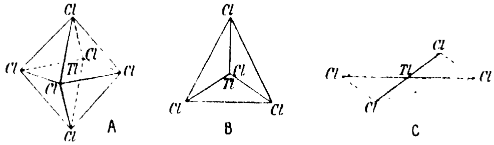
According to A. Lamy, when thallium or thallous chloride is heated in a slow current of chlorine, so long as the product remains liquid, a yellowish-grey liquid is obtained which solidifies to a crystalline mass with about 26·15 per cent. of chlorine and 73·85 per cent. of thallium—approximately Tl : Cl=1 : 2—**thallium dichloride,** $TlCl_2$, or Tl_2Cl_4. According to V. Thomas, this product represents the highest stage in the chlorination of thallous chloride by chlorine in the presence of methyl chloride, or carbon tetrachloride. If chloroform be used there is a slight decomposition of the solvent and a little carbon tetrachloride is formed. G. Neumann claims to have made it by dissolving thallium sesquioxide in hydrochloric acid. Thallium dichloride is a pale yellow deliquescent solid which is more fusible than the sesquichloride, and which is transformed into the sesquichloride when heated. It is decomposed by water into thallic chloride and thallium sesquichloride. J. J. Sudborough prepared a double compound with nitrosyl chloride—$TlCl.TlCl_3.2NOCl$—and V. Cuttica and co-workers, **thallosic trinitrosyl chloride,** $TlCl_2.3NOCl$.

R. J. Meyer regards thallium dichloride as a solid soln. of thallous in thallic chloride. In 1865, J. E. Willm summed up reasons for believing that the intermediate chlorides of the types $TlCl_2$ and Tl_2Cl_3 respectively called the tetra- and sesqui-chlorides should be regarded as double salts and formulated $TlCl_3.TlCl$, and $TlCl_3.3TlCl$, because (i) they resemble in their general behaviour well-defined double salts of the types $TlCl_3.CuCl$; $TlCl_3.3KCl$; $TlCl_3.3NH_4Cl$; etc.; (ii) they can be made by mixing the thallic and thallous halides in the proper proportions; (iii) no oxides are known corresponding with these intermediate halides; and (iv) if the intermediate halides are treated with alkali they form the alkali halide and precipitate insoluble thallic and thallous oxides. G. Neumann also favours this hypothesis. The double salts which thallium can form with itself can be represented, according to C. W. Blomstrand's views:

$$\mathrm{Tl}\begin{matrix}\diagup\mathrm{Cl}\\ -\mathrm{Cl}\\ \diagdown\mathrm{Cl{=}Cl{-}Tl}\end{matrix}$$

$$\mathrm{Tl}\begin{matrix}\diagup\mathrm{Cl{-}Cl{-}Tl}\\ -\mathrm{Cl{-}Cl{-}Tl}\\ \diagdown\mathrm{Cl{-}Cl{-}Tl}\end{matrix}$$

but this does not show why no pentahalide of thallium has been observed—$TlCl_3.2TlCl$ should be as capable of existing as $TlCl_3.TlCl$ and $TlCl_3.3TlCl$. According to A. Werner, there is a dominant thallium atom of the centre of an octahedron as indicated in the appended diagram—Fig. 16, *A*; and in the cases of the so-called sesquichloride, and of the tetra-salt the dominant thallium atom is at the centre of a tetrahedron, Fig. 17, *B*; or the configuration of the molecule, is in a plane, and one axis is unsaturated—Fig. 18, *C*. In symbols $[TlCl_6]Tl_3'$ and $[TlCl_4]Tl'$ respectively. This view makes thallium sesquichloride to be **thallous hexachlorothallate,** Tl_3TlCl_6; and thallium dichloride to be **thallous tetrachlorothallate,** $TlTlCl_4$.



Figs. 16–18.—A. Werner's Nuclei for $[TlCl_6]Tl_3'$ and $[TlCl_4]Tl'$.

§ 9. The Thallium Bromides

A. Lamy[1] found that bromine unites directly with thallium less energetically than is the case with chlorine. The attack is appreciable at ordinary temperatures only after many weeks. According to J. Nicklès, the reaction proceeds more quickly in the presence of water or alcohol. Thallium forms the bromides TlBr, and $TlBr_3$, with the intermediate bromides Tl_2Br_3 and Tl_2Br_4, as well as a number of chlorobromides.

Thallous bromide, TlBr, is prepared by methods analogous to those employed in preparing thallous chloride—*e.g.* J. E. Willm made it by precipitation from a thallous salt by means of potassium bromide; and J. Nicklès, by the action of sulphur dioxide on the compound of thallic bromide with ether. The precipitated salt is white and curdy; the salt can also be obtained in pale yellow cubic crystals from hot soln. R. Lorenz and W. Eitel did not succeed in making optically clear crystals. W. Biltz represented the lattice energy of thallous bromide by 185 Cals. per mol. F. W. Clarke gives the sp. gr. of the precipitated salt as 7·540 at 21·7°, and after fusion, 7·557 at 17·3°. F. A. Henglein found that the mol. vols. of thallous, cuprous, and silver bromides give a straight line when plotted against numbers corresponding with anions or cations. T. W. Richards and G. Jones give the coeff. of compressibility as $5{\cdot}2\times10^{-6}$ per atm. T. Carnelley says the salt melts below a red heat between 458° and 463°. K. Monkemeyer gives 450°; and H. von Wartenberg and O. Bosse, 456°. According to E. Carstanjen, thallous bromide forms a dark yellow liquid which solidifies to a pale yellow solid resembling fused thallous chloride. H. Stolzenberg and M. E. Huth give 441° for the m.p. of the iodide, and say that when the molten salt cools the liquid is anisotropic. C. Tubandt and E. Lorenz showed the phenomenon is due to the use of a badly purified salt. According to K. Monkemeyer, fused mixtures of thallous chloride (melting at 426°) and thallous bromide (melting at 450°) give a continuous series of mixed crystals with a minimum at 413° corresponding with 60 molar per cent. of thallous chloride. H. von Wartenberg and O. Bosse found the vap. press., p, to be 70·8 mm. at 634°; 186·8 mm. at 695°; 396·7 mm. at 757°; 565·9 mm. at 791°; 773·6 mm. at 817°; and at the absolute temp. T, $\log p = 25164/1{\cdot}571T + 5{\cdot}059$. The b.p. is 815°. G. D. Roos gave 12·7 cals. per gram for the heat of fusion. The heat of formation, according to J. Thomsen, is Tl + Br = TlBr + 41·3 Cals., and M. de K. Thompson calculates, from the solubility, the heat of formation 39·7 Cals. $TlOH_{aq} + HBr_{aq.} = 27{\cdot}51$ Cals.; and $Tl_2O + 2HBr = 2TlBr + H_2O + 91{\cdot}82$ Cals. J. O. Perrine observed no fluorescence with thallous bromide in X-rays. F. Kohlrausch gives the electrical conductivity of a soln. sat. at 18° as $192{\cdot}20^{-6}$ reciprocal ohms per cm. cube. J. C. Ghosh found the sp. conductivity to be 0·00004 at 523° K.; 0·00055 at 623° K.; 0·00160 at 673° K.; and 0·00470 at 720° K. A. Benrath found the bromide is not affected by exposure to light. W. W. Coblentz and J. F. Eckford measured the photoelectric sensitivity of thallous bromide. G. von Hevesy found the ratio of the conductivities of thallous bromide above and below the m.p. is 130, and the gain of energy in rendering the ions of the crystal neutral is 73 cals.—*vide* the chloride. The chemical reactions resemble those of the chloride.

According to F. Kohlrausch, a litre of water at 18° dissolves 1·49 milligram eq., or 0·420 grm. of thallous bromide; W. Böttger gives at 20°, 0·00164 mols; and W. Biltz, 0·0013 between 16° and 18°. The solubility in 100 grms. of water is therefore 0·042 grm. at 18°, 0·048 grm. at 20°, 0·057 grm. at 25°, and 0·247 grm. at 68·5°. J. Thomsen gives for the heat of soln. in water −13·75 Cals. A. A. Noyes studied the effect of thallous nitrate on the solubility of the bromide. A. Naumann says thallous bromide is insoluble in acetone, and A. Naumann and J. Schröder, insoluble in pyridine. For **thallous triamminobromide,** $TlBr.3NH_3$, *vide* the corresponding chloride. W. Biltz found the vap. press. at −50° to be 287 (307) mm., and at −60°, 160 (165) mm., where the numbers in brackets refer to the vap. press. of liquid ammonia at the given temp. The salt dissociates at −66° under 100 atm. press., and its heat of formation is 7·1 Cals. per mol of ammonia. G. L. Clark made some observations on this subject. J. Barlot and J. Pernot made **mercuric thallous bromide,** $HgBr_2.TlBr$, in long matted needles.

J. Nicklès stirred up thallous bromide with water to form a slurry and passed bromine through the warm liquid. The thallous bromide gradually dissolved furnishing a liquid which in vacuo formed a felted mass of deliquescent, needle-like crystals—**tetrahydrated thallic bromide,** $TlBr_3.4H_2O$—which contained some thallous bromide. While the soln. was found to be fairly stable, the crystals readily decompose. V. Thomas evaporated the soln. obtained by passing bromine through water with thallous bromide in suspension, at 30° to 40°, but not higher, until the soln. crystallizes on cooling. The soln. is very liable to undercooling, and a jet of carbon dioxide from a bomb will cool the liquid and start crystallization. If the warm soln. be conc. too far, it will decompose, giving off bromine. The long, pale yellow, needle-like crystals obtained by this process are likewise tetrahydrated thallic bromide. The crystals melt at 40°, and they lose water and bromine when dried in vacuo. It has not yet been possible to prepare anhydrous *thallium tribromide*, or *thallic bromide*, $TlBr_3$, because when dehydration is attempted in vacuo, bromine and thallium dibromide are produced; the same result was obtained by V. Thomas in the attempt to dehydrate the tetrahydrated salt in a current of air at 30°, and by J. Nicklès, by confining the soln. over sulphuric acid in a desiccator —bromine was given off and Tl_2Br_4 was formed. According to V. Thomas, the heat of formation of the tribromide in aq. soln. is $Tl+3Br_{liquid}+Aq.=TlBr_{3aq.}+56\cdot8$ Cals.; the heat of formation of the tetrahydrated bromide is $TlBr_{liquid}+4H_2O_{liquid}+2Br_{liquid}=TlBr_3.4H_2O+59\cdot0$ Cals.; and the heat of soln. of tetrahydrated thallic bromide is $-2\cdot45$ Cals.

R. J. Meyer reported the formation of yellow hair-like crystals of **monohydrated thallic bromide,** $TlBr_3.H_2O$, by evaporating in vacuo the soln. obtained by shaking thallous bromide in the cold with bromine water. The crystals are said to be very unstable, and soluble in water, alcohol, and ether. J. E. Willm prepared **thallic triamminobromide,** $TlBr_3.3NH_3$, by mixing a conc. alcoholic soln. of thallic bromide with alcoholic ammonia. The resulting white precipitate is washed with alcohol, and dried. The colour soon becomes yellow owing to the partial decomposition of the salt. The compound is decomposed by water with the separation of a black oxide. When heated to 100°, it forms a dark yellow sticky mass, and loses ammonia and bromine to form thallous bromide. J. Nicklès prepared a compound of thallic bromide with ether, $TlBr_3.3(C_2H_5)_2O$.

R. J. Meyer found that when a soln. of thallic bromide in hydrobromic acid is evaporated, a non-crystallizable syrup is produced, but solid *hydrotetrabromothallic acid*, $HTlBr_4.3H_2O$ or $TlBr_3.HBr.3H_2O$, analogous with the corresponding hydrotetrachlorothallic acid, has not been obtained. A similar soln. was made by the action of hydrobromic acid on hydrotetrachlorothallic acid—possibly $TlCl_3.HBr.3H_2O$ is first formed, and this reacts with more hydrobromic acid to form hydrotetrabromothallic acid. J. Nicklès prepared **ammonium tetrabromothallate,** $NH_4TlBr_4.2(4 \text{ or } 5)H_2O$, by the action of bromine on thallous and ammonium bromides, or of ammonium bromide on an ethereal soln. of thallic bromide. The former process furnishes needle-like, and the latter plate-like, crystals. The needle-like crystals lose 12·3 per cent. of water at 100°; and both forms melt in their water of crystallization. J. E. Willm made needle-like crystals by saturating with ammonia a soln. of bromine and thallium bromide suspended in alcohol. His analysis indicated that the solid contained $5H_2O$; J. Nicklès' analyses indicated $4H_2O$, and $2H_2O$. The crystals lose all their water in vacuo.

J. Nicklès made the **dihydrated potassium tetrabromothallate,** $KBr.TlBr_3.2H_2O$, or $KTlBr_4.2H_2O$, isomorphous with the ammonium salt by a similar process. R. J. Meyer made it by evaporating in vacuo a soln. of equi-molar parts of thallic and potassium bromides. The large rhombic plates are stable in air, and, according to R. C. Wallace, the crystals are cubes and octahedra belonging to the cubic system. According to J. Nicklès, the salt begins to melt at 100°, and, according to R. J. Meyer, the salt cannot be dehydrated without losing bromine—the loss of bromine occurs by exposure to air, for the crystals become covered with a crust of pale yellow thallous bromide. C. F. Rammelsberg reported yellow cubic crystals of **trihydrated potassium enneabromodithallate,** $3KBr.2TlBr_3.3H_2O$, or $K_3Tl_2Br_9.3H_2O$, but while R. J. Meyer cast doubts on the existence of this salt, the anhydrous chlorides and bromides of cæsium have been made independently by J. H. Pratt. Pale yellow cubic crystals of **monohydrated rubidium tetrabromothallate,** $RbBr.TlBr_3.H_2O$, were made by J. H. Pratt by crystallization from a soln. containing 3 to 24 grms. of rubidium bromide, and 40 grms. of thallic bromide. The salt cannot be recrystallized from water without change. J. H. Pratt also made golden-yellow tetragonal crystals of **monohydrated rubidium hexabromothallate,** $3RbBr.TlBr_3.H_2O$, from soln. containing 1·5 to 24 grms. of thallic bromide and 50 grms. of rubidium bromide. The axial ratios are $a : c = 1 : 0·8073$. The crystals are feebly double refracting. The salt is sparingly soluble in water, and passes into $RbTlBr_4.H_2O$ when the attempt is made to recrystallize it from water. J. H. Pratt made pale yellow cubes of **cæsium tetrabromothallate,** $CsTlBr_4$, or $CsBr.TlBr_3$, by mixing soln. containing 40 grms. of thallic bromide with 2 to 10 grms. of cæsium bromide. By recrystallization from water, he obtained yellowish-red crystals of **cæsium enneabromodithallate,** $3CsBr.2TlBr_3$; and the same salt again from a mixture of 1–15 grms. of thallic bromide and 50 grms. of cæsium bromide. It can be recrystallized from water.

J. Gewecke prepared sulphur-yellow plates of **thallic fluorodibromide,** $TlFBr_2$, by dropping bromine into a soln. of 30 grms. of thallous fluoride in 120 c.c. of 40 per cent. hydrofluoric acid between 30° and 40° until the yellowish-white precipitate first formed has redissolved; and evaporating the soln. between 30° and 40°. The crystals are more stable than thallic bromide; they are soluble in absolute alcohol; decomposed by water; and form a yellowish-white powder of **thallic tetramminofluodibromide,** $TlFBr_2.4NH_3$, by a process analogous to that employed for thallic tetramminofluorodichloride. This compound is decomposed by water, and is slightly soluble in absolute alcohol.

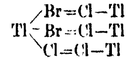
V. Thomas prepared **tetrahydrated thallic bromodichloride,** $TlBrCl_2.4H_2O$, by the action of chlorine on thallous bromide in the presence of a little water. The compound is very unstable, and it is decomposed by water and by heat. V. Thomas also prepared **tetrahydrated thallium dibromochloride,** $TlBr_2Cl.4H_2O$, by the action of a small excess of bromine on thallous chloride in the presence of cold water. The soln. on evaporation furnishes pale yellow needles which have properties recalling those of a mixture of the hydrates of thallic bromide and chloride. In vacuo, the crystals lose chlorine, bromine, and water: $6(TlClBr_2.4H_2O) = 2Tl_3Cl_2Br_4 + 24H_2O + Cl_2 + 2Br_2$. They melt at 40°, the temp. at which decomposition begins. It is not certain if these two compounds are chemical individuals or mixtures of $TlCl_3.4H_2O$ and $TlBr_3.4H_2O$.

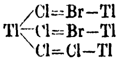
V. Thomas found that thallic chloride at a low temp. absorbs hydrogen bromide, forming presumably **hydrobromodichlorothallic acid,** $TlCl_3.HBr$, or $HTlBrCl_3$; thallic bromide under similar conditions absorbs hydrogen chloride, forming presumably hydrotribromochlorothallic acid, $TlBr_3.HCl$ or $HTlClBr_3$. In an analogous manner, the thallic bromochlorides absorb hydrogen chloride or bromide forming presumably the four compounds: $TlCl_2Br.HCl$; $TlClBr_2.HCl$; $TlCl_2Br.HBr$; and $TlClBr_2.HBr$. All these products are very soluble in water and are so unstable that they have not been isolated in the solid state.

The action of bromine on thallous bromide closely resembles that of chlorine on thallous chloride, a mixture of thallium sesqui- and di- bromides is formed. These two compounds were first prepared by J. E. Willm.[2] According to A. S. Cushman's modification of J. E. Willm's process, thallous bromide is suspended in a very little water and treated with bromine, a yellow compound is formed which dissolves on heating, and crystallizes on cooling in minute yellow needles which under the microscope appear as elongated square prisms of *thallium dibromide*, $TlBr_2$, or Tl_2Br_4; if the soln. be cooled slowly the crystals are orange-red instead of red, and they are contaminated with a little bromine, but, added V. Thomas, never more than corresponds with the formula Tl_2Br_3. When the crystals of thallium dibromide are dissolved in water and recrystallized, dark red hexagonal plates of **thallium sesquibromide,** Tl_2Br_3, or **thallosic bromide,** $3Tl_2Br.TlBr_3$, are produced. The reaction in the presence of water is symbolized: $3TlBr_2 = Tl_2Br_3 + TlBr_3$. In order to prepare the sesquibromide, V. Thomas moistened 4 to 5 grms. of thallous bromide with a few c.c. of water, and agitated the product with 0·5 c.c. of bromine. The mixture was boiled with 50 c.c. of water, and after filtering off the undissolved thallous bromide, the soln. was cooled as rapidly as possible by immersing the containing flask in a freezing mixture when red crystals separated out. J. E. Willm precipitated thallium sesquibromide by adding potassium bromide to a mixed soln. of eq. amounts of thallous and thallic bromides; and he also agitated a soln. of thallic bromide with an eq. amount of thallous bromide. According to R. J. Meyer, the crystals of thallium sesquibromide are more easily decomposed by water than those of the corresponding chloride, and hence J. E. Willm washed them with dilute alcohol. When heated in the absence of air, J. E. Willm found the crystals become yellow, then brown, and finally melt with the evolution of bromine, and the formation of a sublimate which is brown when hot and yellow when cold. According to V. Thomas, thallium sesquibromide forms mixed crystals with thallous bromide which are orange-red or orange-yellow.

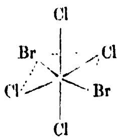
Just as the treatment of thallous chloride with thallic chloride leads to the formation of thallium sesquichloride, Tl_2Cl_3, or thallous hexachlorothallate, $TlCl_3.3TlCl$, or $Tl_3'Tl'''Cl_6$, so does it appear possible that the treatment of thallous bromide with thallic chloride would lead to the formation of $TlCl_3.3TlBr$, while the treatment of thallous chloride with thallic bromide would lead to the formation of $TlBr_3.3TlCl$. The thallium chlorobromides have been principally studied by C. Wiegand (1899), A. S. Cushman (1900), R. J. Meyer (1900), and by V. Thomas (1900–7). Bromine acts on cold thallous chloride in contact with cold water, forming a yellow powder with a composition varying between $TlCl$ and $Tl_4Cl_3Br_3$, dependent upon the proportion of bromine employed. A. S. Cushman prepared **thallous dibromotetrachlorothallate,** $Tl_3'Tl'''Br_2Cl_4$, or $TlClBr_2.3TlCl$, belonging to the type $Tl_3[TlCl_6]$, by shaking thallous chloride with bromine in the presence of water until the white colour of the thallous salt had changed to orange-yellow; this product was washed by decantation with cold water, and finally dissolved in boiling water acidified with nitric acid; on cooling, dark orange hexagonal plates appeared which when purified by two crystallizations, washing, and drying gave analytical numbers in agreement with the indicated formula. V. Thomas employed a similar process for $Tl_4Cl_4Br_2$, and by varying the proportions of bromine up to one gram-atom, he obtained products varying in composition from $TlCl$ to $Tl_4Cl_3Br_3$. R. J. Meyer made thallium dibromotetrachlorothallate by dissolving thallous bromide in a hot soln. of thallic chloride, and cooling; and also by boiling the compound $Tl_4Br_4Cl_2$ with water.

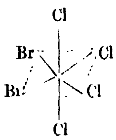
A. S. Cushman prepared what is possibly an isomeric form of this compound and of a citron-yellow colour, by treating thallous chloride with the mother-liquid from which the complex salt was obtained, and recrystallizing from nitric acid. The physical characters of the possible isomers are very much alike, and the difference in colour may really have nothing at all to do with isomerism, but rather be an effect of crystal aggregation and impurities. According to C. W. Blomstrand's, and S. M. Jörgensen's hypotheses, these compounds may be:





or, according to A. Werner's hypothesis:





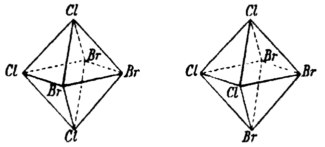
C. Wiegand and R. J. Meyer reported a compound of the composition $Tl_6Cl_5Br_2$, but A. S. Cushman regarded this product as a mixture of $Tl_4Cl_4Br_2$ with thallous chloride. A. S. Cushman also considers C. Wiegand and R. J. Meyer's $Tl_4Cl_2Br_4$ to be $Tl_4Cl_3Br_3$. Working by analogous methods it should be possible to prepare the following series of chlorobromides of the type Tl_4Cl_6: (i) Tl_4Cl_5Br; (ii) $Tl_4Cl_4Br_2$; (iii) $Tl_4Cl_3Br_3$; (iv) $Tl_4Cl_2Br_4$; (v) Tl_4ClBr_5. Of these, only the second, third, and fourth have been reported.

A. S. Cushman found that when thallous bromide, suspended in hot water, is treated with a dil. soln. of thallic chloride, an orange-coloured substance is formed which can be dissolved by boiling. Orange-coloured hexagonal plates of **thallous tribromotrichlorothallate,** or $TlCl_3.3TlBr$, are deposited on cooling the soln. On the other hand, when thallous chloride is suspended in a considerable proportion of hot water, and treated with a soln. of thallic bromide, a dark blood-red compound is formed which dissolves on boiling, and, on rapid cooling, crystallizes out in blood-red hexagonal crystals of thallous tribromotrichlorothallate, $TlBr_3.3TlCl$, presumably an isomeric form of the orange-coloured $TlCl_3.3TlBr$. According to C. W. Blomstrand's, and S. M. Jörgensen's hypotheses of the tervalency of the halides, these possibly isomeric products are formulated:

$$\mathrm{Tl}\left\langle\begin{array}{l}\mathrm{Cl{=}Br{-}Tl}\\ \mathrm{Cl{=}Br{-}Tl}\\ \mathrm{Cl{=}Br{-}Tl}\end{array}\right. \qquad\qquad \mathrm{Tl}\left\langle\begin{array}{l}\mathrm{Br{=}Cl{-}Tl}\\ \mathrm{Br{=}Cl{-}Tl}\\ \mathrm{Br{=}Cl{-}Tl}\end{array}\right.$$

Orange $TlCl_3.3TlBr$. Red $TlBr_3.3TlCl$.

According to A. Werner's hypothesis:



$\left[Tl^{Cl_3}_{Br_3}\right]Tl_3$. $\left[Tl^{Br_3}_{Cl_3}\right]Tl_3$.

FIGS. 19–20.—Werner's Models for $[TlCl_3Br_3]Tl_3'$.

The orange-coloured salt is stable, the red-coloured salt unstable; if orange $TlCl_3.3TlBr$ be treated with an excess of thallic chloride, lemon yellow $TlCl_3.3TlCl$ is gradually formed; while the orange salt is transposed into the red variety by treatment with a conc. soln. of thallic bromide: $TlCl_3.3TlBr+3TlBr_3 = TlBr_3.3TlCl+3TlBr_3$. A. S. Cushman adds that the electrical conductivities of these salts show that the salt $TlBr_3.3TlCl$ dissociates on soln. into thallic bromide and thallous chloride; and when the soln. is cooled, the particular salt which separates depends on the temp. and solubility of the products of the thallous salt and the double salts respectively. If thallic bromide and thallous chloride exist in soln. and are in turn ionized, it is difficult to see why both isomers on recrystallization retain their characteristic individuality instead of at least in part, passing into one another. By varying the conc. of the soln., A. S. Cushman found it possible to prepare yellow needles of $TlBr_3.TlCl$, or hexagonal crystals of red $TlBr_3.3TlCl$, or orange $TlCl_3.3TlBr$.

R. J. Meyer could not prepare a salt by dissolving thallous bromide in a soln. of thallic chloride, but he did obtain the red salt by the action of chlorine on thallous bromide suspended in water, and recrystallizing the product from hot water. V. Thomas also treated 9·6 grms. of thallous chloride, suspended in 50–100 c.c. of water, with 2 grms. of bromine, and obtained a yellow precipitate; he made the soln. up to a litre with water, and boiled the mixture till all excepting a few brown flecks of thallic oxide, the result of hydrolysis, was dissolved. On cooling the filtered soln., about 4 grms. of hexagonal plates of $Tl_4Cl_3Br_3$ separated out between 40° and 33°. The mother-liquid was conc. by evaporation, when a mixture of hexagonal plates and yellow needles separated out—the yellow needles contain more chlorine than bromine. Both kinds of crystals when heated become orange-coloured and then blood-red; the original colour is restored on cooling; both forms melt at 240°. According to A. S. Cushman, if the crystals of the orange and yellow forms of the thallous tribromotrichlorothallates be sealed up in glass tubes separately, under their own mother liquids, and gradually heated, at about 100°, the colour changes, and as the temp. rises still higher white precipitates resembling thallous halides gradually appear. On cooling, the double salts reform in well-defined crystals without any sign of the white thallous salts. The double salts do not exist in soln. above certain temp., for the state of equilibrium is quite different at higher temp. from what it is at the lower temp. This does not invalidate A. Werner's theory, for the fact that ammonium chloride dissociates into NH_3 and HCl above a certain temp. does not affect belief in the existence of the complex $[NH_4]Cl$ at lower temp.

R. J. Meyer sat. a boiling soln. of thallic bromide with thallous chloride, and on cooling the filtered soln. obtained dark red plates of tetrathallium tetrabromodichloride, $Tl_4Cl_2Br_4$, *i.e.* $TlBrCl_2.3TlBr$, or **thallous tetrabromodichlorothallate,** $Tl_3[TlBr_4Cl_2]$; and he also obtained a dark red powder of the same composition by the chlorination of thallous bromide in the presence of a little water. These crystals are very easily decomposed by water. When recrystallized from hot soln., the character of the product depends on the rapidity of the cooling. V. Thomas considers the existence of the compound $Tl_4Cl_2Br_4$ as doubtful. As A. S. Cushman has said:

> The ease with which the sesquihalogen compounds of thallium undergo hydrolysis or decomposition, their hygroscopic nature, their mixed equilibria in relation to water of crystallization and state of oxidation, and their generally complex nature, present dangerous pitfalls to the investigator.

The end-product of the action of bromine on thallous bromide is **thallium dibromide,** $TlBr_2$; V. Thomas heated these two components in a sealed tube at 100° when the reaction proceeds very quickly, but it occupies about 5 hrs. at ordinary temp. The excess of bromine can be driven off by heating the product to 100°. J. E. Willm prepared thallium dibromide by the process indicated above; by mixing an aq. soln. of thallic bromide with an eq. amount of thallous bromide; or by partially reducing a soln. of thallic bromide. Yellow needles of the dibromide separate out as the soln. cools. R. J. Meyer could not make thallium dibromide by J. E. Willm's process, but he evaporated a soln. of thallous bromide in bromine-water in vacuo until bromine was no longer given off. J. E. Willm's process gives good results for thallium dibromide, but it is best made in the dry way on account of the hydrolytic action of water; it is conveniently made by the prolonged action of bromine on thallous bromide suspended in chloroform or carbon tetrachloride. Thallium dibromide forms yellow rhombic prisms which, according to R. J. Meyer, have a peculiar smell; they do not lose in weight when heated to 100°. The salt is slightly soluble in water, and it is gradually decomposed by that menstruum, forming thallium tribromide and a lower bromide. V. Thomas says thallium dibromide is somewhat soluble in bromine.

According to R. J. Meyer, if freshly precipitated thallous chloride be suspended in water, and heated with an excess of bromine, the salt dissolves; and on evaporation of the soln. in vacuo, bromine is evolved and pale yellow crystals of thallium dibromochloride, $TlClBr_2$, are formed. A little thallic oxide, the result of hydrolysis, also separates out. If the evaporation be continued in vacuo over sulphuric acid, yellow rhombic prisms of a compound of the type TlX_2, or Tl_2X_4, namely, **trithallium tetrabromodichloride,** $Tl_3Cl_2Br_4$, are formed. R. J. Meyer, and C. Wiegand made the same compound by treating thallous chloride with a quantity of bromine insufficient to transform all the thallous into thallic salt. V. Thomas prepared this compound by frequently shaking 4·8 grms. of thallous chloride with a soln. of 2·8 grms. of bromine in chloroform; in about a week, the crystals are washed with chloroform. The product with carbon tetrachloride as solvent is not so pure, and still less so with carbon disulphide; in both cases thallium dibromide, TlBr.TlBr$_3$, is formed. The sulphur-yellow rhombic prisms of this salt become matte on exposure to air; they are rapidly decomposed by water, particularly when warm, the colour of the salt becomes dark yellow, and a part passes into soln. R. J. Meyer supposes that thallium dibromotetrachloride, $Tl_4Cl_4Br_2$, is formed; and V. Thomas represents the reactions by the equations: $4Tl_3Cl_2Br_4 = Tl_4Cl_3Br_3 + 3TlBr + 5TlClBr_2$; and $2Tl_3Cl_2Br_4 = Tl_4Cl_3Br_3 + [Tl_2ClBr_5]$ in soln. According to V. Thomas, hydrochloric acid acts like water, forming a salt of the type Tl_2X_3, or Tl_4X_6; hydrobromic acid displaces part of the chlorine; sulphuric and nitric acids decompose the compound, particularly if heated, liberating large proportions of the halogen; and bromine dissolves the salt in the presence of a little water, forming a thallic salt. When heated to about 150°, this salt deepens in colour, it melts to a yellow liquid at about 165°, and begins to decompose at a higher temperature giving off bromine, and leaving behind an orange-coloured crystalline mass of a compound of the type Tl_4X_6, or Tl_2X_3. By passing bromine vapour over thallous chloride, or by heating bromine with thallous chloride in a sealed tube at 100°–120°, V. Thomas prepared a product of the Tl_2X_4 type, namely, **trithallium tribromotrichloride,** $Tl_3Cl_3Br_3$. The salt is not very stable, and is decomposed by water to form a compound of the type Tl_2X_3. R. J. Meyer claims to have obtained an intermediate product, **trithallium tetrachloro-dibromide,** $Tl_3Cl_4Br_2$, by the chlorination of thallous bromide in the presence of a little water, and the same product was obtained by the action of water on bromochlorides of the type Tl_2X_4. When this substance is boiled with water, it passes into $Tl_4Cl_3Br_3$. J. Kendall and co-workers made **thallous tetrabromoaluminate,** TlBr.AlBr$_3$, melting at 210°; and **thallous heptabromoaluminate,** 3TlBr.2AlBr$_2$, melting at 112°.

§ 10. Thallium Iodides

Thallium was shown by W. Crookes[1] *to unite with iodine; it forms thallous and thallic iodides,* TlI and TlI_3, and the intermediate iodides, Tl_2I_3 and Tl_3I_4. **Thallous iodide,** TlI, can be prepared by processes analogous to those employed for the chlorides and bromides. W. Crookes made it as a citron-yellow precipitate by adding potassium iodide to thallous salt soln. It exists in many differently coloured forms—green, yellow, and red. For example, M. Hebberling obtained the red variety by adding potassium iodide to a warm conc. soln. of a thallous salt, and G. Werther found it separated as a dark orange-yellow precipitate, from hot and conc. soln.; while the colour is pale citron-yellow from cold and from dil. soln.; and hot soln. of potassium acetate furnish minute orange-yellow cubes or octahedra. J. E. Willm found hot soln. of potash-lye gave red crystal plates which after a time become yellow. Yellow thallous iodide crystallizes in the rhombic system, the red variety in the cubic system. F. A. Henglein found the mol. vols. of thallium, silver, and cuprous chlorides give a straight line when plotted against numbers corresponding with anions or cations. According to M. Hebberling, the transition temp. from the yellow to the red variety is 190°, but this is probably too high. D. Gernez places it near 168°; B. Gossner at 150°; and K. Mönkemeyer at 174·5°. The conversion from one form to the other is often very slow. A hot filtered aq. soln. of thallous iodide deposits red crystals when rapidly cooled, but yellow crystals if slowly cooled in presence of the yellow form. According to C. van Eyk, the transition temp. is lowered by the addition of thallous nitrate. According to T. Knösel, when freshly precipitated yellow thallous iodide is exposed to the sun's rays, it becomes green and crystalline without changing its composition; the green form is somewhat more soluble in hot water than the yellow form, and it crystallizes from hot water in minute green crystals which have a high refractory power. The green form gradually changes to the yellow form, and the change is accelerated by heating it with aq. iodine or potassium iodide, but not by heating it with water. The green variety becomes red when strongly heated. According to R. E. Liesegang, of all the thallium compounds thallous iodide is the most sensitive to light; and if prepared by double decomposition on gelatine paper, it becomes dark brown by half an hour's exposure to diffuse daylight.

According to F. W. Clarke, the sp. gr. of yellow precipitated thallous iodide is 7·072 at 15·5°, and of red fused thallous iodide, 7·0975 at 14·7°; A. Lamy gave for the latter, 7·056. W. Biltz calculated the lattice energy of thallous iodide to be 180 Cals. The compressibility coeff., according to T. W. Richards and G. Jones, is $6{\cdot}8\times10^{-6}$ per atm. S. Motylewsky found the weight of a drop of thallous iodide at its m.p. is 137 when that of water at 0° is 100; the capillary constant is $\sigma=0{\cdot}076w$; and the sp. cohesion $a^2=2\sigma/D$, where D is the sp. gr. at the m.p. According to M. Hebberling, when thallous iodide is heated it melts to a black liquid which freezes on cooling to a crystalline mass which is first red and then yellow. T. Carnelley first gave 446° for the m.p., and later 439°; K. Mönkemeyer, 431°; H. Stolzenberg and M. E. Huth, and C. van Eyk, 422°; and H. von Wartenberg and O. Bosse gave 440°. H. Stolzenberg and M. E. Huth say that when the molten salt is cooled, the liquid becomes anisotropic; C. Tubandt and E. Lorenz say that the phenomenon is due to the use of an impure salt. W. Crookes, and G. Werther noted that when strongly heated, thallous iodide sublimes with partial decomposition; A. Lamy and A. des Cloizeaux say that the salt is volatile at a red heat; and T. Carnelley and W. C. Williams, that it boils between 800° and 806°. H. von Wartenberg and O. Bosse found the vap. press., p, to be 159·2 mm. at 693°; 385·8 mm. at 763°; 591·4 mm. at 801°; 748·6 mm. at 822°; and, at the absolute temp., $T \log p = -25168/4{\cdot}571T + 5{\cdot}021$. The b.p. is 824°. K. Mönkemeyer obtained unbroken series of mixed crystals of thallium iodide with thallium bromide. The rounded curve of the f.p. of mixed crystals of these two components has a minimum at 411°

with 42 molar per cent. of thallous bromide. With thallium chloride and iodide there is a V-shaped f.p. curve with the eutectic at 316° and 52 molar per cent. of thallous iodide. Thallous chloride can take up only a little thallous iodide, but thallous iodide can take up 18 per cent. of the chloride in the form of mixed crystals. J. Thomsen gives for the heat of formation $Tl+I=TlI+30{\cdot}2$ Cals.; M. de K. Thompson, 29·7 Cals. J. Thomsen gives for the heat of soln. $TlI+Aq.=-17{\cdot}85$ Cals. G. Jones and W. C. Schumb gave 122·11 kj. for the heat of formation, *U*, at 25°, and 125·79 kj. for the free energy of formation at 25°, and 125·48 kj. at 0°. A. Benrath found that the iodide is not affected by exposure to light. W. W. Coblentz and J. F. Eckford measured the photoelectric sensitivity of thallous iodide. The specific conductivity of the sat. aq. soln. at 18° is $22{\cdot}3\times10^{-6}$ reciprocal ohms per cm. cube. J. C. Ghosh found the sp. conductivity at 523° K. to be 0·0001; at 623° K., 0·0010; at 673° K., 0·0027; and at 702°, 0·0048. G. von Hevesy found the ratio of the conductivities above and below the m.p. is 100; and the gain of energy in rendering the ions of the crystal neutral, 81 cals.—*vide* the chloride. G. Jones and W. C. Schumb measured the electrical conductivity of aq. soln. of thallous iodide. The reactions resemble those of the chloride.

The solubility of thallous iodide in water has been measured for about two temp. by W. Crookes, G. Werther, M. Hebberling, A. Lamy, G. Jones and W. C. Schumb, F. Kohlrausch, and W. Böttger. The best representative values for the solubility, *S*, at $\theta°$ in grams per 100 c.c. are:

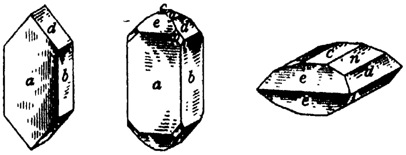
	0°	20°	40°	60°	80°	100°
Solubility . . .	0·002	0·006	0·015	0·035	0·070	0·120 grm.

W. Crookes says that thallous iodide is more soluble in the presence of an excess of *potassium iodide* than in water. A. Lamy, and M. Hebberling say it is less soluble. A. A. Noyes found that the solubility is depressed in the presence of thallous nitrate such that a soln. with 0, 4·336, 7·820, and 25·400 grms. of thallous nitrate per litre dissolve respectively 2·469, 1·164, 0·820, and 0·420 grms. per litre of thallous bromide at 25°. According to J. H. Long, 100 c.c. of 2·5 per cent. *aq. ammonia* dissolve 0·0761 grm. of thallous iodide, and of 6·5 per cent. ammonia, 0·0758 grm.—for **thallous triamminoiodide,** $TlI.3NH_3$, see the corresponding chloride. W. Biltz found the vap. press. of the triammine at −50° to be 274 (307) mm.; at −60°, 159 (165) mm.; and at −79°, 38 (39) mm., when the values for liquid ammonia are indicated in brackets. The temp. of decomposition at 100 mm. press. is −70°, and the heat of formation 7·1 Cals. per mol of ammonia. G. L. Clark made some observations on this subject.

E. Carstanjen says that thallous iodide is less soluble in *acetic acid* than in water, and he, M. Hebberling, G. Werther, and J. H. Long have found the solubility to be diminished in alcoholic soln. According to J. H. Long, 100 c.c. of 90 per cent. *alcohol* dissolve 0·00038 grm. of thallous iodide, and of 50 per cent. alcohol, 0·0027 grm. A. Neumann reports thallous iodide to be insoluble in *acetone;* A. Neumann and J. Schröder, insoluble in *pyridine.* M. Hebberling says that dil. sulphuric acid, hydrochloric acid, and alkali hydroxides do not decompose thallous iodide; and that boiling dil. nitric acid, and the conc. cold acid, liberate iodine; J. E. Willm, that chlorine water and aqua regia dissolve the salt without liberating iodine—and suggests that a *thallic chloroiodide* is formed; G. Werther, that thallous iodide is completely decomposed by zinc and alkali hydroxide soln., and also by boiling soln. of ammonia and silver nitrate; thallous iodide is reduced to thallium by fusion with potassium cyanide; and A. Lamy and A. des Cloizeaux, that it is partially reduced when heated with carbon. J. Barlot and J. Pernot prepared brown elongated crystals of **mercuric thallous iodide,** $TlI.HgI_2$.

A thallium iodide intermediate between thallium mono- and tri-iodides was prepared by W. Strecker, in 1865, by adding potassium iodide to an ammoniacal soln. of a thallic salt in tartaric acid. The black precipitate contains no free iodine or nitrogen iodide; the precipitate obtained from dil. soln. occurs in minute crystalline *rhombic plates, and S. M. Jörgensen says that while the analyses agreed with* Tl_7I_9, *they can be better represented by* Tl_6I_8 *or* Tl_3I_4. *T. Knösel treated thallous iodide with iodine in aq. soln., and obtained a black precipitate which he supposed to be* **thallosic iodide,** or *thallium sesquiodide,* Tl_2I_3, but S. M. Jörgensen considers the assumption that the product is **trithallium tetraiodide,** Tl_3I_4, or $TlI_3.5TlI$, agrees better with T. Knösel's analysis. S. M. Jörgensen obtained a similar product by warming thallous iodide with a conc. soln. of iodine in hydriodic acid, and evaporating to dryness at about 70°; he prepared a less pure product by precipitation from a soluble thallic salt, by adding potassium iodothallate; and by digesting thallous iodide with an ethereal or alcoholic soln. of iodine. According to W. Maitland and R. Abegg, at 25° thallous iodide is stable in soln. with less than 0·0019 grm. or $0{\cdot}76\times10^{-5}$ mol. of iodine, I_2, per litre of water, and if this conc. be exceeded, thallous iodide passes into trithallium tetraiodide, Tl_3I_4, *i.e.* Tl_6I_8; this iodide is stable in soln. with between 0·0019 grm. or $0{\cdot}76\times10^{-5}$ and 0·082 grm. or $3{\cdot}3\times10^{-4}$ mol of iodide, I_2, per litre, and with greater conc. than this, the salt is converted into thallium tri-iodide, TlI_3. According to S. M. Jörgensen, trithallium tetraiodide is sparingly soluble in water and organic liquids with partial decomposition; when trithallium tri-iodide is boiled with alcohol, it loses iodine and becomes yellow and the iodide is reduced to thallous iodide; when kept over sulphuric acid in a desiccator at 110°, it behaves similarly. When warmed with zinc and dil. ammonia, the thallium separates out in a metallic form.

J. Nicklès first prepared **thallic iodide or thallium tri-iodide,** TlI_3, by evaporating an ethereal soln. of thallous iodide and iodine. He stated that he did not obtain it in a pure condition because his product was always contaminated with a little free iodine. H. L. Wells and S. L. Penfield say that they modified J. Nicklès' method by using alcohol as solvent, and encountered no difficulty in preparing the pure product. The amount of iodine used was slightly in excess of the theoretical amount, and the soln., produced after a long digestion, was evaporated over sulphuric acid until crystallization occurred. The crystals obtained were often large, and quite black; and the bright lustre was slowly lost on exposure. The crystals belong to the rhombic system and are isomorphous with the rhombic alkali trihalides. The crystal habits are illustrated in Figs. 21 to 23. The axial ratios of thallic iodide agree closely with those of rubidium and cæsium tri-iodides. The ratios $a:b:c$ are 0·6858 : 1 : 1·1234 for rubidium tri-iodide; 0·6824 : 1 : 1·1051 for cæsium tri-iodide; and 0·6828 : 1 : 1·1217 for thallium tri-iodide. The small influence of the effect of substituting thallium for rubidium is remarkable when the great difference in the atomic weights of the elements is considered.



FIGS. 21–23.—Habits of Crystals of Thallium Tri-iodide.

The isomorphism between the higher iodides of thallium and the alkali metals led H. L. Wells and S. L. Penfield to conclude that the arrangements of the atoms in this series of compounds is the same, and this in spite of the apparent tervalency of thallium in the thallic compounds. They say that this compound is therefore *thallous tri-iodide,* $TlI.I_2$; this does not mean that all thallic salts are similarly constituted, for thallium tri-iodide may not be a true thallic salt at all, and the thallic salts may possess quite a different kind of structure. H. L. Wells and S. L. Penfield also suggest that thallium may really belong to the alkali metal group in the periodic table occupying one of the vacancies between metals of at. wt. 170 and 220.

W. Maitland and R. Abegg say that the thallium tri-iodide, TlI_3, may be regarded as a tautomeric substance: $Tl^{\cdot}I_3 \rightleftharpoons Tl^{\cdot\cdot\cdot}I_3$, since it reacts towards a soln. either as a compound of univalent thallium with the $3I'$-ions or as an iodide of tervalent thallium depending on the substances with which it is brought into contact. From its solubility relations and the fact that a change in the composition of the solid substances in equilibrium with the soln. produces only a relatively small change in the thallous iodide conc., it follows that the solid tri-iodide is to be regarded as essentially a thallous compound. J. Nicklès says that thallium tri-iodide is sparingly soluble in ether, but W. Maitland and R. Abegg say that this is an erroneous observation because iodine appears in the soln. J. Nicklès adds that at a red heat an orange-yellow sublimate—presumably thallous iodide—is formed. H. L. Wells and S. L. Penfield obtained no evidence of the formation of *thallous pentaiodide*, analogous with the cæsium pentahalides, by mixing increasing proportions of iodine with thallium tri-iodide in alcoholic soln.

Thallium tri-iodide forms a number of double salts with the metal iodides. J. Nicklès prepared red plates of **ammonium tetraiodothallate,** $NH_4I.TlI_3$, similar to the corresponding bromothallate. When treated with water, iodine separates from this salt; at 100°, it blackens, and loses about 34 per cent. of iodine, leaving a yellow powder of presumably thallous iodide mixed with some black substance. J. E. Willm boiled thallous iodide with an alcoholic soln. of potassium iodide and iodine in the calculated proportions until all was dissolved. The conc. soln. furnishes large black cubic crystals of **potassium tetraiodothallate,** $KI.TlI_3$, or $KTlI_4$, which in transmitted light appear garnet-red. According to G. S. Johnson, the salt prepared by J. E. Willm's process is $KI.TlI_3.2H_2O$. The crystals are stable in dry air nor is any weight lost in vacuo. This salt can be recrystallized from alcohol; it is decomposed by water with the separation of iodine. Iodine vapours are evolved when this salt is heated to 50°–60°, leaving a residue of potassium and thallous iodides; the decomposition is complete at 100°. C. F. Rammelsberg reported the formation of black octahedral crystals of **trihydrated potassium enneaiodothallate,** $3KI.2TlI_3.3H_2O$, from a soln. of thallous iodide in aq. potassium iodide. The crystals are said to be decomposed by water with the separation of thallous iodide. G. S. Johnson could not confirm C. F. Rammelsberg's work on this salt. J. H. Pratt prepared **dihydrated rubidium tetraiodothallate,** $RbI.TlI_3.2H_2O$, or $RbTlI_4.2H_2O$, from soln. of thallic and rubidium iodides. The ruby-red crystals become matte on exposure to air, and are decomposed by water. J. H. Pratt made similar crystals of **cæsium tetraiodothallate,** $CsI.TlI_3$, or $CsTlI_4$. S. M. Jörgensen sat. a soln. of thallous iodide in hydriodic acid mixed with a little iodine, with ammonia, and added the product to a warm dil. soln. of cupric tetrammino-sulphate; the reddish-brown needles which formed were washed rapidly with cold water, pressed between filter-paper, and dried in a desiccator over calcium chloride. The analysis of the product agrees with **cupric tetrammino-octoiodothallate,** $CuI_2.2TlI_3.4NH_3$. On heating to 120°, iodine and ammonia are lost, and cuprous and thallous iodides remain. This compound is decomposed by a prolonged washing; and it is decomposed by aq. ammonia in which it is partially soluble. It dissolves in alcohol. When digested with zinc and water, the metals thallium and copper separate out.

§ 11. Thallium Sulphides

Thallium unites directly with sulphur when the two elements are fused together. According to H. Pelabon,[1] when fused mixtures containing more than 2 gram-atoms of thallium for one gram-atom of sulphur form two layers, the upper layer consists of thallium sulphide, Tl_2S, containing 7·26 per cent. of sulphur, and solidifying at 448°, whilst the lower is pure thallium, solidifying at 302°. The portion of the m.p. curve corresponding with such mixtures is horizontal, Fig. 24. The curve for mixtures containing 7·26 per cent. to 28·2 per cent. of sulphur corresponds with the separation of Tl_8S_7, m.p. 295°. The m.p. curve becomes again horizontal for mixtures containing a greater proportion of sulphur; these, on fusion, form two layers, the lower consisting of the pentasulphide, Tl_2S_5, m.p. 127°, and the upper of sulphur.

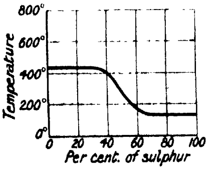

FIG. 24.—Melting-point Curve of Binary Mixtures of Sulphur and Thallium.

According to W. Crookes, and A. Lamy, thallous sulphide, Tl_2S, is precipitated when hydrogen sulphide or ammonium sulphide is added to an alkaline or acetic acid soln. of a thallous salt; but A. Lamy obtained a crystalline mass by melting the amorphous precipitate. M. Hebberling obtained crystalline thallous sulphide by passing hydrogen sulphide on a cold, not too dil., soln. of thallous sulphate acidified with only a trace of sulphuric acid. V. Stanek also obtained crystals by heating a mixture of amorphous sulphide with colourless ammonium sulphide, $(NH_4)_2S$, in a sealed tube at 150°–200°; if ammonium polysulphide is used no crystals are obtained. In a cold moderately conc. soln. of thallous sulphate acidified by a trace of sulphuric acid, E. Carstanjen obtained the crystalline sulphide by boiling an alkaline soln. of a thallous salt with sodium thiosulphate. O. Brunck obtained an incomplete precipitation of the amorphous sulphide by adding sodium hyposulphite to a thallium salt soln. The precipitate appears first reddish-brown, then violet, and finally black. No precipitation occurs in the presence of many acids. E. Carstanjen obtained a crystalline mass by melting together eq. proportions of the two elements—*vide supra.* W. Crookes obtained the crystalline sulphide by melting thallous sulphate with potassium cyanide; K. Brückner, by melting it with sulphur; and W. R. Hodgkinson and C. C. French, by the action of dry ammonia at a red heat. C. Winssinger prepared a chocolate-brown **colloidal solution of thallous sulphide** by treating a very dil. soln. of thallous sulphate with hydrogen sulphide, and dialyzing the product.

W. Crookes, and A. Lamy found the dark brown or black precipitate flocculates when boiled with the mother-liquid. E. Carstanjen said the crystals are six-sided plates or needles; and M. Hebberling said that the plates are tetrahedral with twinned forms. E. Carstanjen showed that the thallous sulphides prepared by fusing the two elements and by precipitation with ammonium sulphide are the same. A. Lamy said that the sp. gr. is about 8. According to W. Crookes, and A. Lamy, when heated out of contact with air, thallous sulphide melts and volatilizes; and the cold mass has a crystalline fracture. The m.p. is 448°. H. von Wartenberg and O. Bosse studied the volatilization of thallium sulphide. H. Pelabon found the partial press., p, of the hydrogen sulphide at 625°, starting with hydrogen in contact with a mixture of sulphur and thallium, are 1·90 and 99·14 cms., when the amounts of sulphur in at. per cent. are, respectively, 33·33 and 60·00. The intermediate values give a straight line. J. Thomsen gave for the heat of formation (2Tl, S) =27·7 Cals. H. Pelabon measured the electrical conductivity of thallous sulphide and found it to be influenced by the temp. and by the mode of preparation. O. Weigel measured the solubility of the sulphide.

A. Lamy said that thallous sulphide oxidizes readily to the sulphate when exposed to air; and, added M. Hebberling, the amorphous sulphide oxidizes more readily than the crystalline form. The last-named also said that when heated on the water-bath, thallous sulphide slowly burns. According to W. Böttger, thallous sulphide is very sparingly soluble in water—a litre of water at 19·9° dissolves 0·0215 mol. A. Classen and O. Bauer found thallous sulphide to be readily oxidized and completely dissolved by an ammoniacal soln. of hydrogen peroxide. E. Carstanjen stated that thallous sulphide is reduced when heated in a current of hydrogen. W. Crookes, and A. Lamy found thallous sulphide to be virtually insoluble in aq. soln. of ammonia, potassium cyanide, ammonium sulphide, and alkali hydroxides and carbonates. W. Crookes, and M. Hebberling found it to be sparingly soluble in an aq. soln. of oxalic acid, and in acetic acid; W. Crookes found it to be sparingly soluble in hydrochloric acid, and readily soluble in nitric acid; while J. E. Willm found it dissolves readily in sulphuric acid. E. Schürmann found that thallous sulphide is dissolved by soln. of salts of cobalt, nickel, and iron, but not by salts of manganese—manganese sulphide is converted into nitrate by a soln. of thallous nitrate.

Thallous sulphide was shown by J. W. Gunning, and L. F. Hawley to form complexes with the sulphides of arsenic, antimony, and tin, and they are precipitated from soln. of the mixed salts. L. Bruner and J. Zawadsky showed that the value of the constant $K=[Tl^{\cdot}]^2[H_2S]/[H^{\cdot}]^2$ alters when the sulphides of other metals are precipitated along with thallium; they found that copper and thallous sulphides form **thallous pentasulphocuprate,** $Tl_2S.4CuS$, or $Tl_2Cu_2S_5$, over the interval 20-36 molar per cent. of thallium sulphide. The salt forms a series of solid soln. which are best explained as being soln. of **thallous trisulphocuprate,** $Tl_2S.2CuS$ in $Tl_2S.4CuS$, and of Tl_2S in $Tl_2S.2CuS$. At conc. of more than 36 molar per cent. normal values of the equilibrium constant are obtained; there are then two solid phases, consisting of thallium sulphide and probably a soln. of thallium sulphide in the compound $Tl_2S.2CuS$. H. Huber measured the equilibrium conditions in the system Ag_2S-Tl_2S by the thermal method. The results are summarized in Fig. 25. There is a eutectic point at 306° with 55 per cent. of thallous sulphide; and with less than 31 per cent. of thallous sulphide there is an arrest in the cooling curve due to the formation of crystalline **thallous silver sulphide,** $4Ag_2S.Tl_2S$. The break at 175° is due to the transformation of silver sulphide.

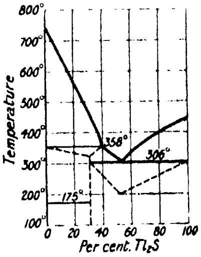

FIG. 25.—Equilibrium Diagram of the Binary System, Ag_2S-Tl_2S.

A. Strecker showed that **thallic sulphide,** Tl_2S_3, cannot be obtained by the action of hydrogen sulphide on an aq. soln. of a thallic salt, for the thallic sulphide, if formed, is instantly reduced to thallous sulphide and free sulphur; but if ammoniacal soln. of thallic oxide in the presence of phosphoric or tartaric acid be treated with hydrogen sulphide, the precipitate is probably thallic sulphide. E. Carstanjen made thallic sulphide by melting thallium with an excess of sulphur and distilling off the free sulphur. The amorphous black mass becomes soft and plastic at tem *exceeding 12°. Thallic sulphide gives off hydrogen sulphide and dissolves whe treated with dil. mineral acids; no sulphur separates in E. Carstanjen's process, but, with A. Strecker's process, sulphur does separate. According to E. Carstanjen, no sulphide is dissolved by carbon disulphide, and it is reduced to the metal when heated in hydrogen. According to J. W. Gunning, the sulphide reported by R. Böttger to be produced by boiling flue-dust with sodium thiosulphate soln.* is really thallium sulphoarsenide. R. Schneider prepared **potassium tetrasulphothallate,** $K_2S.Tl_2S_3$, or $KTlS_2$, by fusing together one part of thallous sulphate or chloride, 6 parts each of potassium carbonate and sulphur, and extracting the cold mass with water. The dark red crystalline powder has a sp. gr. 4·263–4·60. When heated in hydrogen, sulphur is given off and a mixture of thallous and potassium sulphides remains; G. Krüss and H. Solereder found thallium and potassium sulphides are formed. According to R. Schneider, the double sulphide is stable in air at ordinary temp. It melts without decomposition when heated out of contact with air, but if heated while exposed to air, the sulphur is oxidized. With hot nitric acid, sulphur separates. If the powder is treated with silver nitrate, some thallium and potassium are replaced by silver.

R. Schneider prepared **thallium pentasulphide,** Tl_2S_5, by heating thallous sulphate with sodium thiosulphate, or sodium carbonate and sulphur. It is a brick-red powder which rapidly turns brown on exposure to air. The pentasulphide prepared by H. Pelabon—*vide supra*—melts at 127°. K. A. Hofmann and F. Höchtlen saturated a conc. aq. soln. of ammonium polysulphide with thallous chloride, and obtained glistening black opaque prisms of the pentasulphide by allowing the soln. to stand for a few days. L. F. Hawley doubts if the pentasulphide is a chemical individual.

E. Carstanjen reported a number of intermediate sulphides—**thallosic sulphides.** He obtained $Tl_2S : Tl_2S_3 = 5 : 3$ by the action of ammonium sulphide on thallosic chloride, Tl_4Cl_6; and 1 : 1 by fusing thallium with rather less than an eq. proportion of sulphur. R. Schneider also obtained 1 : 2 by melting one part of thallous sulphate with six parts each of sodium carbonate and sulphur, and extracting the mass with water. According to L. F. Hawley, the highest sulphide corresponds with Tl_2S_3, and a complete series of solid soln. exists between Tl_2S and Tl_2S_3. By treating thallous sulphide with sodium sulphide soln. in which varying amounts of sulphur have been dissolved and afterwards saturating with hydrogen sulphide, products are obtained containing from 90·49 per cent. of thallium (corresponding with Tl_2S) to about 70 per cent. of thallium. By adding acid soln. of a thallium salt to a slight excess of sodium polysulphide, precipitates can be obtained containing from 25 per cent. to nearly 100 per cent. of sulphur. It is found that between pure thallous sulphide and the product containing about 81 per cent. of thallium, the solid is homogeneous; from 81 per cent. to 76 per cent. of thallium, phases are distinguishable, whilst from 76 per cent. of thallium to pure sulphur the solid is again homogeneous.

§ 12. Thallium Sulphates

The early workers on thallium—W. Crookes,[1] and A. Lamy—prepared both thallous and thallic sulphates. When thallium, thallous hydroxide, or carbonate dissolves in sulphuric acid, a soln. of **thallous sulphate,** Tl_2SO_4, is formed. W. O. Rabe covered the metal with water and added enough conc. acid to dissolve the metal. The dissolution is best conducted on a water-bath when hydrogen is rapidly evolved; the attack with dil. sulphuric acid, sp. gr. 1·17, is comparatively slow. The filtered soln. gives colourless needle-like crystals on cooling. The salt is also obtained by evaporating thallous chloride or nitrate soln. with an excess of sulphuric acid. The excess sulphuric acid must be driven off at a red heat or the hydrosulphate may be obtained. J. Krause converted thallous chloride to sulphate by fusion with sodium hydrosulphate.

The colourless prismatic crystals were measured by L. Pasteur, V. von Lang, G. Werther, and A. Lamy and A. des Cloizeaux and found to be isomorphous with potassium and ammonium sulphates. W. Stortenbeker prepared mixed crystals of the type $(K, Tl)_2SO_4$; and he obtained good crystals of thallous sulphate by crystallization from a soln. slightly acidified with sulphuric acid. According to A. E. H. Tutton, the bipyramidal rhombic crystals have the axial ratios $a : b : c = 0·5555 : 1 : 0·7328$; and the sp. gr. is 6·765 at 20°/4°. A. Lamy gave 6·603 for the crystals, and he found that the salt melts at a red heat and freezes to a transparent glass of sp. gr. 6·77. T. Carnelley gave 632° for the m.p. of the salt. R. von Sahmen and G. Tammann found that the coeff. of expansion between 400° and 450° is three to six times smaller than that below or above this interval. W. Crookes found that thallous sulphate could be heated for a long time in a covered crucible without loss of weight; and E. Carstanjen added that over the gas blowpipe, or in air, sulphur dioxide is evolved and thallic oxide formed. J. B. J. D. Boussingault found 0·321 grm. of thallous sulphate volatilizes completely when heated in an open platinum crucible over the gas blowpipe flame. The observations of C. F. Rammelsberg, G. Werther, R. J. Meyer, W. Stortenbeker, and P. E. Browning show that thallous sulphate is stable enough to be ignited and weighed in this form for gravimetric analysis; but if too strongly heated, it rapidly loses weight. A. E. H. Tutton found the three refractive indices to be:

	Li·	*C*	Na·	Tl	*F*-line
α . . .	1·8493	1·8509	1·8600	1·8704	1·8859
β . . .	1·8563	1·8579	1·8671	1·8778	1·8935
γ . . .	1·8739	1·8755	1·8853	1·8964	1·9126

The double refraction is positive. K. A. Hofmann and co-workers found that thallous sulphate fluoresces when exposed to the cathode rays; but does not act in darkness on a photographic plate. E. Franke measured the eq. electrical conductivity, λ, in reciprocal ohms, at 25°, and found that for a mol of the salt in v litres of water:

v . . .	16	32	64	128	256	512	1024
λ . . .	101·3	113·1	129·9	131·2	138·3	143·1	146·4

A. Heydweiller investigated the sp. gr. and electrical conductivity of soln. of thallous sulphate. A. A. Noyes and K. G. Falk found the percentage ionization of soln. with 1, 5, 20, and 200 millieq. of salt per litre to be respectively 94·8, 88·2, 78·0, and 56·1. C. Drucker found that the depression of the f.p., and the conc. potentials of aq. soln. of thallous sulphate agree with the assumption that during ionization some Tl˙˙-ions are formed. The law of mass action applies for dil. soln., and also for conc. soln. when due allowance is made for the oxidation—*vide* thallous nitrate. C. Drucker found the first ionization constant of thallous sulphate to be 0·23, and the second ionization constant, 0·014. G. N. Lewis and M. Randall measured the activity coeff. W. Schmidt found the dielectric constant to be 28.

W. Crookes, A. Lamy, and G. Wyrouboff made some observations on the solubility of thallous sulphate in water. The Earl of Berkeley found the following percentage solubilities, S grms. Tl_2SO_4 per 100 grms. of soln:

	0°	10°	20°	30°	50°	70°	90°	99·7°
S .	2·63	3·57	4·64	5·80	8·44	11·31	14·19	15·57

Observations were also made by A. E. H. Tutton, A. A. Noyes, F. S. Farrel, and M. A. Stewart. E. Cohen and co-workers represented the effect of press., p atm., on the solubility, S, of thallous sulphate in grms. per 100 grms. of sat. soln., at 30°, by $S=5·831+0·003377p-0·0_6175p^2$, or by $S=5·831+0·003295p-0·0_6109p^2$; they observed for the solubility at 30°, 5·831 at 1 atm.; 7·48 at 500 atm.; 9·03 at 1000 atm.; and 10·50 at 1050 atm. W. Stortenbeker found that thallous sulphate dissolves more readily in dil. sulphuric acid than in water. F. Ishikawa studied the vol. change which occurs when thallous sulphate is dissolved in water, and found −0·05407 c.c. per gram by the sp. vol. method, and −0·04906 c.c. per gram by the e.m.f. method; he also found the heat of soln. to be −14·58 to −14·75 cals. per gram. A. A. Noyes and M. A. Stewart found that, at 25°, soln. with 4·878 and 9·747 grms. of sulphuric acid per litre dissolved respectively 59·09 and 62·95 grms. of thallous sulphate per litre. According to W. O. Rabe, 100 grms. of water dissolve 4·74 grms. of thallous sulphate and 10·3 grms. of potassium sulphate at 15°; 11·5 grms. Tl_2SO_4 and 16·4 grms. K_2SO_4 at 62°; and 18·52 grms. Tl_2SO_4 and 26·2 grms. K_2SO_4 at 100°. A. A. Noyes and M. A. Stewart found that, at 25°, soln. with 26·51 grms. of thallous nitrate per litre dissolved 42·17 grms. of thallous sulphate; soln. with 7·062 and 28·25 grms. of sodium sulphate per litre dissolved respectively 56·44 and 59·13 grms. of thallous sulphate per litre; and soln. with 12·12 grms. of sodium hydrosulphate per litre dissolved 58·53 grms. of thallous sulphate per litre. A. Lamy said the aq. soln. has a neutral reaction; while M. C. Lea said the soln. reacts acid to litmus, but he obtained no other evidence of the existence of free sulphuric acid in the soln. The aq. soln. exhibits the characteristic reactions of thallous salts. E. Carstanjen found that hydrogen; W. R. Hodgkinson and C. C. French, that ammonia; and W. Crookes, that fused potassium cyanide, reduced thallous sulphate to the sulphide, etc. A. J. Berry studied the oxidation of thallous sulphate in alkaline soln. by hydrogen dioxide; and P. E. Browning and H. E. Palmer, by potassium ferricyanide. A. Benrath found the sulphate, unlike the halides, is not reduced by oxalic, tartaric, or citric acid. R. Weber obtained **thallous heptasulphatosulphate**, $Tl_2SO_4.7SO_3$, by melting below 100° a mixture of the constituents, and purifying by heating in a sealed tube at 100°. L. Meyer observed no sign of thallous sulphate acting as a catalytic agent in promoting the union of a mixture of sulphur dioxide and oxygen passing through an aq. soln. of the salt. H. Erdmann, and P. Köthner found that cold and hot soln. of thallous sulphate give no precipitate when treated with acetylene; not even when the soln. is also mixed with sodium acetate and hydroxide.

Thallous sulphate forms a number of complex salts with the sulphates of the magnesium series. The general formula is $TlSO_4.MSO_4.6H_2O$, where M denotes bivalent iron, nickel, cobalt, copper, manganese, zinc, or magnesium; these salts are isomorphous with the corresponding potassium, ammonium, rubidium, and cæsium salts. J. d'Ans could not make *thallous calcium disulphate* analogous to $K_2Ca(SO_4)_2H_2O$. J. E. Willm obtained pale greenish-blue, monoclinic crystals of hexahydrated **thallous cupric sulphate**, $Tl_2SO_4.CuSO_4.6H_2O$, which lose nearly 4 mols of water at 100°, and all at 185°. G. Canneri prepared blue crystals of the same salt. J. Locke found the solubility per litre of water at 25° to be 81 grms. of the anhydrous salt; and a litre of the soln. contains 0·122 mol of the salt. The salt decomposes when recrystallized from aq. soln. J. E. Willm also prepared monoclinic crystals of hexahydrated **thallous magnesium sulphate,** $Tl_2Mg(SO_4)_2.6H_2O$, by the spontaneous evaporation of a soln. of the component salts. According to G. Werther, and C. F. Rammelsberg, the axial ratios are $a : b : c = 0·742 : 1 : 0·5$, and $\beta = 106° 24'$. G. Werther said that the salt melts below a red heat; it is more readily soluble in water than the corresponding zinc salt; and it is scarcely affected when recrystallized from water by slow evaporation. F. R. Mallet prepared optically anisotropic crystals of **thallous dimagnesium sulphate,** $2MgSO_4.Tl_2SO_4$, by fusing together the constituent salts. J. E. Willm, and G. Werther likewise obtained hexahydrated **thallous zinc sulphate,** $Tl_2Zn(SO_4).6H_2O$, by a process analogous to that employed for the magnesium salt. The axial ratios of the monoclinic crystals were shown by G. Werther to be $a : b : c = 0·7406 : 1 : 0·4956$, and $\beta = 106° 21'$. A. Lamy and A. des Cloizeaux gave 0·7388 : 1 : 0·5010, and $\beta = 196° 10'$. The sp. gr. is 3·720 at 20°. The mean refractive index for the *D*-line is 1·6064. The crystals have a negative double refraction. According to J. Locke, a litre of water dissolves 86 grms. or 0·129 mol of the anhydrous salt. G. Werther found that the salt loses its water at 120°; but does not decompose at 300°; it melts below a red heat, and decomposes at a bright red heat.

Univalent thallous sulphate may also take the place of the alkali metals in the alums. A mixed soln. of the component salts was found by A. Lamy, L. Pasteur, J. E. Willm, and A. Cossa to give regular octahedra of *thallic alum*, $Tl_2SO_4.Al_2(SO_4)_3.24H_2O$, or **thallous aluminium disulphate,** $TlAl(SO_4)_2.12H_2O$. A. Lamy prepared a complex $3K_2SO_4.4Al_2(SO_4)_3.Tl_2SO_4.96H_2O$, *i.e.* $3\{KAl(SO_4)_2.12H_2O\}TlAl(SO_4)_2.12H_2O$, by crystallization from a soln. of the component salts. J. W. Retgers showed that the product is a soln. of the two alums. C. Soret and L. Duparc gave 2·329 for the sp. gr. of the crystals of thallic alum; J. W. Retgers, 2·318 at 15°; W. Spring, 2·3256 at 0°; 2·3250 at 20°; 2·3212 at 50°; and 2·3159 at 70°. After compressing the crystals for three weeks at 20,000 atm., the sp. gr. was 2·320 at 22°, and 2·314 at 16°. The coeff. of thermal expansion corresponds with a change from unit vol. at 0° to 1·00267 at 20°, 1·00188 at 50°, and 1·004178 at 70°. J. Locke gave 91° for the m.p. J. H. Gladstone found the refraction eq. to be 278·34. C. Soret found the indices of refraction, μ, between 10°–23° to be:

	G-	*F*-	*b*-	*E*-	*D*-	*C*-	*B*-	*a*-line
λ . .	4310	4860	5170	5260	5890	6560	6860	7180
μ . .	1·51076	1·50463	1·50209	1·50128	1·49748	1·49443	1·49317	1·49226

Observations were also made by C. Soret and L. Duparc, A. Fock, and M. le Blanc and P. Rohland. F. Klocke discussed the strong abnormal double refraction of thallic alum. L. de Boisbaudran prepared *thallous gallic alum*, $Tl_2SO_4.Ga_2(SO_4)_3.24H_2O$, or **thallous gallium disulphate,** $TlGa(SO_4)_2.12H_2O$, from a soln. of the component salts. C. Soret gave for the indices of refraction, between 10°–20°:

	G-	*F*-	*b*-	*E*-	*D*-	*C*-	*B*-	*a*-line
λ . .	4310	4860	5170	5260	5890	6560	6860	7180
μ . .	1·52007	1·51387	1·51131	1·51057	1·50665	1·50349	1·52228	1·50112

W. Crookes evaporated thallous sulphate with fuming sulphuric acid, or treated thallous chloride with an excess of sulphuric acid, and obtained **thallous hydrosulphate,** $TlHSO_4$. A. Lamy prepared it by heating hydrated thallic sulphate to 400°. P. E. Browning, and W. Stortenbeker found that if heated to 220°–240°, the composition is so constant, $TlHSO_4$, that in gravimetric analysis thallium could be weighed in this form; at a higher temp., thallous sulphate is produced. P. S. Oettinger reported a trihydrate, $TlHSO_4.3H_2O$, to be formed in short thick prisms by allowing the acid salt to stand in contact with very acid mother-liquor for some months. According to W. Stortenbeker, if a sulphuric acid soln. of thallous sulphate be conc. on the water-bath, a crop of monoclinic plates is obtained and afterwards a crop of rhombic needles. The composition of both forms is the same. A third modification exists so that the crystals are isotrimorphous with potassium hydrosulphate, and he made mixed crystals of the type (K, Tl)HSO_4. The crystals of thallous hydrosulphate melt at 115°–120°, and the molten mass is at first quiescent, but it suddenly develops vapours of sulphuric acid and passes to the normal sulphate. W. Stortenbeker prepared crystals of $Tl_2SO_4.6TlHSO_4$, like the corresponding potash salt; and also hexagonal plates of $Tl_2SO_4.TlHSO_4$, *i.e.* **trithallium hydrodisulphate,** $Tl_3H(SO_4)_2$. J. d'Ans and O. Fritsche showed that the solubility curves at 25° of thallous sulphate in mixtures of water and sulphuric acid consist of two straight lines with the solubility increasing continuously with the conc. of the acid. Representing conc. in mols per 1000 grms. of sat. soln.:

H_2SO_4 .	0	4·55	4·79	4·89	4·92	4·78	4·26	4·03
Tl_2SO_4 .	0·103	0·56	0·55	0·59	0·66	0·75	1·01	1·08
	Tl_2SO_4	$TlHSO_4$						

There are transition points with $2·999H_2SO_4$ and $0·66Tl_2SO_4$, the solid phases are Tl_2SO_4 and $Tl_3H(SO_4)_2$; and with $4·25H_2SO_4$ and $0·61Tl_2SO_4$, the solid phases are $Tl_3H(SO_4)_2$ and $TlHSO_4$. B. Gossner found the trigonal crystals of trithallium hydrosulphate to have the axial ratio $a : c = 1 : 3·717$, and $\alpha = 42° 55'$; the crystals have a medium negative double refraction. There are probably two modifications of $Tl_3H(SO_4)_2$, since the salt is isodimorphous with the corresponding potassium compound. W. Stortenbeker prepared mixed crystals of the type $(K, Tl)_3H(SO_4)_2$.

W. Crookes, and A. Lamy dissolved thallic hydroxide in warm dil. sulphuric acid and obtained crystals of **heptahydrated thallic sulphate,** $Tl_2(SO_4)_3.7H_2O$; A. Strecker recommended removing the mother liquid by press. since, as W. Crookes showed, the salt is decomposed by water, forming the brown hydroxide. J. E. Willm prepared thallic sulphate by boiling an aq. soln. of thallous sulphate with barium or lead dioxide, and conc. the filtered soln. for crystallization. Neither H. Marshall nor R. J. Meyer and E. Goldschmidt succeeded in preparing this salt. A. Strecker, and W. Crookes said that at 220° the salt loses between 6 and 7 mols of water, and forms a small proportion of thallous sulphate; at a higher temp. it forms thallous sulphate, and loses sulphur trioxide, sulphuric acid, and oxygen. R. J. Meyer and E. Goldschmidt said that thallic hydrosulphate at 220° is completely converted into anhydrous **thallic sulphate,** $Tl_2(SO_4)_3$. G. Grube and A. Hermann found the oxidation potential of thallous to thallic sulphate in sulphuric acid soln. to be 1·211 volt; R. Abegg and J. F. Spencer's value 1·156 is too low.

Reports by the early workers on the preparation of thallic sulphate are not in agreement; this probably arises from the instability of the salt in aq. soln. In the first place, the salt is partially reduced to thallous sulphate, and the mixed products explain the series of products described in literature as *thallosothallic sulphates*, or **thallosic sulphates.**

J. E. Willm obtained prismatic crystals of a product $Tl_2SO_4 : Tl_2(SO_4)_3 : H_2O = 2 : 3 : 22$, which, according to R. J. Meyer and E. Goldschmidt, is obtained best by dissolving thallic hydroxide in moderately conc. sulphuric acid, and evaporating the soln. A basic product was found at the same time. J. E. Willm represented the composition of the first-named salt by $Tl_2SO_4.2TlHSO_4.3Tl_2(SO_4)_3.24H_2O$. H. Marshall obtained yellow crystals of 5 : 3 : 0, by the electrolysis of a sat. acid soln. of thallous sulphate, or by allowing thallous sulphate to stand in air for a long time; if allowed to crystallize from a nitric acid soln., H. Marshall obtained 2 : 3 : 0. R. J. Meyer and E. Goldschmidt made crystals of 7 : 1 : 6 by partially reducing thallic sulphate with nitric acid. B. Lepsius reported octahedral crystals belonging to the cubic system of the 1 : 1 : 0 salt to be obtained by crystallization from a soln. containing eq. proportions of the component salts. H. Marshall said the crystals are rhombic. R. J. Meyer and E. Goldschmidt regarded this compound as the thallous salt of thallisulphuric acid, $H_2Tl_2(SO_4)_4$, or $HTl(SO_4)_2$—viz. *thallous thallisulphate*, or *thallous sulphatothallate*. The acid is also the parent of the complex sulphates $M_2'SO_4.Tl_2(SO_4)_3$. H. Benrath and H. Espenschied could prepare only the 1 : 1 : 0 and the 5 : 1 : 0 salts. The former is stable above 48°, and the latter between 23·5° and 30°. Between 30° and 48°, there is a state of transition, and mixtures of various compositions are formed.

In the second place, thallic sulphate is so readily hydrolyzed that it can be obtained only from acid soln. Even in moist air, the salt becomes brown owing to the formation of the hydroxide. If the soln. are not strongly acid, they are decomposed by heat, or when diluted with water. Hence, **basic sulphates** have been reported. As a consequence of the neglect to control the temp. and acidity of the soln., what appear to be similar processes furnished A. Strecker with the normal sulphate; J. E. Willm, and H. Marshall, a basic sulphate; and R. J. Meyer and E. Goldschmidt an acid sulphate. J. E. Willm, and H. Marshall reported fine needle-like crystals of dihydrated basic sulphate, $Tl(OH)SO_4.2H_2O$, or *thallic oxyhydrosulphate*, $O:Tl.HSO_4.2H_2O$, or *thallic hydroxysulphate*, $HO.Tl:SO_4.2H_2O$, to be formed by dissolving thallic hydroxide in warm, moderately conc sulphuric acid, and cooling the soln.; after some days large crystals of the thallosic sulphate 2 : 3 : 22 appeared, and finally the monohydrate $TlOHSO_4.H_2O$. According to J. Meyer, the solubility diagrams of thallic oxide, the hydrosulphate, $TlH(SO_4)_2.4H_2O$, and the basic sulphate, $Tl(OH)SO_4.2H_2O$, in sulphuric acid show the presence of no other thallic sulphate than the two just indicated, and hence the other sulphates which have been described in literature are mixtures which appear owing to the slowness of the change from one salt to another. The transition point of the two sulphates just indicated is 45°.

R. J. Meyer and E. Goldschmidt reported tetrahydrated **thallic hydrosulphate**, $TlH(SO_4)_2.4H_2O$, or $HSO_4.Tl:SO_4.4H_2O$, to be formed by saturating boiling dil. sulphuric acid with thallic sulphate, and evaporating the strongly acidified filtrate on a water-bath. If the soln. be allowed to crystallize at a low temp., the hexahydrate, $TlH(SO_4)_2.6H_2O$, is formed. They regard this salt as *thallisulphuric acid*—or *hydrosulphatothallic acid* -from which the alkali complexes $MTl(SO_4)_2.4H_2O$ are derived. For the thallous salt of this acid, *vide supra*.

Thallic sulphate forms a series of **complex thallic sulphates** which are of special interest because tervalent thallium is the end-member of the Al, Ga, In, Tl-family, and it might therefore be expected to form a series of alums, $MAl(SO_4)_2.12H_2O$. However, J. Locke,[2] A. Piccini and V. Fortini, H. Marshall, R. J. Meyer and E. Goldschmidt, etc., failed in the quest. It was, however, shown that the faculty of forming alums in this family of tervalent elements decreases as the at. wt. increases, so that indium has but a slight tendency to form alums, and thallium none at all. The nearest approach to alum-formation with tervalent thallium is the series of mixed crystals between ammonia alum and ammonium thallic sulphate obtained by A. Piccini and V. Fortini.

H. Marshall prepared **ammonium thallic trisulphate,** $(NH_4)_3Tl(SO_4)_3$, from a soln. obtained by saturating an acid soln. of thallic sulphate with ammonium sulphate; when recrystallized from dil. sulphuric acid, it forms tetrahydrated **ammonium thallic disulphate,** $NH_4Tl(SO_4)_2.4H_2O$. V. Fortini obtained the tetrahydrate by dissolving thallous sulphate in a conc. aq. soln. of chlorine, adding ammonia, and washing and drying the precipitate. The latter was then dissolved in the right proportion of sulphuric acid, and mixed with ammonium sulphate. The soln., on evaporation between 0° and 20° in vacuo, furnished monoclinic prisms of the tetrahydrate. The axial ratios are $a:b:c=0{\cdot}9559:1:0{\cdot}6836$, and $\beta=125° 38'$. The crystals effloresce in air at 20°-25°; and lose all their water of crystallization at 100°. The salt is easily soluble in acids, and is hydrolyzed by water. H. Marshall made small needle-like crystals of the anhydrous salt, $NH_4Tl(SO_4)_2$, by crystallization from a warm soln. of the component salts. G. L. Clark gave 293° for the temp. at which **thallic decamminosulphate,** $Tl_2(SO_4)_3.10NH_3$, dissociates at 100 mm. press.

R. J. Meyer and E. Goldschmidt obtained fine needle-like crystals of trihydrated **lithium thallic disulphate,** $LiTl(SO_4)_2.3H_2O$, from a soln. of the component salts; they also made a similar **sodium thallic disulphate,** $NaTl(SO_4)_2.2\frac{1}{2}H_2O$. A. Strecker made the last-named salt in an anhydrous form, $NaTl(SO_4)_2$, by adding a sat. soln. of sodium sulphate to a soln. of thallic sulphate in dil. sulphuric acid. The crystals were washed with cold water, pressed between filter-paper, and dried over conc. sulphuric acid. H. Marshall prepared tetrahydrated **potassium thallic disulphate,** $KTl(SO_4)_2.4H_2O$, by crystallization from a nitric acid soln. of the basic salt; R. J. Meyer and E. Goldschmidt obtained it by boiling a soln. of the basic salt in sulphuric acid; and V. Fortini, by crystallization, at 0°–20°, from a soln. of the component salts. This salt is less stable than the corresponding ammonium salt. A. Strecker prepared **potassium thallic hydroxydisulphate,** $K_2SO_4.Tl(OH)SO_4$ (H. Marshall), or $2K_2SO_4.Tl_2O(SO_4)_2$ (A. Strecker), by mixing a dil. sulphuric acid soln. of thallic oxide with an aq. soln. of potassium hydrosulphate; on standing for some time, colourless crystals of the basic salt appear. They are coloured superficially brown by cold water owing to hydrolysis, and they dissolve with difficulty in warm dil. sulphuric acid. H. Marshall made the same salt, which he obtained by warming an aq. soln. of thallous sulphate, potassium sulphate, and carbonate. H. Marshall, and R. J. Meyer and E. Goldschmidt prepared anhydrous **rubidium thallic disulphate,** $RbTl(SO_4)_2$, by a process similar to that used for the ammonium salt. The aq. soln. furnishes crystals of the tetrahydrate, $RbTl(SO_4)_2.4H_2O$, when cooled. V. Fortini found the crystals to be so efflorescent that he could not get crystallographic data. J. Locke obtained rhombic crystals of trihydrated **cæsium thallic disulphate,** $CsTl(SO_4)_2.3H_2O$, from a soln. of the component salts. They are sparingly soluble in cold water, copiously soluble in hot water. The further conc. of the mother liquid gave rhombic crystals of the sesquihydrate, $CsTl(SO_4)_2.1\frac{1}{2}H_2O$. V. Fortini could not prepare a complex salt of constant composition.

R. J. Meyer and E. Goldschmidt reported a **mixed salt** to be formed by treating an aq. soln. of thallous sulphate with bromine, and evaporating the liquid over conc. sulphuric acid. The straw-yellow, needle-like crystals of **thallous bromosulphatothallate,** $Tl_2Br_2SO_4$, are represented as a thallous salt of a *Thallibromschwefelsäure*, $Tl'.SO_4.T''' : Br_2$. The salt is sparingly soluble in water, and is hydrolyzed by a large proportion of water; ammonia gives a pale brown precipitate which when heated forms brown thallic oxide; and hydrochloric acid precipitates a crystalline chlorobromide.

§ 13. Thallium Carbonates

A. Lamy[1] observed that thallous oxide or hydroxide readily absorbs carbon dioxide from the atm. W. Crookes stated that when the moist metal is exposed to the air, it is soon covered by a film of the carbonate. R. Böttger obtained a soln. of the carbonate by allowing the finely divided metal to stand in contact with water and carbon dioxide. A. Lamy, and F. Kuhlmann prepared **thallous carbonate,** Tl_2CO_3, by saturating a soln. of thallous hydroxide with carbon dioxide, and allowing the conc. soln. to crystallize. A. Lamy also obtained crystals of the carbonate by exposing a soln. of thallium hydroxide in thallium ethoxide to carbon dioxide. G. Streit, and E. Carstanjen made a soln. of the carbonate by the action of barium carbonate on a soln. of thallous sulphate. According to E. Carstanjen, if the crystals have a yellow colour, due to the presence of organic matter, they can be purified by adding alcohol to the aq. soln. when the salt is precipitated as a white crystalline powder; or by filtering the aq. soln. through animal charcoal.

The white crystals are monoclinic prisms which, according to A. Lamy and A. des Cloizeaux, have the axial ratios $a:b:c=1\cdot3956:1:1\cdot9586$, and $\beta=94^\circ\ 47'$. They have a strong negative double refraction. The sp. gr. is 7·164. T. Carnelley and W. C. Williams found the m.p. to be 272°–273°. The molten liquid is reddish-brown, and A. Lamy, and G. Werther said that a slight decomposition occurs during the fusion. E. Carstanjen obtained thallous oxide as a residue when the carbonate is heated in a glass tube; if heated while exposed to air, a mixture of thallous and thallic oxide is formed. According to A. Lamy, 100 parts of water dissolve 5·23 parts of the carbonate at 18°; 12·85 parts at 62°; and 22·4 parts at 100·8°; while W. Crookes found 100 parts of water dissolve 4·2 parts of the carbonate at 15·5°; and 27·2 parts at 100°. A. Lamy said the salt is insoluble in *alcohol;* E. Carstanjen, in *ether;* A. Naumann, in *acetone;* and A. Naumann and J. Schröder, in *pyridine.* The aq. soln. has an alkaline reaction. According to W. Crookes, the soln. supersaturated with carbon dioxide has an alkaline reaction; but, according to O. L. Erdmann, this is not the case. G. Wyrouboff said that prismatic crystals of thallous oxycarbonate, $Tl_2O.Tl_2CO_3$, were formed in a vessel containing thallium and water which had been standing some years. E. Franke gave for the eq. electrical conductivity, λ, of aq. soln. of thallous carbonate, at 25°, expressed in reciprocal ohms, for soln. with a mol of the salt in v litres:

v	32	64	128	256	572	1024
λ	93·5	107·3	119·2	129·9	137·1	143·4

W. Schmidt gave 17 for the dielectric constant. C. Winkler observed that the reduction of thallium carbonate, mixed with magnesium powder, proceeds explosively. Thallous carbonate dissolves in many organic and inorganic acids, and is a convenient starting-point for the preparation of many salts of thallium.

E. Carstanjen claimed to have made **thallium hydrocarbonate** by supersaturating a cold soln. of thallous carbonate with carbon dioxide, and adding alcohol; the precipitated thallous carbonate is filtered off; and the soln. furnishes crystals approximating in composition to $Tl_2CO_3.2TlHCO_3$. Neither A. Lamy nor G. Werther could obtain the hydrocarbonate from soln. of the hydroxide sat. with an excess of carbon dioxide—acicular crystals of the normal carbonate were always obtained. G. Giorgis said that the hydrocarbonate is obtained in needle-like crystals by slowly evaporating a moderately conc. cold soln. of thallous hydroxide in an atm. of carbon dioxide; if the soln. be heated or rapidly evaporated a mixture with the normal carbonate is obtained. G. Bollmann made **thallous magnesium carbonate**, $Tl_2CO_3.MgCO_3.4H_2O$, by allowing a mixed soln. of magnesium carbonate in carbonetted water and one of thallous carbonate to stand for some time, when crystals of the compound are deposited.

§ 14. Thallium Nitrates

The early workers on thallium prepared **thallous nitrate**, $TlNO_3$, by the action of nitric acid on normal thallous hydroxide, or thallous carbonate. According to E. Carstanjen,[1] nitric acid is the best solvent for the metal (*q.v.*). W. Crookes stated that the soln. obtained by using an excess of nitric acid contains a little thallic salt, which appears as thallic hydroxide when the ammonia precipitation is made. The white prismatic crystals belong to the rhombic system, and, according to W. H. Miller, they have axial ratios $a:b:c=0·5109:1:0·6507$. V. von Lang, C. F. Rammelsberg, and F. Wallerant made observations on the properties of the crystals. A. Lamy and A. des Cloizeaux found the sp. gr. at ordinary temp. to be 5·50, and after fusion, 5·8; J. W. Retgers gave 5·3 for the sp. gr. of the molten nitrate at 205°. F. M. Jäger gave 4·892 for the sp. gr. at 214°; 4·824 at 254°; and 4·744 at 290°; or, at $\theta°$, the sp. gr. $4·917—0·00175(\theta—200)$, between 206° and 430°. A. J. Rabinowitsch measured the sp. gr. and viscosity of aq. soln. of thallous nitrate.

W. Herz found the coeff. of expansion of molten thallous nitrate to be 0·0003981; the sp. gr. at 214° is 4·892, and at 290°, 4·744. J. W. Wagner found the viscosity of N-, $\frac{1}{4}N$-, and $\frac{1}{8}N$-soln., at 25°, to be respectively 0·9471, 0·9865, and 0·9932. J. Hausmann measured the capillary rise of soln. with 10 per cent. of gelatine. F. M. Jäger, and R. Lorenz and W. Herz gave 99·5 for the surface tension of the salt at the b.p. (430°), and 117·3 at the m.p. (210°); and for the mol. surface energy 1681·9 ergs. per sq. cm. at 210°, and 1506·5 ergs. per sq. cm. at 430°.

When heated to between 70° and 80°, the rhombic crystals of ordinary thallous nitrate, γ-$TlNO_3$, or III-$TlNO_3$, change into a rhombohedral form β-$TlNO_3$ or

II-$TlNO_3$; and the latter, between 125° and 151°, changes into a cubic modification α-$TlNO_3$ or I-$TlNO_3$. Somewhat discordant values have been given for the reversible transition temp. Thus, for the change γ-$TlNO_3 \rightleftharpoons$ β-$TlNO_3$, F. Wallerant, and B. Gossner gave 80°; P. W. Bridgman, 75°; C. van Eyk, 72·8°; and A. G. Bergmann, 78·5°; and for the change, β-$TlNO_3 \rightleftharpoons$ α-$TlNO_3$, F. Wallerant gave 125°; C. van Eyk, 142·5°; A. G. Bergmann, 142·5°; P. W. Bridgman, 144·6°; and B. Gossner, 151°. C. van Eyk found the transition temp. of thallous nitrate at 142° is lowered by admixture with the iodide; and the transition temp. of thallous iodide at 169° is lowered by the addition of nitrate. P. W. Bridgman's observations on the effect of press. between 1 kgrm. and 12,000 kgrms. per sq. cm. on the two transition temp. are shown in Table I, and graphed in Fig. 26. The slopes of the curves are represented by dT/dp. The volume changes are small and sluggish; they are represented by δv in c.c. per gram; C. van Eyk found 0·0004 c.c. per gram for the II→III transition. There was evidence of a change from the thallous to the thallic form at the higher press., but no transitions were observed other than those just indicated.

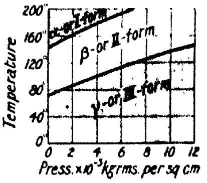

FIG. 26.—Effect of Pressure on the Transition Temperatures of Thallous Nitrate.

TABLE I.—THE EFFECT OF PRESSURE ON THALLOUS NITRATE AT DIFFERENT TEMPERATURES.

Press.	II→III				I→II.			
	Temp.	δv c.c. per gram.	$\frac{dT}{dp}$	Latent heat kgrm.-metres per gram.	Temp.	δv c.c. per gram	$\frac{dT}{dp}$	Latent heat kgrm.-metres per gram.
1	75·0°	0·00073	0·00668	0·38	144·6°	0·00244	0·00830	1·22
1,000	81·6°	0·00070	0·00655	0·38	152·9	0·00242	0·00825	1·25
3,000	94·5°	0·00065	0·00632	0·38	169·2	0·00239	0·00810	1·305
5,000	107·0°	0·00060	0·00616	0·37	185·3	0·00235	0·00790	1·37
7,000	119·2°	0·00055	0·00606	0·355	200·7	0·00232	0·00745	1·48
9,000	131·3	0·000495	0·00600	0·335	-	-	-	—
11,000	143·2	0·000445	0·00592	0·313			-	-
12,000	149·1	0·00042	0·00587	0·302	-	-	-	-

The difference in the compressibility of the phases, computed from the difference in the slope of the isothermals above and below the transition, show that at 75°, the compressibility of III-$TlNO_3$ in c.c. per gram per kgrm. per sq. cm. is $0{\cdot}0_65$ greater than II-$TlNO_3$; at 105°, $0{\cdot}0_63$ greater; and at 140°, $0{\cdot}0_615$ greater. The difference in expansion, computed from the difference of compressibility and the slope of the change of volume along the transition line, shows that III-$TlNO_3$ is more expansible, the average difference being 0·00005 c.c. per gram per degree. W. Crookes said that the m.p. of thallous nitrate is about 205°, and that a little thallic salt may be formed, but no decomposition occurs. J. W. Retgers gave 205°; A. G. Bergmann, 207°; F. M. Jäger, 206°; and C. van Eyk, 205·0°–206·1°. The presence of the silver or mercury (ous or ic) nitrate depresses the m.p., and molten mixtures of these salts and thallous nitrate alone were recommended as heavy liquids for mineral separations; with equimolar parts of thallous nitrate and silver, mercurous or mercuric nitrate the sp. gr. at the m.p. are respectively 4·8 (70°), 5·3 (76°), and 5·0 (110°). The approximate b.p. is 430°. R. Lorenz and W. Herz found the ratio of absolute temp. of the m.p. and b.p. of many inorganic salts to be nearly constant. The effects of various nitrates on the m.p. are indicated in Figs. 26 to 30. According to P. W. Bridgman, the latent heats of the transition are indicated in Table I, where they are expressed in kilogrammetres per gram. V. Thomas noted that the nitrate is slowly decomposed at 300°, and the reaction is rapid at 450°—oxygen, nitrogen, and nitrogen oxides are given off, and crystalline thallic oxide remains; a little thallous nitrate may be volatilized unchanged. W. Crookes said that a little thallous nitrite also accompanies the thallic oxide.

M. P. Appleby and W. Hughes found the vap. press. p mm., of sat. soln. of thallium nitrate at different temp. as determined by the b.p. method, to be:

	93·55°	99·99°	103·79°	105·12°	106·00°	107·54°	108·84°
p . .	547·1	659·8	740·5	773·0	795·1	827·6	859·1

The value of $dp/dT=22·3$ mm. per degree; the Earl of Berkeley found $dp/dT=16·1$ mm. per degree at 762 mm. The low b.p. of the sat. soln. is probably due to the mol. association of the salt, and is not due to the volatility of the salt, for at 104° the salt is non-volatile whether solid or in soln. The osmotic press., P, in atm. for soln. of mol. conc. C, is:

	94°	96°	98°	100°	102°	104°	106°	108°
P . .	147·1	173·3	195·9	217·8	237·0	254·6	268·8	288·4
C . .	6·230	6·760	7·323	7·990	8·775	9·816	11·257	(13·44)
P/C .	23·61	25·64	26·75	27·26	27·01	25·93	23·88	(21·46)

The value of P/C thus attains a maximum. The curve is probably the resultant of two effects: (i) the normal increase of P/C with conc.; and (ii) a factor due to the association of the salt, which diminishes the osmotic press. per mol with increasing conc. C. Drucker measured the lowering of the f.p. of water by thallous nitrate.

Aq. soln. of thallous nitrate were found by W. N. Hartley to give an absorption band between $\lambda=3240$—2740; and with a dilution 0·001N, rays to $\lambda=2420$ are absorbed. The double refraction of crystals of γ-thallous nitrate is negative; that of β-thallous nitrate is positive; and that of α-thallous nitrate is negative. W. H. Miller gave 1·817 for the mean refractive index. A. A. Noyes, G. Jones and W. C. Schumb, and E. Franke measured the eq. electrical conductivity, λ, at 25°, for soln. with a mol in v litres. The former gave:

v . .	4	16	32	64	128	256	512	1024	∞
λ . .	95·7	114·3	121·0	125·4	129·0	130·9	132·2	133·5	138·2

and for the degree of ionization of 0·0204N-soln. 0·906 and 0·910 at respectively 25° and 68°; and of 0·0970N-soln., 0·735 and 0·687. The ionization constants at 25°, calculated from solubility and conductivity determinations, are respectively 5·45 and 7·11 for 0·0161N-soln., and 4·81 and 2·90 for 0·1500N-soln. C. Drucker's observations on the f.p. and conductivity of soln. of thallous nitrate led him to infer that complex ions, corresponding with $2Tl^{\cdot}=Tl_2^{\cdot\cdot}$, are formed, and that the ionization then follows the law of mass action. A. J. Rabinowitsch studied the anomalous ionization of soln. of thallium nitrate. A. A. Noyes and K. G. Falk found the percentage ionization of soln. with 1, 5, and 100 millieq. of salt per litre to be respectively 97·7, 94·8, and 78·8. G. N. Lewis and M. Randall measured the activity coeff. W. Schmidt gave 16·5 for the dielectric constant. H. Greinacher found that in the electrolysis of a flame charged with the vapour of thallous nitrate, using spark electrodes, the metal ions migrated to the negative pole.

Observations on the solubility of thallous nitrate were made by W. Crookes, A. Lamy, and A. Étard. Expressing the solubility, S, in grams of thallous nitrate per 100 grms. of *water*, the Earl of Berkeley found:

	0°	10°	20°	30°	40°	60°	80°	100°	105°
S . .	3·91	6·22	9·55	14·3	20·9	46·2	111	414	594

A. Lamy found thallous nitrate to be insoluble in *alcohol*; and W. Eidmann, soluble in *acetone*. The aq. soln. has a neutral reaction. P. Schottländer found thallous nitrate reduces a soln. of auric nitrate: $3TlNO_3+2Au(NO_3)_3=2Au+3Tl(NO_3)_3$. C. van Eyk obtained the f.p. curve, Fig. 27, for binary mixtures of thallous iodide and nitrate. The m.p. curve belongs to H. W. B. Roozeboom's fourth type (1. 10, 2); it rises immediately from the f.p. of the nitrate showing that mixed crystals are deposited from the melt. The white mixed crystals contain 0–8 molar per cent. of iodide, and the red mixed crystals 65–100 molar per cent. of iodide. Mixtures with 18–65 molar per cent. of iodide solidify at 215·5° to a conglomerate of the limiting mixed crystals.

A. Ditte assumed that in aq. soln., nitric acid forms a complex **thallous trihydronitrate,** $TlNO_3.3HNO_3$, but it could not be isolated; H. L. Wells and F. J. Metzger saturated nitric acid, sp. gr. 1·5, with thallous nitrate, and at 0°, obtained crystals of **thallous dihydronitrate,** $TlNO_3.2HNO_3$. The salt loses nitric acid rapidly on exposure to air. If the thallous nitrate be dissolved in hot nitric acid of sp. gr. 1·5, H. L. Wells and F. J. Metzger found some thallic nitrate is formed, for the soln. deposits colourless prismatic crystals of **thallosic nitrate,** $2TlNO_3.Tl(NO_3)_3$, which are stable in dry air, but rapidly blacken in moist air.

According to F. Wallerant, ammonium and thallous nitrates form a continuous series of mixed crystals; the transformation temp. of cubic ammonium nitrate is lowered from 125° to 104° by 32 per cent. thallous nitrate, and the transformation temp. of cubic to rhombohedral thallous nitrate is lowered to 104° with 32 per cent. of thallous nitrate by the addition of ammonium nitrate. Likewise the transformation temp. of rhombohedral to rhombic thallous nitrate is lowered to 68° with 32 per cent. of ammonium nitrate. A. J. Boks found the f.p. curve has the V-shape with a eutectic at 109° and 19·62 per cent. of thallous nitrate. C. van Eyk found that the f.p. curve of thallous and sodium nitrates is of the simple V-type with a eutectic at 162°, Fig. 28. There is no evidence of the formation of a double salt; and since the transition temp. of thallous nitrate, 142° and 72·8°, are not affected by additions of sodium nitrate, it follows that no mixed crystals are formed. The m.p. and f.p. curves of mixtures of potassium and thallous nitrates have been studied by A. Fock, B. Gossner, F. Wallerant, W. Stortenbeker, and C. van Eyk.

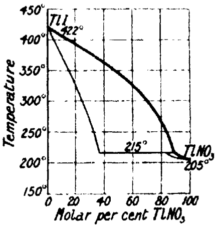

FIG. 27.—Freezing-point Curve of Thallous Iodide and Nitrate.

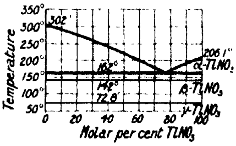

FIG. 28.—Freezing-point Curve of Mixtures of Thallous and Sodium Nitrates.

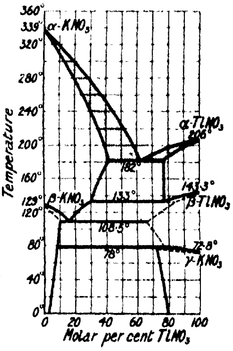

FIG. 29.—Equilibrium Curves of Mixtures of Thallous and Potassium Nitrates.

The two salts are isodimorphous. Two series of solid soln. are formed, Fig. 29. There is a continuous series of rhombohedra with up to 20 per cent., and a continuous series of cubic crystals with 50–100 per cent. of potassium nitrate. With intermediate values, a conglomerate of mixed crystals is formed. Continuous transition curves are obtained for the mixed crystals from 144° to 133° on the thallium side, and 129° to 108·5° on the potassium side. The conglomerate has, however, two transition temp., the first at 133°, at which temp. it changes to a mixture of rhombohedra and rhombic crystals, and the second at 108·5°, where the remaining rhombohedra change to the rhombic form. Although no transition in the conglomerate occurs above 133°, the composition of the two sets of mixed crystals changes with the temp., the percentage of potassium nitrate being 20 and 50 per cent. at 182°, 20 and 69 per cent. at 133°, and 35 and 84 per cent. at 108·5°. The other changes will appear from Fig. 29. F. Wallerant found thallous nitrate with rubidium or cæsium nitrate forms a continuous series of cubic crystals. The cubic crystals become rhombohedral with a positive double refraction at lower temp., Fig. 30; and those with a high thallium content become rhombic at still lower temp. The fused mixtures furnish cubic crystals except those rich in rubidium, which furnish rhombohedral crystals with a negative double refraction. The continuous curves in Fig. 30 refer to the mixtures with rubidium, the dotted lines to those with cæsium nitrate.

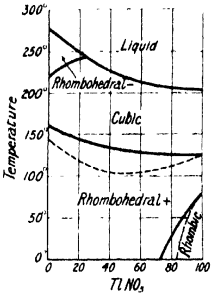

FIG. 30.—Transformations with Thallous and Rubidium or Cæsium Nitrates.

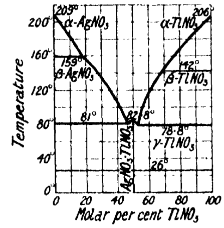

FIG. 31.—Freezing-point Curves of Mixtures of Thallous and Silver Nitrates.

C. van Eyk obtained the f.p. curves, Fig. 31, for mixtures of thallous and silver nitrates. A compound, **silver thallous nitrate,** $AgNO_3.TlNO_3$, appears as a maximum on the curve. J. W. Retgers also prepared the double salt in what were regarded as monoclinic crystals with m.p. 76°; C. van Eyk gave 82·8° for the m.p. The complex salt separates on cooling fused mixtures with 47–53 molar per cent. of silver nitrate down to 80°–85°. C. Sandonnini studied the electrical conductivities of the mixed salts fused and solid. There is no evidence of the formation of appreciable quantities of mixed crystals; and there are only solidified conglomerates of the double salt with excess of silver or thallous nitrate. There is a slowly progressing transformation of the double salt at 26°, but the nature of the change is not understood. The change is attended by a decrease in the volume of the double salt, while that of the admixed silver or thallous nitrate remains unchanged. A. J. Rabinowitsch measured the sp. gr., viscosity, electrical conductivity, and ionization of aq. soln. of thallous silver nitrate. G. Schulze studied the electrolytic valve action of the eutectic mixture. P. Schottländer prepared **thallous auric nitrate,** $TlAu(NO_3)_4$, by mixing a sat. soln. of one mol of thallous nitrate with a soln. of 1 to 3 mols of auric nitrate in nitric acid. J. W. Retgers prepared **mercurous thallous nitrate,** $TlNO_3.HgNO_3$, of sp. gr. 5·3, and m.p. 70°; and likewise **mercuric thallous nitrate,** $TlNO_3.Hg(NO_3)_2$, of sp. gr. 5·0, and m.p. 110°. A. G. Bergmann and co-workers found that thallous nitrate forms two compounds with mercuric chloride. There is a eutectic at 176° and 12·8 per cent. of mercuric chloride; a maximum at 195°, **thallous mercuric dichlorodinitrate,** $2TlNO_3.HgCl_2$; a eutectic at 192° and 37 per cent. of mercuric chloride; a maximum at 202·5°, **thallous mercuric dichloronitrate,** $TlNO_3.HgCl_2$; and a eutectic at 197°. With mercuric bromide, there is a maximum at 152°, **thallous mercuric dibromonitrate,** $TlNO_3.HgBr_2$, and a eutectic at 146° and 30 per cent. of mercuric bromide. A. G. Bergmann found the fusion curve of mixtures of thallous nitrate and mercuric iodide is of the simple V-type with a eutectic at 192°, and a flat portion in the region 33–75 molar per cent. of mercuric iodide indicating the formation of solid soln. There is no indication of chemical combination.

J. E. Willm, A. Strecker, and R. J. Meyer dissolved thallic oxide or hydroxide in nitric acid of sp. gr. 1·4, and found that the conc. soln. deposited colourless deliquescent crystals of **thallic nitrate,** $Tl(NO_3)_3.3H_2O$. C. F. Rammelsberg said that the crystals are rhombohedral. The salt is hydrolyzed in the presence of much water and thallic oxide is formed; it is also decomposed, according to J. E. Willm, if heated even below 100°. When exposed to air, the crystals lose nitric acid. R. J. Meyer found that the soln. of thallic nitrate in nitric acid is a strong oxidizing agent—with mercurous nitrate, mercuric and thallous nitrates are formed. He could not prepare *thallic hydronitrate;* even with thallic anhydride in fuming nitric acid, $Tl(NO_3)_3.3H_2O$ is formed. R. J. Meyer found that thallic nitrate unites with potassium nitrate, furnishing crystals of **potassium pentanitratothallate,** $2KNO_3.Tl(NO_3)_3.H_2O$, or $K_2Tl(NO_3)_5.H_2O$. When heated, nitric acid is given off, and when treated with water, thallic oxide is formed.

§ 15. Thallium Phosphates

W. Crookes[1] found that normal **thallous orthophosphate,** Tl_3PO_4, is obtained as a crystalline precipitate when an excess of phosphoric acid and ammonia is added to a soln. of thallous nitrate. A. Lamy mixed conc. soln. of sodium hydrophosphate and thallous sulphate; about one-third of the thallium was precipitated as orthophosphate, and two-thirds remain in soln. as a complex salt; he also made it by melting equi-molar proportions of thallous metaphosphate and thallous carbonate; and by adding alkali hydroxide to soln. of thallous hydrophosphate—alkali carbonate will not do in place of the hydroxide. C. F. Rammelsberg made it by saturating a soln. of phosphoric acid with thallous carbonate; and by adding an excess of ammonia to a soln. of one of the acid phosphates. The salt appears in white, silky, acicular crystals. C. F. Rammelsberg said that normal thallous and lithium orthophosphates resemble one another closely. A. Lamy gave 6·89 (10°) for the sp. gr. of the molten salt. W. Crookes found that the salt melts to a brown liquid, and on cooling it appears orange, then white, and finally as a crystalline mass. He also found that 100 parts of water at 15° dissolve 0·497 part of salt, and boiling water 0·673 part of the salt. A. Lamy found that thallous phosphate is quite insoluble in alcohol; E. Carstanjen, that it is sparingly soluble in soln. of ammonium salts; and C. F. Rammelsberg, that it is soluble in soln. of thallous hydrophosphate. The aq. soln. has a neutral reaction, and when boiled with silver nitrate, yellow silver phosphate is formed without the soln. losing its neutrality.

A. Lamy regarded the sparingly soluble crystals which he obtained by saturating phosphoric acid with thallous carbonate as anhydrous **thallous hydrophosphate,** Tl_2HPO_4; but, according to C. F. Rammelsberg's analysis, this salt is not a hydrophosphate, but, rather normal thallous phosphate with one to two per cent. of adsorbed water. A. Lamy also said that a hemihydrate, $Tl_2HPO_4.\frac{1}{2}H_2O$, separates when the syrupy soln. obtained by evaporation is allowed to cool, but C. F. Rammelsberg's analysis shows that the product is more probably a complex *thallium pentahydrotriphosphate,* $Tl_2HPO_4.2TlH_2PO_4$. According to A. Lamy and A. des Cloizeaux, the rhombic crystals have the axial ratios $a:b:c=0·9314:1:0·7818$; and they are positively doubly refracting. C. F. Rammelsberg said that they are isomorphous with the corresponding ammonium hydrophosphate and arsenate. A. Lamy said that half a mol of water is lost at 200°, and at a dark red heat, vitreous pyrophosphate is formed, while C. F. Rammelsberg said a mixture of pyro- and meta-phosphates is produced. A. Lamy said the salt is sparingly soluble in water; insoluble in alcohol; the aq. soln. reacts alkaline, but does not coagulate the white of egg; the aq. soln. gives a yellow precipitate with silver nitrate, and at the same time becomes acid. C. F. Rammelsberg found that when the salt dissolves in water, some normal phosphate is precipitated.

A. Lamy, and C. F. Rammelsberg prepared **thallous dihydrophosphate,** TlH_2PO_4, by adding phosphoric acid to a soln. of the preceding salt, or by saturating a boiling soln. of phosphoric acid with thallous carbonate. A. Lamy and A. des Cloizeaux found the monoclinic crystals have the axial ratios $a:b:c=3·1750:1:1·4577$, and $\beta=91° 44'$; the double refraction is negative; the sp. gr. is 4·723; the m.p. about 190°; it loses water at 240°, and forms thallous dihydropyrophosphate; at a red heat, it forms the sparingly soluble metaphosphate. The salt is sparingly soluble in water, and insoluble in alcohol. The aq. soln. has a feebly acid reaction. A. Lamy prepared an **ammonium thallous phosphate** by adding ammonia to a soln. of thallous hydrophosphate, and evaporating the liquid filtered from the precipitated thallous phosphate. According to A. Lamy and A. des Cloizeaux, the anhydrous crystals are tetragonal and have the axial ratio $a:c=1:0·7107$; they are optically negative, and isomorphous with ammonium phosphate. The salt is sparingly soluble in water. A. Lamy's analysis corresponds with $(NH_4)_3PO_4.(NH_4)_2TlPO_4$; and C. F. Rammelsberg regards it as an isomorphous mixture of $(NH_4)H_2PO_4$ and Tl_2HPO_4 in the molar proportions 5 : 1. G. Bollmann made **thallous magnesium orthophosphate,** $TlMgPO_4.6H_2O$, by dropping a soln. containing equimolar proportions of thallous and magnesium sulphates into one of sodium hydrophosphate. The filtered soln. after some hours deposits crystals of this salt.

A. Lamy prepared normal **thallous pyrophosphate,** $Tl_4P_2O_7$, by heating his hemihydrated thallous hydrophosphate. A syrupy soln. of the sparingly soluble salt crystallizes with difficulty. C. F. Rammelsberg made this salt by adding thallous carbonate to the mother liquid remaining after the preparation of thallous dihydropyrophosphate. P. Glühmann obtained the anhydrous salt by allowing a soln. of sodium triphosphate and thallous sulphate to stand in air for some time. The salt dried at 100° has 0·21 per cent. of water. A. Lamy and A. des Cloizeaux found the monoclinic prisms have the axial ratios $a:b:c=1{\cdot}4274:1:1{\cdot}2921$, and $\beta=114°$. The sp. gr. is 6·786; the double refraction is negative. A. Lamy found that the salt softens near 120°, and melts at a higher temp. The glassy mass obtained on cooling the molten salt is non-hygroscopic. 100 parts of water dissolve about 40 parts of the salt; at the same time some of the salt is hydrolyzed, and an insoluble white mass separates—possibly thallous dihydropyrophosphate. Silver nitrate gives a white precipitate and the mother liquid is neutral. According to A. Lamy, the spontaneous evaporation of the mother liquid remaining after the deposition of the crystals of the anhydrous salt furnishes the **dihydrated thallous pyrophosphate,** $Tl_4P_2O_7.2H_2O$. A. Lamy and A. des Cloizeaux found the monoclinic crystals have the axial ratios $a:b:c=2{\cdot}1022:1:1{\cdot}9217$, and $\beta=114° 57'$; the double refraction is negative. When exposed to air, the salt becomes superficially moist and sticky. When heated, the salt loses two mols of water below a red heat. It dissolves in water more quickly than the anhydrous salt. A. Lamy prepared **thallous dihydropyrophosphate,** $Tl_2H_2P_2O_7$, by heating thallous dihydrophosphate to 240°, or, according to C. F. Rammelsberg, to 275°. A. Lamy reported that the salt is sparingly soluble in water, and the acid soln. yields short prismatic crystals which melt at 270°, and lose 2·85 per cent. of water at a red heat.

According to A. Lamy, **thallous metaphosphate,** $TlPO_3$, exists in two forms. One is an opaque glass made by calcining thallous dihydrophosphate. The product dissolves with difficulty in water, and it does not coagulate white-of-egg directly, but only after the addition of a few drops of phosphoric acid. The second form is obtained by calcining ammonium thallous orthophosphate; it is a glassy mass readily soluble in water, and the soln. coagulates white-of-egg directly. If the sparingly soluble form be fused with a few drops of phosphoric acid it passes into the soluble form.

J. E. Willm prepared normal **thallic orthophosphate,** $TlPO_4.2H_2O$, by mixing a syrupy soln. of thallic nitrate with phosphoric acid; the white gelatinous mass is insoluble in water. When boiled with water, a basic salt and some thallic hydroxide are formed. A. Strecker noted the white slimy precipitate formed when a soln. of sodium hydrophosphate is mixed with one of thallic sulphate; and C. F. Rammelsberg's analysis of the product corresponds with $Tl_8P_2O_{27}.13H_2O$. J. E. Willm made the *basic phosphate*, $2Tl_2O_3.P_2O_5.5H_2O$, by adding ammonia to a hydrochloric acid soln. of the normal phosphate; if too much ammonia is added brown thallic hydroxide is formed.

CHAPTER XXXVII

SCANDIUM

§ 1. The History and Occurrence of Scandium

THERE are differences of opinion as to whether scandium should or should not be included in the rare earth family of elements. In any case, it is always associated with the rare earths for, in 1879, while studying the ytterbia derived from gadolinite and euxenite, L. F. Nilson[1] obtained 0·3 grm. of a new earth which was characterized by its spark spectrum, its low chemical eq., and feeble basicity. He called the element **scandium** in honour of his country, the Scandinavian peninsula where the minerals containing the earth were originally found. Shortly afterwards, P. T. Cleve obtained 0·8 grm. of scandia from 4 kgrms. of gadolinite, and 1·2 grm. from 3 kgrms. of keilhauite. G. Urbain and H. Lacombe believe that scandium should not be included in the rare earths in spite of the fact that it forms a cyanoplatinate resembling those of the ceria earths, and another, which resembles those of the yttrium earths. Unlike the yttrium earths, it forms a sparingly soluble double alkali sulphate, and in this it resembles more the cerium earths. In its low basicity, however, scandia more resembles the yttrium earths. Scandium sulphate is hexahydrated and very soluble in water. R. J. Meyer emphasized that in this and in other qualities, it resembles beryllium. Scandium fits very well into the place assigned by D. I. Mendeléeff to *ekaboron*. P. T. Cleve emphasized the analogies between the prediction and verification, as shown in Table I.

TABLE I.—COMPARISON OF THE PREDICTED AND OBSERVED PROPERTIES OF SCANDIUM.

Ekaboron, Eb.	Scandium, Sc.
At. wt. 44	At. wt. 44
It will form one oxide, Eb_2O_3, of sp. gr. 3·5; more basic than alumina, less basic than yttria or magnesia; not soluble in alkalies; and it is doubtful if it will decompose ammonium chloride.	Scandium oxide, Sc_2O_3, has a sp gr. 3·86; it is more basic than alumina, and less basic than yttria or magnesia. It is not soluble in alkalies; and does not decompose ammonium chloride.
The salts will be colourless, and give gelatinous precipitates with potassium hydroxide, and sodium carbonate. The salts will not crystallize well.	Scandium salts are colourless, and give gelatinous precipitates with potassium hydroxide and sodium carbonate. The sulphate crystallizes with difficulty.
The carbonate will be insoluble in water; and probably precipitated as a basic salt.	Scandium carbonate is insoluble in water, and readily loses carbon dioxide.
The double alkali sulphates will probably not be alums.	The double alkali sulphates are not alums.
The anhydrous chloride, $EbCl_3$, should be less volatile than aluminium chloride, and its aq. soln. should hydrolyze more readily than that of magnesium chloride.	Scandium chloride, $ScCl_3$, begins to sublime at 850°—aluminium chloride begins to sublime above 100°. In aq. soln. the salt is hydrolyzed.
Ekaboron will probably not be discovered spectroscopically.	Scandium was not recognized by spectrum analysis.

Scandium is sparsely but widely distributed. J. H. L. Vogt estimated that the ten-mile crust, the hydrosphere, and lithosphere of the earth contained 0·000000000*x*

per cent. of scandium; F. W. Clarke and H. S. Washington, 0·0000x per cent. From spectroscopic observations it is inferred that scandium occurs relatively abundantly in the sun and stars. M. N. Saha[2] observed evidence of it in the high-level solar chromospheric spectrum. Since the lines of the scandium spectrum are observed in the spectra of stars in diverse stages of development—for example, in α-Persei, which is younger than our sun, and in the red stars α-Orionis and α-Herculis, which are older than our sun—G. Eberhard argued that scandium must be universally distributed on the earth. Consonant therewith, he found that the arc spectra of 459 minerals and rocks showed that small quantities of scandium are present in 204; the evidence with 74 was doubtful; and the element was absent in 181. He finally concluded that scandium in small quantities is one of the most widely distributed of the elements on the earth's crust. It was found to occur most frequently in the zirconium minerals, in beryls, in titanates, columbites, titanocolumbites of the rare earths, in micas, and in specimens of wolframite and cassiterite. R. J. Meyer, and W. Crookes verified these conclusions, and found that scandium can be detected in most of the rocks forming the earth's crust. Even the rocks and, with a couple of exceptions, the minerals richest in scandium contain very small proportions—less than two per cent. G. Eberhard, and W. Vernadsky say that these rocks are all derived from granites and pegmatites. Most of the yttrium minerals contain scandium, but the yttrium always predominates. Scandium is found in keilhauite, euxenite, auerlite, cerite, cryptolite, koppite, mosandrite, orangite, orthite, pyrochlore, thorianite, thorite, widite, etc. T. Uemura detected scandium in a Japanese beryl. R. J. Meyer found that the wolframite from Zinnwald contains 0·15 per cent. R. J. Meyer and A. H. Winter's analyses of wolframite from Zinnwald and Sadisdorf are respectively:

WO_3	FeO	MnO	TiO_2; Ta_2O_5	PbO; SnO_2	CaO	Rare earths
75·41	9·34	14·00	0·50	0·18	0·55	0·15
73·47	15·13	9·81	0·63	0·47	0·54	0·20

Scandium constitutes 56·4 per cent. of the total rare earths present. H. S. Lukens found scandium in American wolframite; and C. James in Brazilian zirconite. J. Sterba-Böhm said that after tungsten has been removed from the wolframite, in the manufacture of sodium tungstate, the separation of the scandium is easy and could be profitable if there were any demand.

G. Urbain said that he found no scandium in his fractions of the rare earths. W. B. Hicks did not detect this element in the minerals fergusonite, æschynite, euxenite, and samarskite. R. J. Meyer found a Finnish orthite containing about one per cent. of scandia; and W. Crookes and R. J. Meyer obtained a similar amount from the mineral *wiikite*, which occurs with the monazite from a felspar quarry near Impilaks, Finland, in black masses which show no signs of a crystalline structure or action on polarized light. The mineral is so complex that a definite formula has not been obtained. W. Crookes' analysis is:

Ta_2O_5, Cb_2O_5	TiO_2, ZrO_2	Ce_2O_3	Y_2O_3	Sc_2O_3	ThO_2	FeO	UO_2	SiO_2
15·91	23·36	2·55	7·64	1·17	5·51	15·52	3·56	16·03

The volatiles—helium, neon, hydrogen sulphide and water—amounted to 5·83 per cent. Traces of lime, magnesia, stannic oxide, and sulphur were also present. L. H. Borgström has discussed and analyzed the mineral, and suggested the idealized formula $FeTiSiO_5$. The type rich in uranium is called wiikite, and one rich in yttrium, *loranscite*. The sp. gr. is 4·85, and the hardness 6. The mineral is feebly radioactive. The evolution of gas which attends the heating of the mineral is almost explosive, and is accompanied by a curious fracture. Wiikite is partially attacked by acids, and readily by fused potassium hydrosulphate.

Scandium occurs as an essential constituent of only one mineral, namely, **thortveitite.** This was analyzed and recognized as a new mineral by J. Schetelig; it was found in a pegmatite vein in granite in Iceland, and in the felspar quarries at Sætersdalen, Norway. A. Lacroix found it at Befanamo, Madagascar. The composition, according to J. Schetelig and R. J. Meyer, corresponds with that required for a silicate of the yttria earths and scandia approximating to **scandium orthodisilicate**, $R_2O_3.2SiO_2$, or $R_2S_2O_7$, where R represents Sc, Y, . . . The scandia forms about 37 per cent. of the whole; this with yttria and small quantities of other yttria bases make up 54·5 per cent.; the members of the ceria group are almost absent; traces of thoria are present; and ferric oxide with traces of manganic oxide and alumina make up nearly 3 per cent. The mineral occurs in radial aggregates. The colour is white, greyish-green, or reddish-grey; it appears yellowish-green by transmitted light. The refraction is strong, and the birefringence strongly negative. The crystals are rhombic with axial ratios $a:b:c=0{\cdot}7456:1:1{\cdot}4912$. *The sp. gr. is 3·571, and the hardness 6 to 7. The mineral fuses with difficulty, and it is only partially attacked by hydrochloric acid. C. Boulanger and G. Urbain analyzed thortveitite from Madagascar.*

§ 2. The Extraction of Scandium

R. J. Meyer,[1] and C. R. J. Sterba-Böhm have described the extraction of scandium from wolframite or tin-stone residues; and the separation of scandia from the contained rare earths depends (i) on the formation of a sparingly soluble fluoride when the soln. is treated with hydrofluoric acid or sodium fluosilicate; or (ii) on the formation of the hydroxide when boiled with sodium thiosulphate. If thorium be present it will accompany the scandia. Traces of yttria earths can be removed by repetitions of the process. The raw scandia prepared by R. J. Meyer's process was found by W. Crookes still to contain yttria and ytterbia—particularly when the fluosilicate method was used. P. and G. Urbain extracted scandia from thortveitite of Madagascar by the following process:

The mineral is easily attacked when fused with soda and the silica contained in it is eliminated when the residue is taken up with water. The insoluble residue is then treated with sulphuric acid, and the soln. of sulphates is precipitated with hydrofluoric acid. The fluorides of scandium and the rare earths are washed and then decomposed with sulphuric acid in excess. The scandium can be precipitated in a very pure state by means of potassium sulphate, after the sulphates have been transformed into nitrates. Ammonia never precipitates all the scandium from liquids containing it, but the precipitation of scandium phosphate is quantitative in an ammoniacal medium, provided that ammonium carbonate is absent. The latter appears to dissolve all scandium precipitates, and the soln. obtained are decomposed by heat, hydroxycarbonates being usually precipitated. The yttria earths containing scandium which have been concentrated in the mother liquors of the precipitates of the double potassium sulphates are transformed by ammonia into hydroxides. These are finally treated with a slight excess of acetylacetone Only a trace of scandium is found

in the mother liquors and the rest of the earths are converted into the crystalline acetylacetonates. When these are treated with chloroform all the scandium is dissolved and a residue of yttric acetylacetonates is left. The final separation is effected by sublimation in vacuo at about 200°, the scandium compound only being volatile.

To extract the crude scandia from wolframite, R. J. Meyer employed the following process:

The residues remaining after the extraction of tin are fused with sodium carbonate, and the cold product extracted with water. Sodium tungstate passes into soln. The washed residue is dissolved in hydrochloric acid, and the rare earths precipitated by either oxalic or hydrofluoric acid. An excess of the precipitant is required so as to keep the iron and manganese in soln. The precipitate of rare earths contains 90–95 per cent. of scandium; and it is ignited for the oxide, which is then dissolved in hydrochloric acid, and the soln. boiled for half an hour with sodium fluosilicate, when the scandium is precipitated as fluoride. Traces of the yttria earths may be removed from this by reprecipitation with sodium thiosulphate. The scandia is dissolved in hydrochloric acid. The excess of acid is removed by evaporation, and basic scandium thiosulphate precipitated at 100°. The washed precipitate is decomposed by hydrochloric acid, and the process repeated. The washed precipitate is thus freed from yttria earths, decomposed by hydrochloric acid, and reprecipitated as oxalate, and ignited for the oxide. The scandia so obtained is contaminated with thoria.

R. J. Meyer and co-workers found that 0·5 per cent. of thoria is difficult to remove from scandia—the oxalate process gives but an incomplete separation; the thoria cannot be precipitated by the hydrogen peroxide process; it cannot be detected spectroscopically; and the ignited oxides dissolve in hydrochloric acid, even though the thoria alone would be insoluble. R. J. Meyer and H. Goldenberg showed that the most convenient method of detecting traces of thoria in scandia is the magnetic susceptibility test.

Thoria can be separated by the following methods: (i) R. J. Meyer and A. Gumperz, and A. H. Winter separated thorium from scandium by the fractional sublimation of the anhydrous chlorides—scandium chloride is the more volatile; (ii) by boiling a neutral soln. of the chlorides with a large excess of a 20 per cent. soln. of sodium carbonate. Scandium sodium carbonate is precipitated while most of the thorium remains in soln. This process was found by R. J. Meyer and co-workers to yield a product so free from thoria that no radioactivity could be detected.

The conc. chloride soln. is poured into one of sodium carbonate containing 20 per cent. of anhydrous carbonate. One litre of sodium carbonate soln. is used for every 10 grms. of scandium oxide. The scandium dissolves entirely on stirring and warming. It is then boiled rapidly for half an hour, when the double carbonate is precipitated as a powder. The vol. of the soln. should be kept constant during the boiling. After the crystalline powder has settled, the liquid is poured off, and the precipitate washed by boiling with 20 per cent. sodium carbonate soln. for 15 mins.—this is repeated three times. The double carbonate is dissolved in two litres of cold water—4 hrs. and constant stirring are required for this purpose. The liquid is then filtered, acidified with hydrochloric acid, and the hydroxide precipitated by ammonium hydroxide while boiling. The scandium hydroxide is filtered off and well washed with boiling water until free from alkali. If necessary, the operation is repeated. Finally, the chloride soln. is precipitated with oxalic acid.

(iii) Another method used by R. J. Meyer and H. Goldenberg is to drop slowly a neutral soln. of the scandium salt into a 10–20 per cent. neutral soln. of sodium tartrate, and to boil the clear soln. with ammonia. The precipitated ammonium scandium tartrate is then washed with a dil. soln. of ammonium tartrate. (iv) According to R. J. Meyer and M. Speter, and B. Schweig, most of the thoria can be removed by the iodate process. An excess of potassium iodate sufficiently great to precipitate some of the scandia is added to a nitric acid soln. of the nitrates. The thorium iodate precipitate is separated from the soln., and the scandia precipitated in the usual way. (v) R. J. Meyer separated thoria from scandia by fractional crystallization of scandium ammonium fluoride. In this process, a neutral soln. of the chloride is mixed with an excess of aq. ammonium fluoride contained in a platinum dish, and vigorously stirred. A gram of scandia requires 8 grms. of ammonium fluoride.

On evaporating at 100°, insoluble thorium fluoride separates. Any scandium ammonium fluoride which crystallizes out can be redissolved by warming with more water. The soln. of scandium salt is then filtered off. R. J. Meyer and A. H. Winter also fractionally crystallized the acetylacetonates; W. Crookes, the metanitrobenzoates; R. J. Meyer, the hydrazine sulphates; and C. R. J. Sterba-Böhm, the formates. *It is claimed that the last traces of ytterbia can be removed from scandia by the fractional crystallization of the formates.* The various methods were examined by B. Schweig.

W. Crookes employed the following process for extracting scandia from wiikite. He did not consider a sample of scandia to be satisfactory if it had an at. wt. higher than 44·1, and if it showed the least trace of the dominant ytterbia spectral line $\lambda = 36944{\cdot}344$.

The ground mineral is passed through an 80-mesh sieve, then mixed with five times its weight of powdered potassium bisulphate and fused in a clay crucible. At first much frothing occurs, due to the escape of permanent gases and aq. vap. This ebullition can be abated by stirring with an iron rod. When in quiet fusion, the heat is raised to full redness for 10 mins. and the liquid mass poured on an iron plate. When cold, the melt is finely ground, mixed with water in the proportion of 1 kilo. to 5 litres, and mechanically agitated for about 12 hrs. It is then thrown on a linen filter and well washed. This treatment extracts most of the rare earths, together with a little titanic, niobic, and tantalic acids, and zirconia, but the bulk of these bodies is left behind. The soln. is supersaturated with ammonia and well boiled; this treatment precipitates all the earths, together with iron, titanic acid, zirconia, etc. The precipitate of crude earths is filtered and well washed. The precipitated crude earths are converted into oxalates by heating the pasty precipitate in a dish with crystals of oxalic acid added gradually, excess being avoided as much as possible. When cold, the oxalates are filtered off, and the iron, etc., in the filtrate is precipitated with ammonia. As scandium oxalate is slightly soluble in water, the iron precipitate will contain a certain proportion, which must be kept for subsequent working up. The washed oxalates are dried and ignited; the resulting earths form about 17 per cent. of the mineral and contain about 7 per cent. of scandia. The crude oxides are converted into sulphates by heating with sulphuric acid, the excess of acid being driven off by heat—not using too high a temp. The dry sulphates are agitated with plenty of water, and filtered from a little insoluble residue of the so-called metallic acids. Ammonia in excess is then added to the filtrate, and the precipitated oxides are washed, once more converted into oxalates in the manner already described, and the oxalates again washed, dried, and ignited. The ignited oxides are boiled in dil. nitric acid, filtered from a little insoluble matter, and evaporated to dryness. These somewhat complicated operations are to insure the removal of sulphuric and metallic acids, the presence of which interferes with subsequent fractionation. The earthy nitrates rich in scandium are mixed with an equal bulk of potassium nitrate and fused in large porcelain crucibles with constant stirring until the mass has the appearance of cream—fluid when hot, solidifying on cooling to a white enamel-like mass. On boiling this mass in water, a dense white basic nitrate separates and undecomposed nitrates are left in soln. Scandium and ytterbium, forming easily decomposed nitrates, concentrate in the insoluble end, while the yttrium and cerium earths, whose nitrates are less easily decomposed by heat, are left in the soluble end. Fractionation on these lines is now continued until spectrum photographs show the scandium to be pure. It is not difficult to obtain scandia free from all earths present except ytterbia and yttria; but the final elimination of pure scandia from these earths is a matter demanding much time and patience.

§ 3. The Properties of Scandium

W. R. Mott[1] gave 1200° for the m.p. of the metal, and calculated 2400° for the b.p. Scandium acts as a tervalent element and furnishes a basic oxide which is stronger than alumina, but weaker than that of any of the rare earths of the type R_2O_3. The salts are distinctly hydrolyzed in aq. soln. They have a sweet astringent taste, and are colourless.

Many organic salts of scandium have been prepared—*e.g.* the formate, acetate, acetylacetonate, propionate, butyrate, isobutyrate, isovalerate, oxalate, succinate, picrate, benzoate, *o*- and *m*-toluates, phenylacetate, pyromellitate, camphorate, mono-chloroacetate, malonate, malate, fumarate, tartrate, racemate, mesotartrate, αβ-dibromopropionate, citrate, phthalate, tetrachlorophthalate, 2-nitrophenyl-4′-tolylamine-4-sulphonate, octomethyltetraminodihydroxyparadixanthylbenzenetetracarboxylate, and metanitrobenzoate.

Scandium gives no absorption spectrum in the visible region; and P. T. Cleve[2] observed no flame spectrum.

In preparing the rare earths for spectroscopic examination G. Eberhard recommended that the part which could be extracted with acids was first separated from the non-extractive part, and the former was then further separated by treatment with oxalic acid into a part which was precipitated by this acid, and a part which was not precipitated by oxalic acid, but gave a precipitate with ammonia. This precipitation of the remaining liquors with ammonia was always necessary, as scandium oxalate is exceedingly soluble even in weak mineral acids, such as the extraction always contains, and thus a part of the scandium remains in the liquid after precipitation with oxalic acid. The preparation of other minerals and rocks was essentially simpler. They were first finely powdered and then heated to a bright red heat for some time in a porcelain crucible to remove the gases and water contained in them. If this preliminary treatment is neglected unpowdered particles spurt with little explosions, and powdered pieces crumble up as soon as the arc is started. Since vaporization in the arc is a kind of fractional distillation, the material should be all completely vaporized until the spectral lines disappear. In the early stages the more volatile constituents—*e.g.* the alkalies—vaporize first, and scandium, zirconium, thorium, tantalum, etc., do not appear.

The list of lines in the spark spectrum of scandium given by L. F. Nilson includes some lines derived from impurities; R. Thalen worked with a better purified material, and H. A. Rowland identified a few of these lines with the Fraunhofer lines in the solar spectrum. The more intense of the numerous lines in the spark spectrum are 6305, 6080, 6038 in the orange-yellow; 5527 and 5031 in the green; and 4415, 4400, 4374, 4325, 4320, 4314, and 4240 in the blue and violet. Measurements have been made by F. Exner and E. Haschek, J. N. Lockyer and F. E. Baxendall, and W. Crookes. The arc spectrum has been examined by A. Fowler, S. P. de Rubies, A. S. King, J. M. Eder and E. Valenta, and F. Exner and E. Haschek. The more intense lines are 3353·90, 3372·33, 3558·69, 3567·89, 3572·73, 3576·53, 3614·00, 3630·93, 3642·99, 3907·69, 3912·03, 4020·60, 4023·88, 4247·02, 4314·31, 4320·98, 4325·22, 4374·69, 4400·63, 4415·78, and 6305·94. According to A. Fowler, the arc spectrum of scandium consists of two distinct sets of lines, which behave very differently in solar spectra. Each set includes both strong and faint lines. Lines belonging to one set correspond with the enhanced lines of other elements, notwithstanding that they appear strongly in the ordinary arc spectrum. (*a*) These lines are very feeble or missing from the arc-flame spectrum, and are strengthened in passing to the arc in hydrogen, or the spark. (*b*) They occur as relatively strong lines in the Fraunhofer spectrum. (*c*) They are weakened in the sun-spot spectrum. (*d*) They occur as high-level lines in the chromosphere. The remaining lines show a great contrast when compared with the first group. (*a*) They are relatively strong lines in the arc-flame. (*b*) They are very feebly represented in the Fraunhofer spectrum. (*c*) The stronger lines are prominent in sun-spot spectra. (*d*) They have not been recorded in the spectrum of the chromosphere. The special development of the enhanced lines in the Fraunhofer spectrum, together with their presence in the upper chromosphere, indicates that the greater part of the scandium absorption in the solar spectrum originates at a higher level than that at which the greater part of the iron absorption is produced. The flutings which occur in the arc and arc-flame spectra do not appear when the arc is passed in an atm. of hydrogen. As suggested by R. Thalen, they are probably due to scandium oxide. W. J. Humphreys studied the effect of press. on the spectral lines. M. A. Catalan, W. M. Hicks, and E. Paulson studied the regularities in the structure of the scandium line spectrum; A. S. King, the Zeeman effect. J. M. Eder and E. Valenta gave drawings of typical spectra of the arc and spark spectra, Figs. 1 and 2. G. Eberhard showed spectroscopically the wide distribution of scandium. F. W. Dyson, G. Hofbauer, A. Fowler, and W. S. Adams studied the scandium lines in the solar spectrum, and the last-named identified 45 scandium lines in that spectrum.

H. G. J. Moseley, E. Hjalmar, and E. Friman studied the high-frequency or X-ray spectrum; and W. M. Hicks found that the high-frequency spectra of scandium, yttrium, lanthanum, and ytterbium show doublet series. V. Dolejsek, *H. Fricke, E. Hjalmar, M. Siegbahn, and* H. Stensson *gave for the* K-series $\alpha_2\alpha'=3{\cdot}02863$; $\alpha_1\alpha=3{\cdot}02526$ A.; α_3 and $\alpha_4=3{\cdot}006$ A.; $\beta_1\beta=2{\cdot}77366$ A.; and $\beta_2\gamma=2{\cdot}7555$ A. The atomic structure and the paramagnetic properties observed by B. Cabrera were discussed by A. Dauvillier.

Reactions of scandium salts of analytical interest.—According to P. T. Cleve, a soln. of a scandium salt gives no precipitate with hydrochloric acid or with hydrogen sulphide. **Alkali hydroxides or ammonia** give a voluminous precipitate insoluble in an excess of the reagent; tartaric acid hinders the precipitation in the cold, but when heated, an abundant precipitation occurs. **Alkali or ammonium carbonate** gives a voluminous precipitate fairly soluble in an excess of the reagent. **Ammonium sulphide** gives a precipitate of the hydroxide. An excess of a sat. soln. of **potassium or sodium sulphate** with conc. soln. of the scandium salt precipitates the double alkali sulphate. **Sodium phosphate** gives a gelatinous precipitate; **sodium thiosulphate** with a boiling soln. gives an incomplete precipitation of a basic thiosulphate. **Hydrogen peroxide** in neutral or slightly acid soln. gives no precipitate. **Iodic acid** readily precipitates scandium iodate which is readily soluble in nitric acid. **Hydrofluoric acid** precipitates a fluoride which is soluble in alkali fluorides, but much less soluble in acids than are ceric or yttrium salts. Hydrofluosilicic acid or **sodium fluosilicate** gives a white precipitate of scandium fluoride. Thorium fluoride is similarly precipitated. **Tartaric acid** gives no precipitate, but if ammonia be present, the double tartrate is precipitated.

A curdy precipitate is produced when **oxalic acid** is added to a soln. of scandium chloride. This is speedily transformed into a crystalline powder; the precipitate is sparingly soluble in acids, but readily soluble in ammonium oxalate. The precipitation is incomplete in acid soln. Scandium oxalate is slightly but distinctly soluble in water; it is less soluble than the oxalates of the rare earths in dil. acids, and unlike the rare earth oxalates, it is more soluble in dil. sulphuric acid than in dil. hydrochloric acid. In these respects it resembles thorium oxalate. Scandium oxalate forms sparingly soluble potassium, and sodium oxalates, and readily soluble ammonium oxalate. Although *scandium oxalate*, $Sc_2(C_2O_4)_3.5H_2O$, appears to be more soluble than the oxalates of the rare earths, it is found in the first fractions when a mixture of ytterbium and scandium salts is fractionally precipitated. F. Wirth found at 25°, 100 grms. of a sat. soln. of scandium oxalate, in presence of 1·624, 2·4, and 4·478 grms. of ammonium oxalate, contain respectively 0·3019, 0·4012, and 0·7108 grm. of scandia. The solid phase with the first two soln. is the pentahydrate, and with the last-named soln. a mixture of the pentahydrate and ammonium oxalate. F. Wirth, and R. J. Meyer measured the solubility of scandium oxalate in hydrochloric and sulphuric acids, and, expressing the results in grams of scandium oxalate in 100 grms. of soln., with acids of normality *N*-, the solubilities at 25° and 50°, found by R. J. Meyer, are:

Normality		0·1	0·5	1·0	2·0	5·0
HCl	25°	0·0299	0·0650	0·1020	0·1716	0·4170
	50°	0·0420	0·0870	0·1435	0·2556	0·6533
H_2SO_4	25°	0·0385	0·0997	0·1663	0·3176	0·7761
	50°	0·0562	0·1481	0·2493	0·4429	1·1280

The results are plotted in Fig. 1. In quantitative analyses scandium is precipitated as oxalate, ignited and weighed as scandia, Sc_2O_3. Acid potassium oxalate precipitates a crystalline double salt.

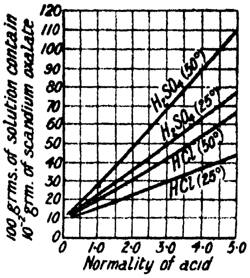

Fig. 1.—Solubility of Scandium Oxalates in Hydrochloric and Sulphuric Acids.

The atomic weight of scandium.—The relations between ekaboron—*vide* Table I—and scandium agree with the assumption that scandium is a tervalent element. The X-ray spectrum fits in with the atomic number, 21. This was confirmed by the observations of R. J. Meyer and co-workers,[3] A. H. Winter, and G. T. Morgan and H. W. Moss on scandium acetylacetonate. Mol. wt. determinations from its action on the f.p. of benzene, and on the b.p. of benzene, chloroform, and carbon disulphide, show that the formula is $Sc[CH(COCH_3)_2]_3$, and not $Sc[CH(COCH_3)_2]$ or $Sc[CH(COCH_3)_2]_4$. F. M. Jäger's observations on the isomorphism of the scandium and indium acetylacetonates and ethylsulphates; and L. F. Nilson and O. Pettersson's observations on the sp. ht. of the oxides and sulphates of alumina, gallia, india, scandia, and yttria also agree with the tervalency of scandium. The difficulty in eliminating the rare earth elements from scandium salts explains the high results obtained by the early workers on the at. wt. of scandium. P. T. Cleve ignited the anhydrous sulphate, and from the ratio $Sc_2(SO_4)_3 : Sc_2O_3$ obtained 44·96; from the synthesis of the sulphate, P. T. Cleve obtained from the ratio $Sc_2O_3 : Sc_2(SO_4)_3$, 45·20; L. F. Nilson, 44·13; and R. J. Meyer and H. Goldenberg, 44·09. J. Meyer and B. Schweig obtained 45·23; R. J. Meyer and A. H. Winter, 45·0; and O. Hönigschmid, 45·099 ± 0·014. The International Committee on at. wt. determinations gives 44·1 as the best representative value. The **atomic number** of scandium is 21. F. W. Aston found scandium is a simple element without **isotopes.** G. Kirsch and H. Pettersson found that when bombarded with long-range α-**rays,** scandium does not give long-range particles in evidence of **atomic disintegration.** L. F. Bates and J. S. Rogers made observations on this subject.

§ 4. Scandium Oxide and Hydroxide

When scandium hydroxide, carbonate, oxalate, sulphate, or nitrate is ignited, **scandium oxide,** Sc_2O_3—scandium sesquioxide, or scandia—is formed as a fine white powder. According to L. F. Nilson and O. Pettersson,[1] the sp. gr. is 3·864, and the sp. ht. 0·1530 between 0° and 100°. R. J. Meyer and co-workers found the magnetic susceptibility to be $-0{\cdot}05\times10^{-6}$ electromagnetic mass units. E. Wedekind and P. Hausknecht found the mol. magnetism of scandium oxide to be $-1{\cdot}2\times10^{-6}$. According to L. F. Nilson, scandia dissolves slowly in cold acids and rapidly in hot acids, forming scandium salts. According to W. Crookes, ignited scandia dissolves with difficulty in dil. cold acids, but readily, in warm acids, and particularly so in conc. acids. Conc. sulphuric acid dissolves ignited scandia with the evolution of much heat. When alkali hydroxide or ammonia is added to a soln. of a scandium salt, a white voluminous gelatinous precipitate of **scandium hydroxide,** $Sc(OH)_3$, is formed. It is insoluble in an excess of the precipitant. When dried in air, at ordinary temp., it forms a hard horny mass which, according to W. Crookes' analysis, has the composition $Sc(OH)_3$. W. Crookes added that the hydroxide is a weak base with a marked tendency to form basic salts. It dissolves readily in dil. acids, forming, as in the case of the oxide, scandium salts. J. Böhm and H. Niclassen studied the X-radiograms of the sol and gel hydroxide.

§ 5. Scandium Halides

W. Crookes[1] prepared **scandium fluoride,** ScF_3, by heating scandia with aq. hydrofluoric acid; the semi-transparent gum-like mass changes on boiling to a white mass difficult to filter. When hydrofluoric acid is added to a soln. of scandium nitrate or sulphate, a white precipitate is formed, which on boiling resembles the preceding one. R. J. Meyer also precipitated scandium fluoride from warm—not cold—neutral or acid soln. by means of hydrofluosilicic acid. This behaviour is attributed to the ready hydrolysis of the fluosilicate in hot soln.: $Sc_2(SiF_6)_3+6H_2O=2ScF_3+3SiO_2+12HF$, and the reaction is utilized in separating scandium from other rare earths. C. R. J. Sterba-Böhm said that W. Crookes' process does not give a pure fluoride because of its great adsorptive power for salts in the mother-liquor; a pure preparation is obtained by the action of hydrofluoric acid on the oxide, and drying at 150°–180°. When dried over sulphuric acid, scandium fluoride is anhydrous, ScF_3; it loses a little weight at a red heat; at a higher temp. it sinters together; and fuses before the blowpipe flame. The salt is very stable, for it is but imperfectly decomposed by conc. sulphuric acid; it is completely decomposed by fusion with potassium bisulphate; the melt dissolves in acidulated water; and the soln. gives a precipitate of scandium hydroxide with ammonia. Unlike the fluorides of thorium and the rare earths, the solubility of the fluoride in mineral acids is less than that of the other rare earth fluorides, and approaches that of thorium fluoride. Scandium fluorides are very sparingly soluble in hydrochloric acid. R. J. Meyer found that unlike all the other earths —excepting zirconium—scandium fluoride is readily soluble in soln. of the alkali fluorides when acids are absent. According to C. R. J. Sterba-Böhm, fluoscandic acids do not exist in the free state, and of the fluoscandiates those of the type R_3ScF_3 are limiting forms. In its fluoride, scandium resembles calcium more than titanium, and in its property of forming complex fluorides, it resembles titanium and zirconium, and differs from the rare earths. Its co-ordination number is 6, that of boron 4.

R. J. Meyer prepared **ammonium fluoscandate,** $(NH_4)_3ScF_6$, or $3NH_4F.ScF_3$, by treating a neutral or feebly acid soln. of a scandium salt with ammonium fluoride and evaporating the clear soln. in a platinum dish on a water-bath. The clear octahedral crystals are very soluble in water; the aq. soln. is not decomposed by boiling; hydrochloric acid precipitates scandium fluoride; and with dil. sulphuric acid, ammonium scandium sulphate is precipitated. It is assumed that the aq. soln. has the ions $3NH_4^{\cdot}$ and ScF_6''' because it does not give any precipitate—hot or cold—with ammonia; sodium or potassium hydroxide, however, does precipitate scandium hydroxide from hot soln. When freshly precipitated scandium fluoride dissolves in conc. soln. of the alkali fluorides; and, when conc., the soln. deposit crystals of the double fluorides. When a soln. of scandium chloride is treated with potassium fluoride, the liquid becomes turbid; the turbidity clears up on dilution or boiling. C. R. J. Sterba-Böhm found that on hydrolysis; $(NH_4)_3ScF_6 \rightarrow (NH_4)_2ScF_5 \rightarrow (NH_4)ScF_4$, the solubility decreases progressively as ammonium fluoride is removed. Clear octahedral crystals of **potassium fluoscandate,** K_3ScF_6, are obtained on evaporating the soln. The salt is less soluble than the ammonium salt in water; and it behaves like the ammonium salt with dil. acids, but when boiled with ammonia, scandium hydroxide is precipitated. The corresponding **sodium fluoscandate,** Na_3ScF_6, is less soluble than the potassium salt, for it dissolves but sparingly in hot water. The microscopic crystals are easily soluble in dil. acids.

R. J. Meyer and H. Winter prepared anhydrous **scandium chloride,** $ScCl_3$, by C. Matignon and F. Bourion's process, namely, by the action of a mixture of the vapour of sulphur chloride, S_2Cl_2, and chlorine on the heated oxide. The reaction begins about 500°, and is soon completed, and the chloride begins to sublime between 800° and 850°—rather higher than thorium chloride. W. Biltz and W. Klemm found that molten scandium chloride freezes at 939°, and that the electrical resistance runs from 3 ohms at about 933° to nearly 10 ohms at 935°, and on melting it rises abruptly becoming nearly 70 ohms at 950°. Scandium chloride is a white solid which deliquesces rapidly in air; and dissolves in water with a hissing sound, and the development of much heat; the aq. soln. reacts acid owing to hydrolysis. The hydrolysis is more marked than with lanthanum and yttrium. R. J. Meyer found the eq. conductivity rose with dilution. Thus, for soln. with a mol of scandium chloride in *v* litres of water at 25°:

v . . .	32	64	128	256	512	1024	$\lambda_{1024}-\lambda_{32}$
$\lambda(ScCl_3)$ . .	104·7	111·7	119·0	126·2	133·6	142·5	37·8
$\lambda(AlCl_3)$ . .	99·9	106·9	114·1	123·8	131·0	138·0	38·1

H. Ley found for the chlorides of the strongly basic earths—*e.g.* yttrium and cerium earths—a difference in the eq. conductivity of approximately $\lambda_{1024-32}=26$ units. This constant is fairly general for normally ionized and unhydrolyzed chlorides of the tervalent metals. Scandium chloride is considerably hydrolyzed in aq. soln. and it has a higher value, 37·8, than the normal one, 26, for $\lambda_{1024-32}$. Scandium chloride is insoluble in dry alcohol. When heated in air it forms an oxychloride which resists the action of acids and alkalies. P. T. Cleve obtained a mass of felted needle-like crystals by crystallization from a conc. soln. of the earth in hydrochloric acid. According to W. Crookes, the crystals can be dried by press. between filter-paper followed by a few hours in a desiccator—the composition corresponds with **hexahydrated scandium chloride,** $ScCl_3.6H_2O$. The crystals are deliquescent, but not so much as the nitrate; and they are readily soluble in alcohol. *When heated for 6 hrs. at 100°, water is given off, and the oily liquid solidifies to a* white crystalline mass of **sesquihydrated scandium chloride,** $2ScCl_3.3H_2O$; when heated to redness, water and hydrogen chloride are given off, and scandia, Sc_2O_3, remains.

R. J. Meyer failed to prepare double compounds of scandium chloride with sodium, potassium, ammonium, and rubidium chlorides in acid or alkaline soln., but he did make **cæsium chloroscandate,** probably Cs_3ScCl_6, which had so great a solubility that it was not obtained pure enough to justify analysis. The corresponding salts of praseodymium, neodymium, and samarium have the formula $Cs_3MCl_6.5H_2O$, and lanthanum, $Cs_3LaCl_6.4$ or $5H_2O$. Thorium forms two cæsium salts. In general, the tendency of the chlorides of the rare earths to form double salts is small; this is possibly due to the relatively strongly positive characteristics of the metals because the tendency to form double salts is most marked with the chlorides of the feebly positive metals—platinum, gold, bismuth, antimony, tin, etc. W. Crookes prepared a mass of felted yellow deliquescent needle-like crystals of **henicosihydrated auric chloroscandate,** $3ScCl_3.2AuCl_3.21H_2O$, by slowly evaporating over sulphuric acid in vacuo a mixture of conc. soln. of the component chlorides. When these crystals are allowed to stand about a fortnight in a desiccator over sulphuric acid, the weight rapidly diminishes, and remains constant when the composition corresponds with **octohydrated auric chloroscandate,** $3ScCl_3.2AuCl_3.8H_2O$; and when heated at 100°, for about six days, there are indications of an arrest in the rate of dehydration when the composition corresponds with **dihydrated auric chloroscandate,** $3ScCl_3.2AuCl_3.2H_2O$; but by continuously drying anhydrous **auric chloroscandate,** $3ScCl_3.2AuCl_3$, is finally obtained.

W. Crookes prepared deliquescent rhombic crystals of **hexahydrated scandium bromide,** $ScBr_2.6H_2O$, by evaporating on the water-bath a soln. of scandium hydroxde or carbonate in hydrobromic acid. When these crystals are heated in an air-bath to 120°, **sesquihydrated scandium bromide,** $2ScBr_3.3H_2O$, is formed. O. Hönigschmid obtained the bromide, $ScBr_3$, by heating a mixture of the oxide and carbon in a stream of bromine, and resubliming in vacuo. It sublimes above 1000°. Its sp. gr. is 3·910–3·913. It slightly attacks quartz at a high temperature: $4ScBr_3+3SiO_2=3SiBr_4+2Sc_2O_3$.

§ 6. Scandium Sulphide and Sulphate

F. Wirth[1] prepared **scandium sulphide,** Sc_2S_3, by heating scandium sulphate in hydrogen sulphide. The yellow solid is stable in air even at 100°, but it is decomposed by boiling water and by dil. acids with the evolution of hydrogen sulphide. L. F. Nilson, and P. T. Cleve made a soln. of **scandium sulphate,** $Sc_2(SO_4)_3$, by dissolving the oxide, hydroxide, or carbonate in dil. sulphuric acid. E. Wedekind and P. Hausknecht found the mol. magnetism to be $-62·5\times10^{-6}$. The ignited oxide dissolves with difficulty in the dil. acid, but readily in the conc. acid with the evolution of heat. Unlike most of the sulphates of the rare earths, P. T. Cleve showed that when a conc. soln. is heated, it does not deposit crystals, for it may be evaporated to a supersaturated syrup which L. F. Nilson found to deposit, on standing, globular aggregates of crystals of the *hexahydrate*, $Sc_2(SO_4)_3.6H_2O$. W. Crookes found 100 parts of a sat. soln., at 12°, contains 44·5 parts of the anhydrous salt. F. Wirth found that the pentahydrate is the stable phase in contact with the soln. at 25°, for he said that at this temp. 100 grms. of the sat. soln. contain 28·52 grms. of the anhydrous sulphate, and added that, unlike the rare earth sulphates, the solubility of scandium sulphate does not decrease with a rise of temp. The hexahydrate, said W. Crookes, is not deliquescent in the ordinary air of a room even in damp weather, but it effloresces in dry air, loses one mol of water, and forms the *pentahydrate*, $Sc_2(SO_4)_3.5H_2O$, which appears to be the most stable hydrate at ordinary temp. Scandium sulphate, said W. Crookes, is insoluble in alcohol so that the addition of alcohol renders turbid a conc. aq. soln. of scandium sulphate, and a heavy oily liquid separates out. This may be separated by filtration through paper moistened with alcohol, when the residue is left as a viscid liquid with the composition of the hexahydrate. The oily liquid becomes more viscid on exposure to air. When a mol of the hexahydrate is heated to 100° for 3 hrs., W. Crookes found that four mols of water are expelled and a *dihydrate* is formed; and when kept in a desiccator over conc. sulphuric acid for 170 hrs., two mols of water are expelled and a *tetrahydrate* is produced. W. Crookes found that a mol of the pentahydrate loses nearly five mols of water or about 20 per cent. at 150°; and at about 500°, it loses weight corresponding with a little more than the theoretical amount of water because a little basic sulphate is formed. At 250°, the hydrated sulphate loses all its water, and becomes anhydrous $Sc_2(SO_4)_3$. The anhydrous sulphate is obtained by evaporating the acid soln. of the sulphate to dryness so as to get rid of the excess of sulphuric acid. At dull redness, say 550°, W. Crookes said that a mol of the sulphate loses a mol of sulphur trioxide, forming **scandium oxysulphate,** $Sc_2O(SO_4)_2$. At a higher temp. all the sulphuric acid is expelled and white powdered scandia, Sc_2O_3, is formed. L. F. Nilson and O. Pettersson give 2·579 for the sp. gr., and 0·1639 for the sp. ht. between 0° and 100°. It is difficult to expel the last traces of sulphur trioxide by ignition, and therefore W. Crookes recommends moistening the ignited sulphate with water, adding a little ammonium carbonate, drying and igniting again. L. F. Nilson said that when the anhydrous sulphate is treated with water, a turbid liquid is produced. The anhydrous salt is hydrated very slowly with water before it dissolves. When heated with water, a clear soln. is produced.

F. Wirth found the solubility of scandium sulphate is at first increased and then diminished by the addition of sulphuric acid, thus:

Grms. H_2SO_4 per litre	0	24·5	49·0	121·5	243·3
Grms. $Sc_2(SO_4)_3$ in 100 grms. soln. . .	28·52	29·5	19·87	8·36	1·32
Solid phases . . .	$\underbrace{\hspace{6em}}_{Sc_2(SO_4)_3.5H_2O}$				$Sc_2(SO_4)_3.3H_2O$

The pentahydrate dissolves in sulphuric acid of sp. gr. 1·6, and crystals of an acid sulphate, **scandium trihydrosulphate,** $Sc_2(SO_4)_3.3H_2SO_4$, or **scandiumsulphuric acid,** $H_3Sc(SO_4)_3$, separate out. The scandium is slowly and incompletely precipitated from aq. soln. of the sulphate by the addition of oxalic acid, or sodium thiosulphate.

The eq. conductivity, λ, of the soln. is such that $\lambda_{1024}-\lambda_{32}$, is less than would be anticipated; thus contrasting scandium and aluminium sulphates for soln. containing a mol of the salt in v litres of water:

v . . .	32	64	128	256	512	1024	$\lambda_{1024}-\lambda_{32}$
$Sc_2(SO_4)_3$.	28·3	33·8	40·1	47·7	75·6	72·1	43·8
$Al_2(SO_4)_3$.	51·1	60·6	71·2	83·1	95·3	107·2	56·1

R. J. Meyer and co-workers assume that scandium sulphate is really the scandium salt, $Sc[Sc(SO_4)_3]$, of the complex acid $H_3Sc(SO_4)_3$, for in migration experiments, nothing abnormal occurs with scandium nitrate or chloride, but with the sulphate much scandium migrates to the anode. R. J. Meyer, and N. Drapier found that **sodium scandium sulphate,** $Sc_2(SO_4)_3.3Na_2SO_4.10H_2O$, or $Na_3Sc(SO_4)_3.5H_2O$, can be prepared only in the presence of a large excess of sulphuric acid. It is readily soluble in water, and, like sodium thorium sulphate, in a conc. soln. of sodium sulphate. L. F. Nilson, and P. T. Cleve prepared **potassium scandium sulphate,** $Sc_2(SO_4)_2.3K_2SO_4$, or $K_3Sc(SO_4)_3$, by adding an excess of a sat. soln. of potassium sulphate to one of scandium sulphate. He noted that the salt dissolves with difficulty even in boiling water, and not at all in a sat. soln. of potassium sulphate. He continued: "The composition of the double salt shows that scandium belongs to the group of gadolinite and cerite metals since all these metals give salts of the same typical composition." On the other hand, P. T. Cleve gave $Sc_2(SO_4)_3.2K_2SO_4$ for the composition of the double salt, and he said that the salt is soluble in a sat. soln. of potassium sulphate. W. Crookes' analyses of the salt agree with L. F. Nilson's results, and he found that for every 100 c.c. of a cold sat. soln. of potassium sulphate the eq. of 1·473 grms. of scandium sulphate remained in soln. R. J. Meyer and A. H. Winter made **ammonium scandium sulphate,** $Sc_2(SO_4)_3.3(NH_4)_2SO_4$, or $(NH_4)_3Sc(SO_4)_3$, like the potassium salt; and R. J. Meyer and co-workers found that when boiled with water the sparingly soluble double salt $Sc_2(SO_4)_3.2(NH_4)_2SO_4$ separated out. R. J. Meyer obtained **hydrazine scandium sulphate,** $Sc_2(SO_4)_3.3(N_2H_4)_2SO_4.H_2O$, in a similar manner, and found it to be fairly soluble in water.

§ 7. Scandium Carbonate, Nitrate, and Phosphate

According to W. Crookes,[1] **scandium carbonate,** $Sc_2(CO_3)_3.12H_2O$, is formed as a bulky white precipitate when a soluble carbonate is added to a soluble scandium salt. When air-dried it appears to be dodecahydrated. The salt is inclined to decompose, and when dried at 100°, it loses a little carbon dioxide. Scandium carbonate is very sparingly soluble in cold aq. soln. of sodium or ammonium carbonate, but readily soluble in hot soln. Since under the same circumstances yttrium carbonate is sparingly soluble, the difference can be utilized as a basis for the fractional separation of yttrium and scandium. When these soln. are boiled, crystalline precipitates of sparingly soluble **sodium scandium carbonate,** $Sc_2(CO_3)_3.4Na_2CO_3.6H_2O$, or **ammonium scandium carbonate,**

$2Sc_2(CO_3)_3.(NH_4)_2CO_3.6H_2O$, are formed. R. J. Meyer and H. Winter stated that these complex carbonates are less soluble in cold than in hot conc. soln. of alkali carbonate, showing that at a lower temp. more easily soluble double salts, possibly containing more water, are stable; the double carbonates dissolve in a large volume of cold water, but even in a 2 per cent. soln. the appearance of turbidity owing to hydrolysis can be observed after standing 16 hrs., and when the soln. are boiled, a basic carbonate or the hydroxide is precipitated.

P. T. Cleve, and W. Crookes prepared **scandium nitrate,** $Sc(NO_3)_3.4H_2O$. Scandium hydroxide easily dissolves in dil. nitric acid, and ignited scandia dissolves in the hot conc. acid. The acid soln. over sulphuric acid dries to a gummy mass in which groups of stellate crystals appear; while a neutral aq. soln. when conc. on the water-bath and cooled furnishes prismatic, colourless crystals of the tetrahydrate. The salt is very deliquescent, and readily dissolves in water and in alcohol. When heated scandium nitrate decomposes more readily than any of the rare earth nitrates; the crystals get pasty at 100°, but do not melt; in vacuo, at 100°, the crystals give off water, and frit together, without melting, forming the anhydrous salt, $Sc(NO_3)_3$. The dried crystals show signs of melting at 125°, but melt to an opaque white liquid at 150°.

The hydrated nitrate, gradually heated in a silica crucible, fuses and boils, becomes opaque and evolves much water. If the heating be stopped at the proper time, the anhydrous nitrate is left, the whole of the water having been driven off. On continuing the heat nitrous vapours come off and the liquid becomes clear and liquid like water. Increasing the heat turns the liquid brown and drives off more nitrous vapours, ebullition becomes sluggish, the fused mass gets white and opaque, and finally there remains a white residue of scandia. When partially decomposed by heat, and the molten mass extracted with hot water, and the soln. well boiled, a basic nitrate, **scandium hydroxynitrate,** $Sc(OH)(NO_3)_2.H_2O$, difficult to filter, is formed. When scandium nitrate is heated for 12 hrs. in a hot-air oven at 120°, **scandium oxynitrate,** $Sc_2O(NO_3)_4$, is formed. P. T. Cleve noted that a white gelatinous precipitate, presumably **scandium phosphate,** is formed when sodium phosphate is added to a soln. of a scandium salt.

CHAPTER XXXVIII

THE RARE EARTHS

§ 1. The Rare Earths

> La terre est une des quatre substances simples, qu'on nomme élémens ou principes primitifs, parcequ'elles sont en effet les plus simples de celles qui entrent dans la combinaison des corps composés.—P. J. Macquer.

As indicated in the first chapter, the term *earth* was in common use by the early chemists; and, up to near the end of the eighteenth century, the earths were considered to be elemental.[1] The different kinds of earth were regarded as mixtures of the elemental earth with calcareous, argillaceous, arenaceous, and other matters; lime thus becomes calcareous earth; clay, argillaceous matter; etc. The term was then gradually restricted to substances with alkaline qualities which do not melt or change when heated; do not effervesce with acids; and are almost insoluble in water. Thus, near the end of the eighteenth century J. W. Nicholson wrote:

> Chemists sometimes in a gross and inaccurate way call those substances earths which remain after the volatile products of distillation have arisen, and which are not soluble in water. This is not, however, sufficiently exact, though it is difficult to exhibit a good positive definition. Earths are bodies simple with respect to the present powers of chemical analysis, brittle, incombustible, infusible by the heat of furnaces, not soluble in many hundred times their weight of water, and destitute of that opaque brilliancy which characterizes metals. There are few earthy substances which may not be reduced by analysis to one of the five following primitive earths; the siliceous, argillaceous, calcareous, ponderous, and magnesian earths; or otherwise, taken substantively, they are called silex, clay, lime, barytes, and magnesia.

A. L. Lavoisier gave reasons for supposing that these earths are not themselves elements, but rather oxides of the elements. This was demonstrated by H. Davy in 1808. The term *alkaline earths* still persists for the oxides of calcium, strontium, and barium oxides derived from certain minerals. In 1794, J. Gadolin obtained yttria; and in 1804, M. H. Klaproth, and J. J. Berzelius and W. Hisinger independently obtained ceria from some comparatively scarce Swedish minerals. These products came to be called the **rare earths.**

A closer study of the rare earths first prepared has shown them to be remarkably complex, and the rare earth group now includes about sixteen elements, which have been generally recognized, and a number of others whose existence has not been satisfactorily established. The term "rare earth" is interpreted in different ways. For example, beryllia, thoria, zirconia, scandia, etc., are sometimes included with the rare earths, but the general tendency is to restrict the term to the sesquioxide components of the original ceria and yttria earths. Thoria and scandia, although closely associated with the rare earths, are often considered to be outside the group of rare earths proper. The rare earths thus comprise a curious group of basic oxides of elements which resemble one another so very closely that they appear to form a series of compounds with properties which change but slightly in passing from member to member. In many of their reactions they resemble aluminium and chromium, in others they resemble bismuth, and the alkaline earths. The group of rare earths is easily isolated, along with thoria and scandia, by adding oxalic acid to the sulphuric acid soln. remaining after the removal of the elements whose sulphides are precipitated by hydrogen sulphide. According to G. Urbain, the precipitate containing the oxalates of the rare earths is then separated into three main groups according to the solubility of their complex salts in a sat. soln. of potassium sulphate. Thus:

TABLE I.—SUB-GROUPS OF THE RARE EARTHS.

Insoluble oxalate (**Rare earth**)	Insoluble potassium sulphates (**Cerium family**)		(Thorium, Th) (Scandium, Sc) Lanthanum, La Cerium, Ce Praseodymium, Pr Neodymium, Nd Samarium, Sa
	Moderately soluble K sulphates (**Terbium family**)		Europium, Eu Gadolinium, Gd Terbium, Tb
	Readily soluble K sulphates (**Yttrium family**)	**Erbium family**	Dysprosium, Dy Holmium, Ho Erbium, Er Thulium, Tm
		Ytterbium family	Yttrium, Y Ytterbium, Yb Lutecium, Lu

The separation of the group into these families is not so clean and sharply defined as can usually be obtained with other elements; because, added W. Crookes, as ordinarily understood **insolubility is a fiction,** and separation by precipitants is impossible. With our present knowledge it is extraordinarily difficult and in some cases impossible to separate the members of these series one from the other, and there is even the uncomfortable uncertainty that some of the so-called elements are not really homogeneous chemical individuals. The rare earths are in many cases so closely related that they can be separated into parts which give evidence of chemical individuality only by very special and laborious methods. The fractionation of the rare earths is described later.

In 1886, W. Crookes argued very ingeniously that the closeness of the relationship between the metals of the rare earths makes it probable that these elements are modifications of one common element. For example, by a laborious process of fractionation, W. Crookes subdivided yttria into some eight components with different phosphorescent spectra, but the difference in the *chemical properties* of the fractions was so slight that, if it were not for a slight difference in the solubilities of the different fractions in ammonia, they could not have been separated from one another. W. Crookes points out that the original yttrium passes muster as an element. It has a definite at. wt., it enters into combination with other elements, and it can be separated from them as a whole; but, the searching process of fractionation sorts the atoms of yttrium into groups with different phosphorescent spectra, and presumably with different at. wt., though, from the usual chemical point of view, all the groups behave alike. W. Crookes added: "Here, then, is a so-called element whose spectrum does not emanate equally from all its atoms; but some atoms furnish some, other atoms others, of the lines and bands of the compound spectrum of the element. Hence, the atoms of this element differ probably in weight, and certainly in the internal motions they undergo. Assuming that the principle is of general application to all the elements, and is limited only by our knowledge of tests delicate enough to recognize the simpler constituent groups of the different elements, it is inferred that there are definite differences in the internal motions of the several groups of the atoms of these chemical elements. The seven series of bands in the absorption spectrum of iodine, for instance, may prove not to emanate from every molecule, but "some of these molecules may emit some of the series, others others, and in the jumble of all these molecules, to which is given the name 'iodine vapour,' the whole seven series are contributors." W. Crookes thus introduced the conception of what he called **meta-elements** for those fractional parts of an element which resemble one another much more closely than one ordinary element resembles any other. The properties of the ordinary elements are supposed to be an average of the properties of aggregates of several meta-elements. The hypothesis did not survive a closer study of the cathodic phosphorescent spectra (*vide infra*), but was resuscitated as the so-called theory of isotopic elements (**4**. 25, 9).

The following monographs deal with the rare earths: C. R. Böhm, *Die Verwendung der seltenen Erden*, Leipzig, 1913; *Die Darstellung der seltenen Erden*, Leipzig, 1905; *Die Fabrikation der Glühkörper für Gasglühlicht*, Halle a. S., 1910; S. J. § 2. The History of the Rare Earths

The false may be true through ignorance, and the true may be false in the light of new knowledge.—C. BASKERVILLE.

Sein und das nicht Sein sind nämliche.—G. W. F. HEGEL.

In 1752, A. J. Cronstedt[1] described a new mineral—*ferrum calciforme, terra quadam incognita intime mixtum*—which he found associated with copper pyrites in a quarry near Ryddarhyttan, Sweden; he called the mineral *Tungstein*, or heavy stone. C. W. Scheele examined a specimen of J. C. Wallerius' *lapides stanniferi spathacei*, or Tennspath, *i.e.* heavy stone, from Bohemia, and found it contained lime and tungstic oxide. A. J. Cronstedt's tungstein did not contain tungstic oxide, and it was regarded as a false variety of tungstein. T. Bergman (1780), and J. J. y Don Fausto d'Elhuyar (1784) showed that the two minerals are distinct, and that while the Bohemian mineral is a calcium tungstate, scheelite, the Ryddarhyttan mineral, is a silicate of calcium and iron. The analysis of M. H. Klaproth, who called the mineral *ochroite*, and J. J. Berzelius and W. Hisinger, who called it *cerite*, showed that T. Bergman, and J. J. y Don Fausto d'Elhuyar had mistaken the rare earths for lime.

In 1794, J. Gadolin[2] discovered the first of the rare earths in a heavy black mineral which had been found at Ytterby. He obtained about 38 per cent. of the new oxide from the mineral, and noted that it resembled in some ways calcium oxide and in other ways alumina. J. Gadolin proposed to call the oxide *ytterbia*, and the mineral *ytterbite*. A. G. Ekeberg (1797) verified J. Gadolin's observations and proposed to call the earth **yttria**, after the locality Ytterby, where the mineral was found, and the mineral from which ytterbia was obtained was termed *yttria-stone*, but later, the name was changed to *gadolinite*, after J. Gadolin ; a few years later, he discovered tantalum in a sample of yttria-stone, and hence named it *yttrotantalite*. The discovery of yttria was confirmed by M. H. Klaproth and L. N. Vauquelin, who analyzed gadolinite and described some properties of yttria. Both J. J. Berzelius, and N. J. Berlin studied yttria, and they considered it to be homogeneous, and a chemical individual ; but T. Scheerer noticed that when yttria was heated in an open vessel, it became yellow ; and when re-heated in a reducing atm., the yellow colour disappeared. He therefore inferred that yttria contains another earth which forms a yellow powder when heated in air. In 1842, in a paper entitled *Nagot om Cer och Lanthan*, C. G. Mosander described how by the fractional precipitation of the oxalates by oxalic acid from acid soln., and of the hydroxides by dil. aq. ammonia, the old yttria could be separated into three new earths. In both processes, erbia separated first, terbia next, and yttria last. He called the most basic one **yttria** ; the least basic one **erbia** ; and the intermediate one **terbia.** The names erbia and terbia were formed from the letters of the word Ytterby, the name of the locality where gadolinite was found. Yttria was white and gave colourless salts ; erbia was orange-yellow and gave colourless salts ; while terbia was white and gave rose-coloured salts. C. G. Mosander's results were confirmed by several other chemists--J. J. Berzelius, L. Svanberg, and T. Scheerer. The fractional decomposition of yttrium nitrate by heat furnished N. J. Berlin two of C. G. Mosander's earths—white yttria, and white terbia. J. J. Berzelius and subsequent writers called C. G. Mosander's terbia, erbia. He could not find C. G. Mosander's erbia, now called terbia. O. Popp in 1864 repeated the work, and failed to find either erbia or terbia, and he suggested that the so-called erbia is a mixture of cerite earths, and terbia a mixture of erbia and yttria. M. Delafontaine, however, maintained that both C. G. Mosander's erbia and terbia were chemical individuals, and he obtained the former by fractional precipitation with potassium oxalate and removed the yttria and terbia with potassium sulphate ; the remaining terbia and yttria were separated by fractionating the oxalates and dissolving out the yttria by repeated treatment with dil. acids. In 1866, J. F. Bahr and R. Bunsen, and in 1872, P. T. Cleve and M. Höglund, corroborated N. J. Berlin's observations, and succeeded in preparing white yttria, and N. J. Berlin's erbia, *i.e.* C. G. Mosander's terbia. N. J. Berlin, O. Popp, J. F. Bahr and R. Bunsen, and P. T. Cleve and M. Höglund failed to get terbia, *i.e.* C. G. Mosander's erbia. The doubts as to the existence of terbia were removed when M. Delafontaine, and J. C. G. de Marignac each succeeded in preparing specimens. In 1905, G. Urbain prepared terbia of a high degree of purity ; and C. James, G. Urbain, and K. A. Hofmann have prepared moderately pure erbia.

M. Delafontaine treated a soln. of yttria with a sat. soln. of sodium sulphate containing crystals of the salt, and fractionated the nitric acid soln. of the precipitate as oxalate ; the first fractions were treated with formic acid when crystals of terbium formate separated from the conc. soln. The portion soluble in the sodium sulphate soln. contained an earth not so deeply coloured as terbia, and it also gave a base of lower mol. wt. It was therefore concluded that a new element was present which was named *philippium*—at. wt. 121 to 123 ; and characterized by an absorption band in the violet, $\lambda=450$. The existence of M. Delafontaine's philippium was disputed. J. L. Soret considered it to be identical with an *earth-X*, which he regarded as the source of a series of absorption bands in his examination of the spectrum of J. C. G. de Marignac's terbia and erbia preparations. M. Delafontaine maintained his philippium to be identical with P. T. Cleve's holmia, and J. L. Soret's earth-X, but P. T. Cleve denied this. H. E. Roscoe fractionated the sulphates of terbia with potassium sulphate and refractionated the first portions with formic acid, but obtained nothing more than a mixture of yttria and terbia. W. Crookes also denied the individuality of philippia. M. Delafontaine indicated methods by which he considered philippia could be obtained, but G. Urbain showed that M. Delafontaine was mistaken.

J. C. G. de Marignac fractionated the nitrates from yttria earth, and obtained yttria at one end of the series and erbia at the other. K. A. Hofmann and G. Krüss also fractionally precipitated a soln. of terbia with aniline hydrochloride and obtained what appeared to be two new earths with elements of at. wt. 148–150, and 160 on the assumption that they were tervalent. They also showed that erbia is complex when fractionated with aniline hydrochloride. G. Krüss also doubted the individuality of erbia; for, by fractionating an alcoholic soln. with aniline, and treating the middle portions with ammonia, he could not obtain an earth with a constant mol. wt. J. F. Bahr discovered the beautiful spectrum of erbia, and W. Crookes mapped the spectral lines. In 1886, L. de Boisbaudran showed that after terbia had been freed from gadolinia and dysprosia, it still appeared complex on fractionation. In 1895, L. de Boisbaudran called attention to an absorption band $\lambda=4877$ in his preparation of terbia; he could not assign this band to any known element, and he provisionally assumed the existence of a new element which he termed Z_δ. W. Crookes found characteristic phosphorescent spectra in the ultraviolet in terbia, and he attributed the results to the presence of two new rare earth elements which he named *incognitum* and *ionium*. C. A. von Welsbach expressed the view that terbia is a complex with at least three different components; C. James and D. W. Bissel fractionated terbia by the bromate process, and found it to be homogeneous—a chemical individual.

J. C. G. de Marignac tried to isolate M. Delafontaine's philippia by the fractionation of the nitrates, and he isolated a colourless earth which he called **ytterbia.** It had no absorption spectrum, and assuming the element to be tervalent, its at. wt. was 172. The spark spectrum of ytterbia was studied by R. Thalen and by L. de Boisbaudran. L. F. Nilson verified the existence of ytterbia, and gave 173 for the at. wt. In 1907 G. Urbain, and in 1908 C. A. von Welsbach independently found ytterbium is really complex. The latter termed the components aldebaranium and cassiopöium; the former, **neoytterbium** and **lutecium.** The latter terms have been adopted by the International Committee on at. wt. C. A. von Welsbach also expressed the opinion that ytterbia contains yet a third element characterized by lines which are not present either in neoytterbium or lutecium; and G. Urbain, in 1911, announced that the lutecium which he obtained by the fractional crystallization of the nitrates from gadolinite furnishes another earth which he named **celtium,** and which is characterized by its arc spectrum and low magnetic susceptibility, but all the evidence adduced proved to be worthless. In the spring of 1922, A. Dauvillier found that a trace of an element with an X-ray spectrum corresponding with that of an unknown element, No. 72 in the periodic table, was contained in these residues, and it was proposed to call it by the very name previously employed for an element which did not exist—*vide* hafnium. J. M. Eder found that two fractions from C. A. von Welsbach's preparations of aldebaranium, showed lines characteristic of two elements which he named *denebium* and *dubhium*.

During his work on ytterbia, L. F. Nilson obtained a white oxide with a lower eq. wt. than ytterbia, and, suspecting the presence of a new element, he isolated an earth which he named **scandia.** The at. wt. of the element, 44, and the properties of the compound corresponded with those predicted by D. I. Mendeléeff for ekaboron. P. T. Cleve verified the individuality of scandium, and placed the at. wt. a little higher than L. F. Nilson. The spark spectrum of scandium was studied by R. Thalen.

P. T. Cleve showed that the fractional crystallization of J. C. G. de Marignac's erbia and terbia materials furnished three earths each of which is characterized by an absorption spectrum; and each spectrum is a portion of that which had been ascribed to erbia. The corresponding elements were called erbium, at. wt. about 166; and **holmium** and **thulium,** with at. wt. between 170 and 171. J. L. Soret, and P. T. Cleve believed that the earth-X was identical with holmia, and M. Delafontaine, that his philippia was identical with both holmia and the earth-X; but P. T. Cleve showed that holmia gave an absorption spectrum while philippia gave none. L. de Boisbaudran fractionated holmia and resolved it into two portions—one had absorption bands $\lambda=640{\cdot}4$ and $\lambda=536{\cdot}3$, while the other had absorption bands $\lambda=451{\cdot}5$ and

$\lambda=753{\cdot}0$. The first two bands were those attributed by P. T. Cleve, and J. L. Soret to holmia, and hence the same name was reserved for this fraction. The other bands were attributed to a new earth which was named dysprosia. In 1906, G. Urbain obtained dysprosia of a high degree of purity. W. Crookes stated that he had isolated an earth with an absorption band $\lambda=451{\cdot}0$, and therefore inferred that dysprosia is itself complex. L. de Boisbaudran agreed with this conclusion. G. Krüss and L. F. Nilson found that the absorption spectra of thulia indicates that the earth is a complex of two components; dysprosia, three; and holmia, four. K. A. Hofmann and G. Krüss also concluded that holmia is a complex earth. In 1911, O. Holmberg obtained holmia of a high degree of purity. The absorption and spark spectrum of thulia has been studied by R. Thalen. In 1911, C. James obtained thulia of a high degree of purity.

L. de Boisbaudran examined the spark spectra of soln. of terbia, and he concluded that two bands, at $\lambda=573{\cdot}0$ and $\lambda=543{\cdot}2$, are caused by two elements which he called respectively Z_α, and Z_β, and later, another band corresponding with a third element, Z_γ. Soln. of yttria showed no such spectrum. By the method of fractional precipitation with ammonia, W. Crookes claimed to have separated the original yttria into nine new earths or oxides of what he called meta-elements, for he showed that all the nine differed from each other and from the original earth. He provisionally posited these supposed elements:

$$S\gamma,\ G\alpha,\ G\beta,\ G\gamma,\ G\delta,\ G\epsilon,\ S\delta,\ G\zeta,\ G\eta.$$

Some, not all, of these earths when sealed up in exhausted tubes and subjected to the induction discharge, phosphoresce. Their phosphorescent spectra are to a certain extent different, and this the more the further the earths were removed from one another in respect of their basicity. The extreme fractions showed considerable differences in their phosphorescent spectra, but the only chemical property in which they appear to differ is a slight difference of basicity among themselves. There are no perceptible differences in the at. wt. of the fractionated earths; spark-spectra of the original yttria, the earth $G\eta$ and the earth $G\delta$ were exactly the same. G. Krüss and L. F. Nilson assumed that each absorption band in the spectrum of a rare earth corresponds with a different element, and hence inferred that the absorption bands of erbia, holmia, didymia, samaria, and thulia showed that these earths are really composed of twenty different elements. There is, however, no foundation for the assumption. W. Crookes made the extraordinary suggestion that only the lines due to the impurity could be observed in the spectrum of an earth and none due to the earth itself. He said:

> The nine earths are chemical elements differing in basic powers and several other chemical and physical properties, but not sufficiently to enable us to effect any but a partial separation. Thus, $G\delta$, for instance, gives a certain spectrum under the influence of the electric spark; the other earths, $G\epsilon$, $G\eta$, . . . are contaminated with a certain quantity of this $G\delta$; and so the spectra of those other earths $G\epsilon$, $G\eta$ . . . is that of $G\delta$ and $G\delta$ only, they themselves presumably not having any spectra at all, or what they do have is masked by the greater intensity of that of $G\delta$.

W. Crookes then argued that the fractionated earths are to be regarded as isomorphous bodies composed of the same atoms arranged in different ways within the molecule. He said:

> Elements are not so simple as we suppose. Our notions of a chemical element have expanded. Hitherto the molecule has been regarded as an aggregate of two or more atoms, and no account has been taken of the architectural design on which the atoms have been joined. We may consider that the structure of a chemical element is more complicated than has hitherto been supposed. Between the molecules we are accustomed to deal with in chemical reactions, and ultimate atoms as first created, come smaller molecules or aggregates of physical atoms; these submolecules differ one from the other according to the position they occupy in the yttrium edifice. We may consider them similar to the carbon atoms in the benzene ring which have the impress of their position, 1, 2, 3, 4, 5, stamped on them.

The sole ground upon which this argument is based is the difference in the phosphorescent spectra of the fractionated earth. Although W. Crookes stated that the

more this method is used the more reliable it appears, yet he also showed that a bright orange line λ=269·3 is found in the spectrum of a mixture of samaria and yttria earths which has been treated with sulphuric acid and ignited. If the two earths are mechanically mixed without the acid treatment, no orange line is obtained; nor is the orange line obtained either with the earth alone, or with either earth mixed with but a small proportion of the other. As H. M. Vernon showed, this makes it appear as if the bright orange line is due to a combination of the two earths in agreement with the fact that the spectra of salts which are not decomposed into their constituents by heat are often very different from the spectra of the constituent elements. Hence also it follows as an alternative to W. Crookes' hypothesis that the phosphorescent spectra of the Crookes' nine earths G_α, G_β, . . . are produced by combinations of two or three simple earths. This view is further supported by W. Crookes' observation that when his new earths are mixed with varying proportions of lime or baryta and ignited, different phosphorescent spectra are again obtained. The nature of the spectrum is dependent on the nature and proportion of the admixed base. W. Crookes has emphasized the fact that the merest trace of a certain earth, unable to be detected by chemical means, can cause great variations in the spectrum of another earth. He said:

> One important lesson taught by the many anomalies unearthed in these researches is that inferences drawn from spectrum analysis *per se* are liable to grave doubt, unless at every step the spectroscopist goes hand in hand with the chemist. Spectroscopy may give valuable indications, but chemistry must after all be the final court of appeal.

The argument that an element can be decomposed into meta-elements by fractional precipitation is based on the power of phosphorescent spectra to distinguish between the unequivocally different elemental forms of matter. The spectral evidence, however, is considerably weakened by the fact that the spectrum of an earth can be greatly altered by admixture or combination with another earth. The difficulty is enhanced by the fact that it is almost if not quite impossible to obtain by fractionation, earths which are quite free from other earths present as impurities, and this the more because the earth under consideration may have properties very like those of half a dozen other earths. There is a large number of these earths with very similar properties, and the resemblance is the closer the larger the at. wt. of the elements under consideration. The fact that yttria obtained from different minerals gave phosphorescent spectra of varying intensity was taken by W. Crookes to mean that a partial separation had occurred in nature. L. de Boisbaudran, and E. Demarçay also opposed W. Crookes' hypothesis and conclusions. The former showed that pure yttria gave no phosphorescent phenomena; and the fluorescent bands obtained by W. Crookes were attributed to the presence of foreign earths—Z_α and Z_β, in fact—very difficult to remove from yttria. W. Muthmann and E. Baur, E. Baur and R. Marc, G. H. Bailey, P. Schottländer, etc., showed that the intensity and nature of the phosphorescent spectrum and absorption bands can be varied in a marked way by the addition of traces of foreign substances; and G. Urbain demonstrated that the phosphorescent spectrum of varying mixtures of gadolinium and terbium sulphates contain the very bands which W. Crookes attributed to meta-elements G_α, G_β, *ionium* and *incognitum*.

In 1896, P. Barrière announced the existence of a new metal which he named *lucium*. The earth from which it was derived occurred in the yttria earths separated from monazite. The at. wt. 104 was assigned to it. W. Crookes, however, showed that lucia is really yttria mixed with didymia, erbia, and terbia. This was confirmed by W. Shapleigh, who found that a sample of lucia contained 94 per cent. of yttria earths, 3·7 per cent. of ceria earths, 1·1 per cent. of thoria, and 1·2 per cent. of other oxides. P. Schützenberger and O. Boudouard fractionated yttria earths from monazite sands, and at the lower limit of fractionation they obtained an earth with a tervalent metal of at. wt. 95 to 102. G. P. Drossbach also obtained a similar earth from monazite, and E. Boudischowsky fractionated the yttria earths with acetyl acetone, and also obtained a lower limit. G. Urbain showed that by fractionation with ethyl sulphate this hypothetical earth could be resolved into terbia, at. wt. 151·4, at one end, and yttria, at. wt. 89, at the other; he then concluded that the hypothetical earth is principally yttria mixed with some erbia and terbia. The separation of a base with a constant mol. wt. as the lower limit of a series of fractions is a phenomenon which does not establish the existence of a new element, for A. E. Nordenskjöld made a rare earth mixture which he knew contained yttria, erbia, and terbia, and yet, under these conditions, gave a constant at. wt. 107. In 1898, W. Crookes announced the existence of a new element which he called *monium*, as a result of fractionating the yttria earths. The principal lines in the spectrum were λ=3120 and 3117. W. Crookes later changed the name to *victorium*, at. wt. 117. G. Urbain showed that the spectrum and at. wt. of a mixture of 58 parts of yttria and 226 parts of gadolinia is the same as that of W. Crookes' victorium. E. Baur and R. Marc came to a similar conclusion.

In 1803, soon after the discovery of yttria in 1794, M. H. Klaproth, and J. J. Berzelius and W. Hisinger simultaneously found another new earth, termed **ceria,** in the minerals cerite, and tungstein or ochröite. Ceria resembled yttria in many respects, but unlike yttria was insoluble in ammonium carbonate, and acquired a light brown colour on ignition, and hence M. H. Klaproth suggested the name *ochroite* for the earth. In 1814, J. J. Berzelius showed that yttria derived from orthite contained considerable quantities of ceria. B. Brauner expressed the belief that what is now recognized as ceria is mixed with another element which he termed *metaceria*. The former is white, the latter rose-brown. G. P. Drossbach could not confirm the existence of metacerium; nor did B. Brauner mention its existence in his later work. P. Schützenberger and O. Boudouard doubted the individuality of ceria, but G. Wyrouboff and A. Verneuil showed that they worked with impure specimens. In 1817, J. J. Berzelius isolated an earth which he called *thorine*, but in 1824, he showed that thorine is a phosphate of impure yttria. In 1828, J. J. Berzelius isolated the **thoria** from the mineral thorite; and in 1851, C. Bergemann, after extracting thoria from the mineral orangeite, obtained a fraction which he stated contained an unknown element to which he gave the name *donarium*. A. Damour, N. J. Berlin, and M. Delafontaine stated that donarium is really a mixture of thorium, lead, and uranium, and about the same time C. Bergemann was convinced that his report was premature.

In 1839, C. G. Mosander showed that ceria is really a complex earth. He was able to separate from it a white earth, **lanthana,** and later he obtained *didymia* from the same source. The means of detecting the element didymium found by C. G. Mosander (1842) in ceria and lanthana, were so imperfect that R. Hermann argued against its very existence. J. H. Gladstone, however, demonstrated that soln. of its salts possess a peculiar absorption spectrum; and this was soon followed by the application of the spectroscope to detecting small quantities of the rare earths and guided chemists in the better purification of ceria, lanthana, and yttria. J. H. Gladstone mentioned two absorption bands; O. L. Erdmann, seven; O. N. Rood, twelve; and J. F. Bahr and R. Bunsen, eleven. L. de Boisbaudran showed that some of the bands formerly attributed to didymium really belonged to samarium. G. Krüss and L. F. Nilson in a paper: *Was bedeutet Dym?* showed that didymia derived from different localities gave an absorption spectrum with bands of varying intensity, and hence concluded that the so-called didymium is probably complex; and P. T. Cleve, C. M. Thompson, and H. Becquerel came to a similar conclusion. In 1882, B. Brauner also expressed the opinion that didymia, from which all known earths have been removed, is a mixture, and in 1885 C. A. von Welsbach discovered that didymium when freed from samarium is a mixture of two elements which he named *praseodidymium* and *neodidymium*, terms which were soon abbreviated to **praseodymium** and **neodymium.** The salts of the former were green, and of the latter, rose-red. G. Krüss and L. F. Nilson examined praseodymia and neodymia spectroscopically, and concluded that at least eight elements are present; C. M. Thompson also assumed that at least five elements are present. W. Crookes added: Neodymium and praseodymium are not to be considered to be the names of actual elements, but rather the names of complex groups of molecules with which the complex molecule didymium splits up by one particular method of fractionation; other methods of fractionation would probably split didymium into different products. W. Muthmann and L. Stützel, and C. R. Böhm denied the elementary nature of praseodymium. No confirmation of the complexity of praseodymia has been obtained, although K. von Chrustchoff claimed to have obtained a third constituent which he called *glaucodidymia* or *glaucodymia*, and which furnished blue salts.

While analyzing the rare earth mineral samarskite, from North Carolina, J. L. Smith isolated an earth which he called *mosandra*; he considered the earth to be new because of the insolubility of its double potassium sulphate in a sat. soln. of potassium sulphate. J. C. G. de Marignac showed that solubility is only a relative quality, and considered mosandra to be identical with terbia; this view was shared by M. Delafontaine. Some years later, L. de Boisbaudran found a sample of mosandra to contain didymia, samaria, gadolinia, and terbia. In 1878, M. Delafontaine described a new oxide *decipia* which he had extracted from impure didymia derived from samarskite. The element, assumed tervalent, was stated to have an at. wt. 159, and to be characterized by absorption bands $\lambda=416{\cdot}0$ and $478{\cdot}0$. L. de Boisbaudran observed some new lines in the spectrum of impure didymia from samarskite. The absorption spectrum showed two strong bands in the blue—$\lambda=4800$ and 4635—and three faint ones, one of which coincided with $\lambda=416$ of M. Delafontaine's decipia. Finally, he separated from decipia a new earth which he called **samaria,** and which exhibited three of these absorption bands. Meanwhile, in 1880, J. C. G. de Marignac isolated two new earths from samarskite, one he called γ_α and the other γ_β. The mixed earths were fractionated by partial decomposition of the nitrates, and by precipitation with a sat. soln. of potassium sulphate. The three fractions were (i) soluble in less than 100 vols. of the potassium sulphate soln.; (ii) soluble in 100 to 200 vols. of potassium sulphate soln.; and (iii) still less soluble. The fraction (i) was termed γ_α, and fraction (iii), γ_β. J. L. Soret showed that spectroscopically γ_β and samaria are identical, and that decipia resembles neither γ_β nor γ_α, but was probably a mixture of both γ_α and γ_β. The residue remaining after the separation of samaria from decipia was found to be a mixture of γ_α and samaria. In his memoir: *Sur les terres de la samarskite,* J. C. G. de Marignac, speaking of γ_α, said:

> L'existence de cette base comme terre distincte est rendue évidente par le fait que son équivalent est un maximum entre celles qui l'avoisinent par leur solubilité dans le sulfate de potasse. . . . Elle ne saurait être confondue avec aucune de celles qui ont été signalées jusqu'ici.

In 1886, L. de Boisbaudran obtained a purified form of γ_α, and named it **gadolinia.** In 1905, G. Urbain obtained gadolinia of a high degree of purity. Thus did decipia disappear from the list of rare earths. Still further, W. Crookes showed that J. C. G. de Marignac's earth, provisionally named γ_α, possessed a spectrum analogous to that of a mixture of samaria 39, and yttria 61, which had been ignited with sulphuric acid, except that a citron band present in the artificial mixture is absent from the spectrum of the γ_α earth. Hence, added W. Crookes:

> The earth γ_α is shown to consist of samaria with the greenish-blue band of yttria, and some of the other yttria bands added to it. It proves further that the citron band, which was hitherto regarded as one of the essential bands of the yttria spectrum can be entirely removed, whilst another characteristic yttrium group, the green double band, can remain with heightened brilliancy. If, now, it were possible to remove the citron-band-forming body from this mixture, the earth γ_α would be left behind; in fact, the earth γ_α would have been recomposed from its elements.

Consequently, as H. M. Vernon has pointed out, the spectral test is unreliable, whether the earth γ_α is identical with or distinct from the yttria-samaria earth.

L. de Boisbaudran did not accept W. Crookes' conclusion. A. Bettendorff separated gadolinia from samaria, but could get it to yield no spark spectrum. The spectra assigned by W. Crookes to the meta-elements, G_α, G_β, and G_ζ, are duplicated by mixtures of terbium and gadolinium. E. Demarçay reported four elements were revealed by the spectroscopic examination of gadolinia, terbia, erbia, and yttria earths; these elements were provisionally designated Γ, Δ, Ω, and Θ. The spark spectrum of the brown oxide obtained from the most soluble portions of *dêjà assez pur* gadolinium magnesium nitrate furnished the lines λ=3704·3, 3703·2, 3676·7, 3568·4, 3561·7, 3540·2, 3523·4, 3508·5, which possibly belong to pure terbium, but since the purity of the material used was indeterminate, they are attributed provisionally to an element denoted by Γ. In some less coloured oxides, the following lines were observed, possibly belonging to the earth Z_γ of L. de Boisbaudran: 4212·6, 4195·5, 4187·3, 3978·6, 3945·0, 3595·0, 3550·0, 3531·3. The element producing these lines is denoted by Δ. In some yttrium, containing fractions intermediate in solubility between holmium and erbium, two intense lines, 3967·9 and 3930·9, were recorded, belonging to the hypothetical element Ω. In the spectra of the slightly basic earths, intermediate between erbium and ytterbium, the two lines 4008·2 and 3906·5 are very intense; these are attributed to an element Θ.

In 1883, P. T. Cleve made an extended examination of samarium. He considered it to be a chemical individual, and described many of the salts. Three years afterwards E. Demarçay separated a new element from P. T. Cleve's samaria, and designated it S_1. A. Bettendorff could not confirm E. Demarçay's result, but in 1892, L. de Boisbaudran found that samaria is really complex, for, when fractioned with ammonia, the least basic fractions differed from the other fractions in showing a spark spectrum with three new blue lines, and a *reversion spectrum* with a new band between λ=6110 and 4593.

In the reversion spectrum, an induction spark is taken between the surfaces of a conc. acid soln. of the chloride and a clean platinum wire a few millimetres apart. The wire is kept negative, the soln. positive. A thin fluorescent light appears at the surface of the liquid. This layer gives a spectrum of nebulous bands. L. de Boisbaudran called such spectra *les spectres de renversement* because the direction of the spark is the reverse of that commonly employed.

He attributed the new spark lines to an element which he provisionally called Z_ϵ, and the band likewise to an element Z_ζ. He expressed no opinion as to the identity of the two elements. In 1893, he showed that Z_ζ is closely related with W. Crookes' S_δ, which exhibited an anomalous band in the phosphorescent spectrum of the rare earths. In 1896, E. Demarçay fractionally crystallized samarium nitrate, and obtained a new earth which he designated Σ, in addition to gadolinia and samaria. The third component was readily soluble in nitric acid, its double potassium sulphate was readily soluble, and the base was feebly basic. C. Benedicks could find no signs of E. Demarçay's Σ. In 1906, E. Demarçay fractionally crystallized the double magnesium nitrate, and obtained the new earth fairly pure. He identified it with the $S\delta$ of W. Crookes and the Z_ϵ and $Z\zeta$ of L. de Boisbaudran, all of which were shown to be the same earth which was called **europia.** In 1917, J. M. Eder considered that the spectra of fractions of samaria show the presence of another element which he named *eurosamarium*; and four years later, he gave spectroscopic evidence of a new element lying between terbium and dysprosium, and named it *welsium* in honour of C. A. von Welsbach.

In addition to thorine, donarium, mosandrum, philippium, decipium, lucium, victorium or monium, incognitium, and ionium, many other elements have been reported, but when tested have been found wanting; there are others—metacerium, glaucodymium, E. Demarçay's Ω and Θ, denebium, dubhium, eurosamarium—which have been reported, but whose claims have not been established. Lists have been compiled by F. P. Venable, C. Winkler, P. T. Cleve, H. C. Bolton, and C. Baskerville.

In 1811, T. Thomson prepared what he called *junonium* from the mineral allanite, but T. Scheerer and T. Thomson himself later showed that the report was based on an error in the analytical work. L. W. Gilbert, in 1818, announced *vestium* or *sirium*. E. Linnemann, in 1886, announced *austrium* in orthite, but L. de Boisbaudran, and R. Pribram showed it to be impure gallium. J. F. Bahr, in 1862, obtained what he called *wasmium* from orthite and gadolinite, but M. Delafontaine, H. P. Stevens, and O. Popp regarded it as impure cerium; J. Nicklès, as mixture of yttria, terbia, and didymia; and J. F. Bahr himself later identified wasmium with thorium. J. L. Smith, in 1884, reported two new elements in samarskite, these he called *columbium* (not niobium) and *rogerium*. K. von Chrustchoff, in 1887, detected spectroscopically what he thought to be a new element in monazite, etc.; he called it *russium*, this was later regarded as being similar to P. Barrière's lucium—*vide supra* —L. Wenghöffer said it is a mixture of thorium and cerium. K. Lauer and P. Antsch, in 1890, announced *damarium*; and H. D. Richmond and H. Off, in 1892, *masrium* in a fibrous alum from Egypt. C. Baskerville, in 1901, reported two radioactive elements, *carolinium* and *berzelium*, in thorium; K. A. Hofmann and W. A. A. Prandtl, in 1901, *euxenium*, in Norwegian euxenite; but O. Hauser and F. Wirth failed to find any signs of the new element in any of the known zirconia minerals. B. Kosmann, in 1896, announced two new elements, *kosmium* and *neokosmium*, which C. Winkler found to resemble lucium. The use of the last two mythical elements for gas-mantles was patented. F. Exner and E. Haschek announced the existence of a new element *E* with a definite spectrum; but J. M. Eder showed that the spectrum was produced by the blending of the gadolinium and terbium of nearly the same wave-length.

A large proportion of unconfirmed discoveries of elements belongs to the rare earth series, and this may be taken as a tribute to the difficulties attending their isolation. There is no adequate test to decide whether a mixture is involved; it is difficult to get definite results; fractionation may give mixtures which cannot be resolved into their constituents; and spectroscopic results are modified by the presence of traces of impurities which cannot be removed. A chronological summary of the announcements of discoveries of new elements derived from the rare earth minerals is summarized in Table II, together with an indication of the fate of the supposed discovery.

TABLE II.—CHRONOLOGICAL VIEW OF REPORTED ELEMENTS OF THE RARE EARTHS.

Year.	Reported Element.	Source.	Discoverer.	Remarks.
1794	Yttrium	Gadolinite	J. Gadolin	Impure yttria.
1804	Cerium	Cerite	J. J. Berzelius, etc.	Impure ceria.
1811	Junonium	Allanite	T. Thomson	Erroneous analysis.
1817	Thorine	Cerite	J. J. Berzelius	Yttrium phosphate.
1818	Vestium	Allanite	L. W. Gilbert	Unverified.
1828	Thorium	Thorite	J. J. Berzelius	Element.
1839	Lanthanum	Ceria	C. G. Mosander	Element.
1842	Didymium	Ceria	C. G. Mosander	Mixture.
1843	Terbium	Yttria	C. G. Mosander	Erbium since 1860.
1843	Erbium	Yttria	C. G. Mosander	Terbium since 1877.
1851	Donarium	Orangeite	C. Bergemann	Mixture.
1862	Wasmium	Orthite	J. F. Bahr	Mixture.
1878	Mosandium	Samarskite	J. L. Smith	Mixture.
1878	Philippium	Yttria	M. Delafontaine	Mixture.
1878	Decipium	Samarskite	M. Delafontaine	Mixture.
1878	Ytterbium	Erbia	J. C. G. de Marignac	Mixture.
1878	X	Erbia	J. L. Soret	Holmium.
1879	Scandium	Ytterbia	L. F. Nilson	Element.
1879	Samarium	Didymia	L. de Boisbaudran	Element.
1879	Thulium	Erbia	P. T. Cleve	Element.
1879	Holmium	Erbia	P. T. Cleve	Element.
1880	γ_α	Samarskite	J. C. G. de Marignac	Gadolinium after 1886.
1880	γ_β	Samarskite	J. C. G. de Marignac	Samarium.
1884	Columbium	Samarskite	J. L. Smith	Mixture (not niobium).
1884	Rogerium	Samarskite	J. L. Smith	Mixture.
1885	Neodymium	Didymia	C. A. von Welsbach	Element.

Year.	Reported Element.	Source.	Discoverer.	Remarks.
1885	Praseodymium	Didymia	C. A. von Welsbach	Element.
1885	Z_α	Terbia	L. de Boisbaudran	Dysprosium.
1885	Z_β	Terbia	L. de Boisbaudran	Terbium.
1886	Z_γ	Terbia	L. de Boisbaudran	Dysprosium.
1886	Z	Terbia	L. de Boisbaudran	Terbium.
1886	S_1	Samaria	E. Demarçay	Possibly Σ below.
1886	Dysprosium	Holmia	L. de Boisbaudran	Element.
1886	Austrium	Orthite	E. Linnemann	Impure gallium.
1886	Meta-elements	Various	W. Crookes	*Vide supra.*
1887	Meta-elements	Various	G. Krüss, etc.	*Vide supra.*
1887	Russium	Monazite	K. von Chrustchoff	Mixture.
1892	Masrium	Egyptian alum	H. D. Richmond, etc.	Unverified.
1892	Z_ϵ	Samaria	L. de Boisbaudran	Europium.
1892	Z_ζ	Samaria	L. de Boisbaudran	Europium.
1894	Demonium	Yttria	H. E. Rowland	Dysprosium.
1895	Metacerium	Cerite	E. Brauner	Unverified.
1896	Damarium	Monazite	K. Lauer and P. Antsch	Unverified.
1896	Σ	Yttria	E. Demarçay	Europium.
1896	Lucium	Yttria	P. Barrière	Mixture.
1896	Kosmium	Yttria	B. Kosmann	Mixture.
1896	Neokosmium	Yttria	B. Kosmann	Mixture.
1897	Glaucodymium	Didymia	K. von Chrustchoff	Unverified.
1898	Monium	Yttria	W. Crookes	Victorium.
1899	Victorium	Yttria	W. Crookes	Mixture.
1900	Γ	Terbia	E. Demarçay	Terbium.
1900	Δ	Terbia	E. Demarçay	Dysprosium.
1900	Ω	Yttria	E. Demarçay	Unconfirmed.
1900	Θ	Yttria	E. Demarçay	Unconfirmed.
1901	Euxenium	Euxenite	K. A. Hofmann, etc.	Unverified.
1904	Carolinium	Thorite	C. Baskerville	Unverified.
1904	Berzelium	Thorite	C. Baskerville	Unverified.
1905	Incognitum	Yttria	W. Crookes	Terbia-gadolinia.
1905	Ionium	Yttria	W. Crookes	Terbia-gadolinia.
1905	Neoytterbium	Ytterbia	G. Urbain	Element.
1905	Lutecium	Ytterbia	G. Urbain	Element.
1907	Aldebaranium	Ytterbia	C. A. von Welsbach	Neoytterbium.
1907	Cassiopeium	Ytterbia	C. A. von Welsbach	Lutecium.
1910	E	Terbia	F. Exner and E. Haschek	Mixture.
1911	Celtium	Gadolinite	G. Urbain	Lutecium.
1912	Tb_1, Tb_2, Tb_3	Terbia	C. A. von Welsbach	Unconfirmed.
1916	Denebium	Ytterbia	J. M. Eder	Unconfirmed.
1916	Dubhium	Ytterbia	J. M. Eder	Unconfirmed.
1917	Eurosamarium	Samarskite	J. M. Eder	Unconfirmed
1920	Welsium	Terbia	J. M. Eder	Unconfirmed.

§ 3. The Occurrence of the Rare Earths

The rare earths are widely distributed, but in minute quantities. F. W. Clarke and H. S. Washington[1] estimated that the ten-mile crust, the hydrosphere, and lithosphere contained 0·019 per cent. of yttrium and cerium earths. The history of the rare earth minerals begins with the discovery of *tungstein*, or *tungsten*, and the confusion of that mineral with the Bohemian *tennspar* heralded the greater confusion which was destined to follow when the composition of the mineral was minutely examined. The early history of this mineral has been previously described. M. H. Klaproth[2] proposed to call it *ochröite*—ὠχρός, brownish-yellow—on account of its colour; and J. J. Berzelius **cerite**, in honour of the discovery of the minor planet Ceres in 1801. M. H. Klaproth accepted J. J. Berzelius' term, but suggested adding another syllable—*cererite*—so that it would not be supposed that the term was derived from κηρός, wax. The proposal was not accepted. M. H. Klaproth reported 34·5 per cent. of silica in the mineral; L. N. Vauquelin, 17·0 per cent.; and R. Hermann, 18·0 per cent. M. H. Klaproth included with the silica in his analysis all the material not decomposed by the method he employed. R. Hermann assumed that two different minerals were in question; and, since appreciable quantities of lanthanum as well as cerium are contained in the mineral, he suggested calling the mineral with a high proportion of lanthanum and a smaller proportion of cerium, *lanthanocerite*. G. A. Kenngott said that lanthanocerite owes its lanthanum to admixed *lanthanite*. R. J. Haüy's term for the mineral was *cérium oxydé siliceux rouge*, in contrast with *cérium oxydé siliceux noir* employed for allanite. Analyses of the Swedish mineral from Bastnaes were reported by W. Hisinger and J. J. Berzelius, M. H. Klaproth, W. Hisinger, J. F. John, A. Arche, R. Hermann, T. Kjerulf, C. F. Rammelsberg, G. Nordström, F. Stolba, W. Muthmann, and L. Stützel. Analyses made after 1843 show the presence of didymium and lanthanum:

SiO_2	Ce_2O_3	Di_2O_3	La_2O_3	Al_2O_3	FeO	CaO	MgO	CO_2	H_2O
16·06	26·55	18·05	16·33	1·68	3·17	1·23	1·25	4·62	8·10
21·35	60·99	3·90	3·51	—	1·46	1·65	—	0·38	6·31

The idealized mineral is usually regarded as a basic cerium silicate, $H_3(Ca, Fe)Ce_3Si_3O_{13}$, with 50·7–71·8 per cent. cerium. P. Groth interprets this formula as representing a basic metasilicate, $(Ca, Fe)(CeO)Ce_2(OH)_3(SiO_3)_3$, a derivative of the acid $H_6Si_3O_9$. C. F. Rammelsberg gave $(Ce, La, Di)_2SiO_4.H_2O$. Numerous other constituents have been reported—*e.g.* bismuth, manganese, copper, phosphoric and sulphuric oxides, etc. H. St. C. Deville found traces of vanadium and titanium oxides. G. Tschermak found 11·7 per cent. of zirconium in a sample from Batoum, and he also found 7·6 per cent. of yttria. W. Crookes, G. Krüss and L. F. Nilson,

etc., have discussed the complexity of the rare earths contained in cerite; but the mineral is too scarce to serve generally for the extraction of rare earths. G. Tschermak, W. Ramsay and M. W. Travers, and R. J. Strutt found a considerable proportion of helium occluded in the mineral. R. J. Strutt found $1{\cdot}36\times10^{-8}$ grm. of radium; G. Bardet found the mineral radioactive. It is rather unusual to find thorium and uranium both absent in the rare earth minerals; G. Tschermak found traces of thorium in a sample from Batoum; but this element is not represented in analyses of the mineral. The mineral occurs massive or granular. A. E. Nordenskjöld and W. Haidinger have discussed the crystalline form. The brown to red translucent or opaque crystals are rhombic with axial ratios $a:b:c=0{\cdot}9988:1:0{\cdot}8127$. The hardness is 5 to 6. L. N. Vauquelin gave 4·530 for the sp. gr.; M. H. Klaproth, 4·660; and G. Nordström, 4·86. G. Spezia showed that cerite turns yellow in the oxidizing flame, and melts to a brown enamel in the reducing flame. A. L. Fletcher found cerite softened at about 1230°, and melted about 1350°. It is readily attacked by sulphuric acid, and with hydrochloric acid it forms a gelatinous silica. From the different proportions of the mineral attacked by the acid, and left in the silica, C. F. Rammelsberg inferred that "cerite is a mixture of silicates which are not all attacked with the same ease by hydrochloric acid." C. A. von Welsbach made a similar observation. J. Schilling compiled a bibliography on cerite.

Cerite and **gadolinite** are two of the most interesting minerals in connection with the discovery of the rare earths. The mineral which J. Gadolin named *ytterbite*, and in which he discovered yttria earth, was afterwards named gadolinite. B. R. Geijer described it in 1788 as a black zeolite. This mineral occurs at Ytterby near Stockholm and at Fahlun, Taberg, and Carlberg in Sweden; it occurs also in Hitterö and Malö in Norway; in the Riesengebirge and the Harz in Germany; in the trapp rock of Galway, and in the granulite of Down County, Ireland; on the Zdjar Mountains in Austria; in the granite of Baveno, Italy; in the granite of Ceylon; and at Disko, Greenland. There is a remarkable deposit at Baringer Hill, Llano Co., near Bluffton in Texas; and near Devil's Head in Colorado.

The giant pegmatite of Texas furnishes large crystals of gadolinite associated with thorogummite, nivenite, fergusonite, allanite, tengerite, cyrtolite, rowlandite, mackintoshite, and yttrocrasite. This deposit has been studied by W. E. Hidden and co-workers. There is here a decomposition product of gadolinite which they named green gadolinite or *yttrialite*. It contains no beryllia, and twice as much silica as the parent mineral, for it approximates to $R_2O_3.2SiO_2$, where R_2O_3 represents the yttria oxides.

The analysis of J. Gadolin was confirmed by A. G. Ekeberg, M. H. Klaproth, and L. N. Vauquelin. In 1802, A. G. Ekeberg showed that the earth reported as alumina was really beryllia, and amounts up to 11·60 per cent. of beryllia were reported by N. J. Berlin, A. Connell, T. Scheerer, etc. From these results it is considered that beryllia is of secondary origin. Amounts of ceria up to 20·28 per cent. were reported by J. J. Berzelius, J. S. Humpidge and W. Burney, T. Thomson, etc. In addition to analyses by those just mentioned, others have been reported by C. F. Rammelsberg, N. Lindström, C. W. Blomstrand, T. Thomson and A. Steel, B. F. Davis and A. G. Maitland, W. Petersson, B. Szilard, J. Fromme, W. C. Brögger and co-workers, J. F. Bahr and R. Bunsen, G. P. Tschernik, G. A. König, M. Websky, L. G. Eakins, A. des Cloizeaux, etc. The silica ranges from 21·86 to 29·20 per cent.: the yttria earths, from 9·50 to 51·46 per cent.; the ceria earths, from 1·80 to 16·69 per cent.; the ferrous oxide, from 7·47 to 16·04 per cent.; the beryllia up to 11·60 per cent.; the lime, 0·23 to 3·47 per cent.; the loss on ignition, up to 5·2 per cent. In addition, ferric oxide, alumina, thoria (0·81–0·89 per cent.), magnesia, manganese oxide, and the alkalies have been reported. The complex character of the rare earths in this mineral is indicated in the preceding section. C. F. Rammelsberg, G. Tschermak, and A. Himmelbauer have discussed the constitution of the mineral. The formula of the idealized mineral is sometimes written $FeBe_2Y_2Si_2O_{10}$, or $2BeO.FeO.Y_2O_3.2SiO_2$; and P. Groth regards it as a basic orthosilicate, $Be_2Fe(YO)_2(SiO_4)_2$, derived from the acid $H_8Si_2O_8$. B. R. Geijer has described the cerium ore of Bastnaes, and microscopically it appears as a fine grained aggregate of cerite, bastnäsite, orthite, lanthanite, fluocerite, and törnebohmite.

Gadolinite occurs in subtranslucent or opaque masses, black, or greenish- or brownish-black in colour. It also occurs in crystals belonging to the monoclinic system with axial ratios $a:b:c=0·62726:1:1·32149$, and $\beta=89° 26' 30''$. The crystals have also been examined by N. S. Maskelyne and V. von Lang, P. Waage, R. J. Haüy, W. Phillips, A. Lévy, T. Scheerer, A. T. Kupffer, G. vom Rath, A. des Cloizeaux, and H. Sjögren. A. Hadding, and H. Küstner studied the X-radiogram of gadolinite. The latter found that the isotropic crystals are truly isotropic, and no colloidal or subcolloidal anisotropic crystals are present. Both the natural anisotropic crystals and the anisotropic crystals formed by heating the isotropic crystals to 1000° furnish characteristic X-radiograms. The sp. gr. is between 4·0 and 4·5, and the hardness 6·5–7·0. E. D. Clarke fused gadolinite in the oxy-hydrogen blowpipe flame to form a black glass; and A. L. Fletcher found the mineral showed signs of melting between 1395° and 1450°. The crystals have a strong positive birefringence. The brown variety is distinctly pleochroic, the green varieties have a weaker pleochroism. According to W. H. Wollaston, T. Liebisch, and K. A. Hofmann and F. Zerban, gadolinite is calorescent at about 430°. W. C. Brögger, W. Petersson, and G. T. Prior examined the hypotheses that on calcination the crystalline mineral becomes amorphous. The heating curve of the crystalline mineral, obtained by T. Liebisch, gives no ground for the assumption; the curve is quite regular. W. Petersson, G. Tschermak, W. Ramsay and M. W. Travers, T. Scheerer, and J. J. Berzelius showed that the sp. gr. of the calcined mineral is greater, and H. Rose, that its sp. ht. about one-fourteenth less, than the original mineral. J. Schilling compiled a bibliography on gadolinite.

According to C. C. von Leonhard,[3] and F. von Kobell, in 1808, H. L. Giesecke sent a package of minerals from Greenland to Copenhagen; the vessel was captured by an English privateer, and brought to Leith. The minerals were purchased by T. Allan; he mistook one mineral for gadolinite and sent it to T. Thomson for analysis. The latter recognized it as a new mineral and called it **allanite.** Judging from the many names which have been assigned to what appear to be varieties of the same mineral, it might almost be called polyonymite—πολυώνῠμος, having many names.

W. Hisinger called a variety from Riddarhyttan, Sweden, *cerine*, and R. J. Haüy designated the mineral *cérium oxydé siliceux noir* in contrast with *cérium oxydé siliceux rouge* employed for the mineral cerite. J. J. Berzelius named a mineral from Finbo, Fahlun, **orthite**—ὀρθός, straight—in reference to the form of its crystals, and another mineral from Kararfvet, Fahlun, *pyrorthite*—πῦρ, fire—in reference to its colour. F. Stromeyer, and T. Scheerer showed that allanite, cerine, and orthite are varieties of the same mineral. A. Lévy described a black mineral from Näskil, Arendal, as *bucklandite*. A. Lévy, G. Rose, and R. Hermann showed that bucklandite is closely related to orthite. R. Hermann, C. F. Rammelsberg, and J. Auerbach called a sample from Miask, Urals, *uralorthite*, and N. von Kokscharoff showed that it is related to orthite. A. Breithaupt called a sample from the trachyte of Laach, *tautolite*—ταὐτόν, the same; λίθος, stone—and G. vom Rath showed its relationship to orthite. A specimen from Eriksberge, near Stockholm, was called *xanorthite* or *xanthorthite*—ξανθός, yellow—by R. Hermann and described as a yellow orthite. N. von Kokscharoff, and R. Hermann described *bagrationite*—named after P. R. Bagration—from Achmatovsk. R. Hermann regarded it as a variety of orthite A. Breithaupt, C. Kersten, and T. Kerndt reported *bodenite* from the soil at Mauersberg, Saxony; T. Kerndt, *muromontite*—Latinized name of Mauersberg—from Mauersberg; *vasite* or *wasite* obtained by J. F. Bahr from Rönsholm, Stockholm, and studied by B. Szilard, and N. Engström; *michaelsonite* found by C. A. Michaelson and E. Nobel near Brevig; and N. J. Berlin, the *erdmannite*—named after O. L. Erdmann—was obtained from Stökö near Brevig. All these are more or less impure varieties of orthite or allanite. Pale green crystals of a mineral named **törnebohmite** were found by P. Geijer to be associated with the cerite of Bastnäs. The analysis is:

SiO_2	Ce_2O_3	$(La,Di)_2O_3$	Al_2O_3	FeO	MnO	MgO	CaO	F	Ignition
22·05	27·52	34·85	8·55	1·91	0·05	0·49	0·23	0·29	1·70

The formula $R_2(ROH)(SiO_4)_2$ approximates to andalusite or topaz; but the mineral is more closely allied to cerite from which it differs in containing more aluminium and calcium. The optical properties differ from those of cerite; the sp. gr. is 4·94.

Allanite or orthite is fairly widely distributed in relatively small quantities. For example, *it is found in Greenland, Riddarhyttan, Ytterby, and Tunaberg in Sweden; at Kragerö, Hitterö, and Fille Fjeld in Norway; at Impilaks near the border of Finland; at Miask in the Urals; at Plauensche Grund near Dresden; in the Laacher See near Coblentz, and near Sahl in the Thüringerwald; at Criffel in* Scotland; in Canada; and in Colorado, Virginia, and Carolina in the United States. Numerous analyses of the varieties of allanite or orthite have been reported—*e.g.* by G. vom Rath, F. Stifft, H. Credner, F. Zschau, T. Kerndt, T. Scheerer, N. Engström and P. T. Cleve, K. A. von Zittel, D. Forbes, C. W. Blomstrand, N. J. Berlin and J. F. Bahr, F. W. Clarke, W. Hisinger, J. J. Berzelius, B. Szilard, M. Schubin, C. F. Rammelsberg, A. Stromeyer, J. Torrey, D. M. Balch, C. Bergemann, D. I. Mendeléeff, P. Keyser, J. W. Mallet, J. A. Cabell, F. P. Dunnington, G. A. König, F. A. Genth, C. Memminger, L. G. Eakins, W. C. Brögger and coworkers, E. P. Valentine, A. Strecker, T. L. Walker and A. L. Parsons, T. S. Hunt, etc. The composition varies very much because the bases can be replaced vicariously. A selection of analyses is shown in Table III. The first three analyses are by N. Engström and P. T. Cleve; the fourth and fifth are by N. Engström; and the last is by F. P. Dunnington.

TABLE III.—ANALYSES OF ALLANITE OR ORTHITE.

Allanite or orthite appears to belong to the epidote family of silicates. This has been emphasized by A. Michel-Lévy, G. Rose, R. Hermann, N. von Kokscharoff, etc.; and P. Geijer's analysis gives $4·29RO$; $2·61R_2O_3$; $5·93SiO_2 : H_2O$. The mineral has accordingly been called *cerium-epidote*. V. M. Goldschmidt found what he called *epidote-orthites*, which he regarded as isomorphous mixtures of orthite with iron epidote; and most of the orthites may be regarded as solid soln. The general formula for epidote is $H_2O.4RO.3R_2O_3.6SiO_2$, where R is tervalent and R'' bivalent, and may be represented by vicarious metals. With allanite, R'' is (Fe″, Ca), and R is (Al, Fe‴, Ce), where Ce stands for elements of the cerium and yttrium families. N. Engström said that some orthites agree in composition with the epidotes $H_2R''_4R_6S_6O_{26}$, but some others agree with $H_4R''_4R_6Si_6O_{27}$; and, in the latter case, it is not clear whether the extra molecule of water is of secondary importance, or whether it represents a special class of orthites. P. Groth regarded allanite as a basic salt, $R_3(OH)R''_2Si_3O_{12}$, of the acid $H_{12}Si_3O_{12}$. The idealized mineral with the epidote formula is $(Ca, Fe)_2(AlOH)(Al, Ce, Fe)_2(SiO_4)_3$, and it may be a solid soln. of isomorphous epidote, ferric-epidote, and cerium-epidote, $Ca_2(AlOH)Ce_2(SiO_4)_3$, or *calcium dicerium aluminohydroxy-triorthosilicate*—*vide* epidote.

The rare earths in allanite range from 3·6 to 5·1 per cent., and the components indicated in Table III no doubt give the impression of having been more accurately determined than the methods of analysis allow. Yttria ranges up to 4·7 per cent., and thoria up to 3·5 per cent. R. J. Meyer found scandia up to 1 per cent. Traces of uranium are often present. W. Ramsay, J. N. Collie, and M. W. Travers found no helium, but R. J. Strutt found some radium to be present in some samples, and therefore the presence of occluded helium is highly probable. T. Kerndt reported 5·52 per cent. of beryllia in a specimen from Mauersberg; J. W. Mallet, 0·52 per cent. in a specimen from Norfolk, Virginia; J. A. Cabell, 0·24 per cent. in a specimen from Amherst; L. G. Eakins, 0·27 per cent. in a specimen from Douglas Co., Colorado; and J. Fromme also reported small quantities of beryllia in some specimens of allanite. R. Hermann reported the presence of some titanite. Carbon dioxide is found in some samples, and the amount of water ranges from zero up to 17 per cent.

Allanite or orthite occurs as an accessory constituent in granite, syenite, diorite, gneiss, limestone, etc. It appears either in compact masses, or as crystals. The colour may be reddish-brown, greyish-green, or even black. The crystals are sometimes broad and tabular, at other times long and slender. A. des Cloizeaux and A. Damour found some well-formed crystals without double refraction. W. Haidinger, G. Rose, A. Sjögren, L. H. Borgström, A. Michel-Lévy and A. Lacroix, N. von Kokscharoff, A. E. Nordenskjöld, R. Hermann, J. Auerbach, etc., have studied the crystals. According to G. vom Rath, the crystals belong to the monoclinic system, and have the axial ratios $a : b : c = 1·55070 : 1 : 1·76838$, and $\beta = 64° 59'$. The hardness and sp. gr. vary with the amount of water in the mineral, and with other conditions. The sp. gr. ranges from 2·53 to 4·32—the average is about 3·5. G. vom Rath found a sample with a sp. gr. 3·983; T. Kerndt, 4·263; C. Kersten, 3·523; T. Scheerer, 3·546; N. J. Berlin and J. F. Bahr, 2·78; R. Hermann, 3·48–3·66; T. S. Hunt, 3·84; C. Bergemann, 3·4917; F. A. Genth, 3·782; L. G. Eakins, 3·52; J. W. Mallet, 4·32, etc. The hardness is between 5 and 6. A. L. Fletcher found that the mineral melted between 1220° and 1265°. Most varieties gelatinize when treated with hydrochloric acid; but if previously ignited, they are not decomposed by the acid.

A complex silicate of the rare earths metals, calcium, iron, etc., with a high proportion of zirconia was found by T. Scheerer at Kangerdluarsuk, Greenland, and on the islands of the Langesund Fiord, Norway. C. U. Shepard,[4] and F. A. Genth have reported it in Arkansas. F. Stromeyer named it from εὐ, easily, and διαλύω, to dissolve, in reference to its easy solubility in acids; **eudialyte** is a corrupted form of this term; T. Scheerer called a Norwegian variety **eucolite**—from εὔκολος, not difficult to satisfy—in allusion to the alleged replacement of iron oxide for zirconia in wöhlerite. Analyses have been made by C. H. Pfaff, F. Stromeyer, C. F. Rammelsberg, A. Damour, T. Scheerer, L. Gruner, O. B. Böggild, F. A. Genth, J. Lorenzen, etc. P. T. Cleve's analysis of a sample from Barkevik is:

Na_2O	K_2O	CaO	MnO	FeO	Y_2O_3	$(Ce, Di, La)_2O_3$	SiO_2	ZrO_2	Cb_2O_5
11·17	0·11	12·11	3·60	3·90	0·32	4·80	45·15	12·51	3·52

and 0·55 per cent. of chlorine, and 2·11 per cent. of water. The constitution has been discussed by C. W. Blomstrand, P. Groth, F. W. Clarke, C. F. Rammelsberg, L. Colomba, etc. J. D. Dana gives the empirical formula $Na_{13}(Ca, Fe)_6Cl(Si, Zr)_{20}O_{52}$; while W. C. Brögger considers it to be a metasilicate, $(Na, K, H)_4R_3Zr(SiO_3)_7$, where R may represent Ca, Fe, Mn, and CeOH; and ZrOCl may act as an acidic radicle in place of silica—*vide* zirconium silicates. G. Hevesy and V. T. Jantzen found 0·7 per cent. of hafnia in Greenland eudialyte, and 0·7 per cent. in Norwegian eucolite. J. Thomsen found that eudialyte contained 0·4 c.c. of occluded gas—CO_2, 10; H_2, 75; CO, 3; N_2, 7—per kgrm. of mineral. The fact that such a complex silicate may occur in well-defined crystals shows what intricate problems in inorganic chemistry are awaiting solution. The crimson, purple, or brown trigonal crystals were studied by W. H. Miller, and

V. von Lang; the axial ratio is $a : c = 1 : 2{\cdot}1116$. Observations by F. Stromeyer, A. Damour, J. Lorenzen, C. F. Rammelsberg, A. Lévy, J. F. Williams, T. Scheerer, and P. T. Cleve show that the reddish-brown crystals have a sp. gr. ranging from 2·624 to 3·104. The hardness is 5 to 6. Eudialyte is optically positive, eucolite negative. W. Ramsay found the zones of positive and negative birefringence as well as isotopic zones can occur on the same minerals, and he suggested that the mineral is really composed of two isomorphous compounds. The optical behaviour of the eudialyte is sometimes anomalous, possibly an effect of repeated twinning, and the lamellar intergrowth of two varieties with slightly different optical properties. E. Jannettaz measured the thermal conductivity. J. Schilling has given a bibliography of eudialyte.

The *eucolitic titanite* of W. C. Brögger[5] from Langesund Fiord, Norway, contains 2·57 per cent. of ceria, 0·59 per cent. of yttria, and 0·18 per cent. of thoria earths. The sp. gr. is 3·59. C. W. Blomstrand's **alshedite**, from Alsheda, Småland, is a variety of titanite with 2·57–2·78 per cent. of yttria earths, the sp. gr. is 3·36. For *alvite*, *anderbergite*, *catapleiite*, and *cyrtolite*, see zirconium silicate. W. C. Brögger and co-workers, and C. B. Benedicks described a monoclinic mineral **thalenite** from a quartz quarry in Oesterby; and T. Vogt, from the pegmatite at Hundholmen. The crystals are reddish-violet. The former had axial ratios $a : b : c = 1{\cdot}1541 : 1 : 0{\cdot}602$, and $\beta = 80° 12'$, the latter $0{\cdot}9190 : 1 : 0{\cdot}6480$, and $\beta = 82° 54\frac{1}{2}'$; hardness 6 to 6·5; sp. gr. 3·945 to 4·454; indices of refraction $\alpha = 1{\cdot}7312$, $\beta = 1{\cdot}7375$, $\gamma = 1{\cdot}7436$ for sodium light. Analyses correspond with $H_2Y_2Si_4O_{15}$, or, according to W. C. Brögger and co-workers, **yttrium orthodisilicate**, $Y_2Si_2O_7$. R. Mauzelius and H. Sjögren's analysis is:

Na_2O	MgO	CaO	Fe_2O_3	SiO_2	SnO_2	ThO_2	Y_2O_3	$(La, Di)_2O_3$	Ce_2O_3
0·08	0·05	0·11	0·45	28·88	0·22	0·18	61·84	4·15	0·83

with loss on ignition 3·33, which includes 1·73 per cent. of water. W. E. Hidden and J. B. Mackintosh found an orange-yellow to orange-green mineral **yttrialite**, or green gadolinite, in the granite of Llano Co., Texas. W. F. Hillebrand's analysis is:

MgO	CaO	MnO	FeO	PbO	Fe_2O_3	SiO_2	TiO_2	Cl	P_2O_5
0·16	0·67	0·88	1·96	0·80	0·76	29·63	0·05	0·11	0·12

with water over 105°, 0·32, and water below 105°, 0·04; undetermined nitrogen, helium, fluorine, and alkalies about 0·31; and

Y_2O_3	La_2O_3	Ce_2O_3	ThO_2	UO_2
43·45	5·18	3·07	10·85	1·64

The formula approximates to $(Fe, Mn)(Y, La)_6ThSi_6O_{24}$, or simplified, $RThSi_2O_7.4Y_2Si_2O_7$. The mineral is regarded as a kind of weathered gadolinite. The sp. gr. is 4·575; the hardness 5 to 5·5. It is readily soluble in hydrochloric acid; but not if it has been calcined. F. W. Clarke has also studied the mineral. A kind of dark reddish-brown garnet, **yttriogarnet**, occurs at Stockö, Norway, and Schreiberhau, Germany, with yttria earths 1·0 to 6·7 per cent., and zirconia, 0 to 3 per cent. It has been investigated by L. Gruner, C. Bergemann, M. Websky, W. C. Brögger, A. T. C. Soltmann, and M. Piners. L. A. Aars', and W. C. Brögger's analysis of brownish-red **hellandite** from Lindvikskollan near Kragerö, Norway, is:

Na_2O	K_2O	MgO	CaO	Al_2O_3	Mn_2O_3	Fe_2O_3	SiO_2	H_2O
0·23	0·06	0·10	9·81	10·12	5·91	2·56	23·66	11·75

with Y_2O_3, 19·29; Er_2O_3, 15·43; Ce_2O_3, 1·01; and ThO_2, 0·62. A possible formula is $Ca_2(R'''OH)_6(SiO_4)_4$ or $2R''O.3R'''_2O_3.4SiO_2.3H_2O$, where R'' stands for Ca, Mg, or $\frac{1}{2}$Th; and R''' for tervalent Al, Fe, Mn, or the rare earth metals. The mineral may thus be regarded as a basic salt of the orthosilicate $H_{16}Si_4O_{16}$. The monoclinic prisms have the axial ratios $a : b : c = 2{\cdot}0646 : 1 : 2{\cdot}507$, and $\beta = 109° 45'$; the sp. gr. is 3·41 to 3·70; the hardness, 5·5. The mineral readily fuses. It dissolves readily in hydrochloric acid with the evolution of chlorine; it does not dissolve as easily in nitric or sulphuric acid. B. Szilard also studied the mineral.

F. Zambonini[6] found a complex titanate of the rare earths in the pegmatite of Craveggia, Italy, and named it **delorenzite**. The analysis is:

FeO	Y_2O_3	TiO_2	SnO_2	UO_2
4·25	14·63	66·03	4·33	9·87

The yttria earth is almost free from ceria. There are traces of columbic oxide. The formula is $2FeO.UO_2.2Y_2O_3.24TiO_2$, with a little tin replacing titanium. The mineral is strongly radioactive. The rhombic crystals have the axial ratios $a : b : c = 0{\cdot}3375 : 1 : 0{\cdot}3412$. The sp. gr. is 4·7, and the hardness 5·5–6·0. Its closest chemical relation is yttrocrasite, but in appearance and angles it resembles polycrase. W. E. Hidden and C. H. Warren analyzed a black mineral from Burnet Co., Texas, which was called **yttrocrasite.** It contains 25·7 per cent. of yttria earths; 2·9 per cent. of ceria earths; 8·7 per cent. of thoria; and 49·7 per cent. titanic oxide. The formula approximates $(Ca, Pb)O.(Th, U)O_2.3R_2O_3.16TiO_2.6H_2O$. The prismatic crystals are rhombic, the axial ratios are unknown. The sp. gr. is 4·80, and the hardness 5·5–6·0. It was also studied by B. Szilard.

P. J. Holmquist described a brown mineral in pseudo-cubic crystals from Alnö, Sweden, which he named **knopite.** It is regarded as a variety of perowskite—*vide* titanium. It contains 26·84–33·32 per cent. of calcium oxide; 3·23 to 5·15 per cent. ferrous oxide; 0·06 per cent. of yttria earths; 4·42 to 6·81 per cent. of ceria earths; and 54·12 to 58·74 per cent. of titanic oxide. C. F. Rammelsberg, and P. Groth have described the formula. The sp. gr. is 4·11 to 4·29; and the hardness, 5 to 6. The black mineral is in rounded crystal grains belonging to the cubic system found at O'Cary, South Australia, was named **davidite.** It was described by D. Mawson, and E. E. H. Renne and W. C. Cook, and appears to be a titanate of iron, uranium, vanadium, chromium, and the rare earths. It contains over 50 per cent. of titanic oxide, and 5 to 10 per cent. of the rare earths. The sp. gr. is about 4.

A brown mineral from Arendal, Buö, Arkerö, Alve, Narrestö in Norway was named **yttrotitanite** by T. Scheerer,[7] and *keilhauite* by A. Erdmann. It is a titanosilicate of calcium, aluminium, iron, and yttria earths; it is monoclinic, and isomorphous with titanite, and it is considered to be a mixture of titanite $CaO.TiO_2.SiO_2$, with the silicate $(Y, Al, Fe)_2SiO_3$. The sp. gr. is 3·52 to 3·77; and its hardness, 6·5. The double refraction is positive and feeble. Analyses were made by A. Erdmann, D. Forbes, C. F. Rammelsberg, and T. Scheerer. The constitution has been discussed by H. Rose, J. J. Berzelius, C. W. Blomstrand, F. Zambonini, P. Groth, and O. Hauser—*vide* titanosilicates.

In 1841, A. Erdmann described a brown mineral which he found in the syenite near Brevig, Norway, and named **mosandrite,** after C. G. Mosander. It was analyzed by W. C. Brögger, and B. Szilard. In 1890, W. C. Brogger described a brown mineral, from the islands of Langesund Fiord, Norway, which he called **johnstrupite,** after F. Johnstrup. N. J. Berlin analyzed mosandrite. The composition and general properties are so much alike that W. C. Brogger regards them as belonging to the same mineral species. Both are titanosilicates of the rare earth metals, aluminium, calcium, magnesium, sodium, etc. There is about 13·5 per cent. of ceria earths; 1·1 of yttria earths; 7 to 8 per cent. of titanic oxide; and 3·6 per cent. of thoria and zirconia. The crystals are monoclinic with axial ratios $a : b : c = 1{\cdot}6229 : 1 : 1{\cdot}3911$, and β 93° 4′ 15″ very close to those of epidote. The sp. gr. of johnstrupite is just over 3, that of mosandrite just below 3. The hardness is 4–5. J. Lorenzen investigated a yellow titanosilicate from the syenites of Kangerdluarsuk, Greenland, and found:

Na_2O	CaO	FeO	Y_2O_3	$(Ce,La,Di)_2O_3$	SiO_2	TiO_2	F
8·93	23·26	0·44	0·92	21·25	29·08	13·36	5·82

The formula has been discussed by W. C. Brögger, and P. Groth—*vide* titanosilicates. The mineral closely resembles johnstrupite. The monoclinic crystals have the axial ratios $a : b : c = 0{\cdot}7844 : 1 : 1{\cdot}4610$, and $\beta = 91° 12′ 45″$. Their sp. gr. is 3·46, and hardness 5. It is pleochroic. J. Lorenzen found a mineral which he called **rinkite** in the syenite of Kangerdluarsuk, Greenland. Analyses were made by J. Lorenzen, and W. C. Brögger gave the formula $(F_2Ti_4)Na_6Ca_{11}Ce_3(SiO_4)_{12}$; and P. Groth, $Na_3Ca_4Ce_2(Si, Ti)_6O_{18}F_3$—*vide* titanosilicates. The flattened crystals are yellowish-brown or straw-yellow. They belong to the monoclinic system with the axial ratios $a : b : c = 1{\cdot}5688 : 1 : 0{\cdot}2922$, and $\beta = 88° 47\tfrac{1}{2}′$. The (100) cleavage is distinct; the sp. gr. is 3·46; and the hardness 5. The pleochroic crystals are optically positive. The mineral is easily decomposed by dil. acids with the separation of silica and some titania. A complex silicate called **steenstrupine** was obtained by J. Lorenzen from Steenstrup, Greenland; it contains 14·40 to 35·18 per cent. of ceria earths; 0·36 to 15·90 per cent. of yttria earths; and 2·13 to 7·09 per cent. of thoria. The mineral has been studied by W. C. Brögger, J. Lorenzen, O. B. Böggild, and J. C. Moberg. The brown crystals belong to the rhombohedral system. The sp. gr. is 3·19 to 3·51, and the hardness 4. The orange-grey mineral **rosenbuschite** was obtained by W. C. Brögger from the islands of Langesund Fiord, Norway. P. T. Cleve's analysis gives:

Na_2O	CaO	MnO	Fe_2O_3	Ce_2O_3	SiO_2	TiO_2	ZrO_2	F
9·93	24·87	1·39	1·00	0·33	31·36	6·85	20·10	5·83

The crystals are monoclinic with axial ratios $a:b:c=1·1687:1:0·9776$ and $\beta=101° 47'$; the sp. gr. is 3·30–3·31; and the hardness 5–6—*vide* titanosilicates. The mineral **tscheffkinite** was obtained by G. Rose from the Ilmen mountains in the Urals, and it has also been found on the coast of Coromandel, in Madagascar, in Virginia, etc. It has been analyzed by H. Rose, R. Hermann, A. Damour, F. S. Beudant, F. W. Clarke, W. R. Dunstan, B. Szilard, F. Pisani, L. G. Eakins, and R. C. Price. It is a titanosilicate of the rare earth elements, thorium, iron, calcium, etc., and contains 23–47 per cent. of ceria earths; up to 3·4 per cent. of yttria earths; 0 to 20 per cent. of thoria and zirconia; and 16–21 per cent. of titanic oxide. R. C. Price's analysis corresponds with $(Ca, Fe)_2(Di, Ce, La, Fe)_2(Si, Ti)_5O_{15}$. The constitution has been discussed by C. F. Rammelsberg, A. des Cloizeaux, R. C. Price, J. D. Dana, and R. Hermann—*vide* titanosilicates. The mineral is velvety-black and amorphous. Its sp. gr. is 4·26–4·55; and its hardness 5·0–5·5. Under the microscope, the mineral is not homogeneous. The mineral is attacked by hydrochloric or nitric acid with the separation of gelatinous silica.

G. P. Tschernik[8] described a kind of titanium zirconosilicate which he obtained from Batum, and called **titanocerite.** The sp. gr. was 5·08 and the hardness 5 to 6. The composition was:

CaO	FeO	CuO	SiO_2	TiO_2	ZrO_2	P_2O_5	SO_3	H_2O
2·33	3·70	0·67	6·57	14·73	11·67	3·30	0·97	3·43

together with

Y_2O_3	La_2O_3	Di_2O_3	Ce_2O_3	Er_2O_3	ThO_2	UO_2
6·97	6·73	2·27	34·20	0·67	0·73	trace

The brown, transparent zirconosilicate of calcium and the rare earth metals occurring near the Sea of Azoff, Russia, called **beckelite,** has, according to J. Morozewicz, the composition:

Na_2O	K_2O	CaO	Mn_2O_3	SiO_2	Al_2O_3	ZrO_2	Loss on ignition
0·78	0·39	15·46	0·07	17·13	0·30	2·50	0·99

with traces of magnesia and ferric oxide; 2·80, $(Y, Er)_2O_3$; 13·60, La_2O_3; 18·0, Di_2O_3; 28·10, Ce_2O_3. The formula may be $Ca_3(Y, Ce, La, Di)_4(Si, Zr)_3O_{15}$. The crystals are octahedral belonging to the cubic system; the sp. gr. is 4·15; and the hardness, 5. It is soluble in hot hydrochloric acid, even after ignition.

W. C. Brögger's analyses[9] of the three borosilicates, **melanocerite, caryocerite, cappelenite**, and N. Engström's analysis of **tritomite,** are shown in Table IV. These minerals were also studied by B. Szilard. The formula of cappelenite approximates $(Y, La, Di)BO_3(Ba, Ca, Na_2, K_2)SiO_3$. Melanocerite dissolves in hydrochloric acid with the separation of silica; cappelenite is likewise decomposed by that acid; and tritomite dissolves with the separation of gelatinous silica and the evolution of chlorine. T. Liebisch noted the thermoluminescence of tritomite. E. S. Larsen studied the optical properties of caryocerite, tritomite, and homilite. S. R. Paijkull analyzed a borosilicate of the rare earth metals, calcium, and iron which occurs near Brevig, Norway. It is accompanied by erdmannite and melophanite, and is named **homilite**—ὁμιλέω, to occur together—*vide* borosilicates. The mineral was also studied by A. des Cloizeaux and A. Damour. It contains up to 2·6 per cent. of ceria earths, and the formula approximates $(Ca, Fe)_2(BO_2(SiO_4))_2$. The crystals are monoclinic and isomorphous with gadolinite. The sp. gr. is 3·34–3·38; its hardness is 4·5 to 5·0; and it is pleochroic. W. C. Brögger found the borosilicate cappelenite in the islands of Langesund Fiord, Norway, in 1885. It contains 4·20 per cent. of ceria earths, 52·55 per cent. of yttria earths, and 0·79 per cent. of thoria, as well as silica, boric oxide, etc. The greenish-brown mineral approximates $BaSiO_3.YBO_3$ in composition. According to B. Szilard, the prismatic crystals are hexagonal. The sp. gr. is 4·407; and the hardness 6·0–6·5. H. Sjögren, and A. E. Nordenskjöld analyzed the yellowish-brown mineral **cainosite** or *cenosite* from Hitteröe, and found

Na_2O	MgO	CaO	FeO	Y_2O_3	$(Ce, La, Di)_2O_3$	SiO_2	CO_2	H_2O
3·6	1·4	16·5	2·9	35·9	trace	31·7	5·1	2·9

corresponding with the carbonatosilicate, $Ca_2Y_2(Si, C)_5O_{18}.2H_2O$; or, according to C. F. Rammelsberg, $CaCO_3.CaY_2Si_4O_{12}.2H_2O$. W. C. Brögger and co-workers made observations on the mineral. According to H. Sjögren, the rhombic crystals have the axial ratios $a:b:c=0·9517:1:0·8832$. The sp. gr. is 3·38–3·413, and the hardness 5 to 6. It is easily decomposed by hydrochloric acid, and carbon dioxide is evolved. There are some decomposition products of thorite and orangite—*vide* thorium—which contain rare earths. Thorite has up to about 5 per cent. of rare earths. The **calciothorite** of W. C. Brögger[10]

TABLE IV.—COMPOSITION OF SOME RARE EARTH BOROSILICATES.

	Melanocerite.	Caryocerite.	Cappelenite.	Tritomite.

approximates 59·3 per cent. of thoria; 0·23 per cent. of yttria earths; and 0·39 per cent. of ceria earths—$5ThSiO_4.2Ca_2SiO_4.10H_2O$. It is a red amorphous mass of sp. gr. 4·114, and hardness 4·5, found on the islands of Langesund Fiord, Norway. The amorphous silicate of the rare earth metals, thorium, aluminium, iron, manganese and sodium, found near Brevig, Norway, and called **freyalite**, has 31·1 per cent. ceria earths; 28·4 per cent. thoria; and 6·3 per cent. zirconia. Its sp. gr. is 4·06–4·17, and its hardness 6. It was studied by W. C. Brögger, and A. Damour. W. E. Hidden and J. B. Mackintosh found **auerlite**, approximating $ThO_2.\frac{1}{3}P_2O_5.SiO_2.2H_2O$, as a yellow or brownish-red tetragonal mineral in North Carolina. Its sp. gr. is 4·422 to 4·766; B. Szilard found 8 to 10 mols of water. The brownish-black mineral **eucrasite** from Brevig, Norway, is likewise an altered thorite; it was studied by W. C. Brögger, and S. R. Paijkull. It contains 14 per cent. ceria earths; 5·9 per cent. yttria earths; 36·0 per cent. of thoria; and 0·6 per cent. of zirconia; in addition, the oxides of calcium, iron, manganese, sodium, and titanium; and water. W. C. Brögger's sample was isotropic and amorphous, S. R. Paijkull's sample was in rhombic crystals. The sp. gr. is 4·39, and the hardness 4·5–5 0. The black opaque mineral **mackintoshite** is found at Bluffton, Llano Co., Texas. It was studied by W. E. Hidden, B. Szilard, F. W. Clarke, and W. F. Hillebrand. It is a complex mixture of silica and oxides of the rare earth metals, thorium, uranium, iron, calcium, magnesium, lead, sodium, boron, tantalum, etc. The thoria amounts to 45·3 per cent., the uranium oxide, UO_2, 22·4 per cent.; the rare earths, 1·9 per cent.; and the zirconia, 1·0 per cent. The tetragonal crystals resemble those of thorite. The sp. gr. is 5·42, and the hardness 5·5. W. E. Hidden and J. B. Mackintosh obtained a silicate of thorium, uranium, etc., with 6·7 per cent. of rare earths. The approximate formula is $UO_2.3ThO_2.3SiO_2.6H_2O$. The mineral was called **thorogummite**, and it is regarded as an altered mackintoshite. The crystals resemble zircon, but it usually occurs massive. The sp. gr. is 4·43 to 4·54, and the hardness 4·0–4·5. The yellowish-brown tetragonal mineral **yttrogummite** was found by W. E. Hidden and co-workers in Llano Co., Texas. It contains 6·7 per cent. of rare earths, and 41·4 per cent. of thoria. The formula approximates $UO_2.2ThO_2.3SiO_2.3H_2O$. Its sp. gr. is 4·43–4·54, and its hardness 4·0–4·5. The bright yellow amorphous mineral **pilbarite** from Pilbara, West Australia, was found by E. S. Simpson to contain traces of ceria and yttria earths. It has 31 per cent. of thoria, and approximates $PbO.UO_2.ThO_2.2SiO_2.2H_2O$. Its sp. gr. is 4·4–4·7, and the hardness 2·5–3·0.

A. G. Ekeberg[11] found black and yellow tantalates of yttrium, iron, and calcium with some uranium in the red felspar at Ytterby, Sweden, and he called them *yttrotantalite.* The mineral was found also at Finbö and Broddbö near Fahlun; R. J. Haüy called it *tantale oxidé yttrifère;* and R. Hermann, *yttroilmenite.* A similar mineral was described by B. Szilard. A tantalo-columbate of the rare earth metals, iron, calcium, and uranium, was discovered in the Urals and analyzed by G. Rose in 1839, and called *uranotantalite,* he also called it *uranoniobite.* H. Rose in 1847 renamed it **samarskite** after a Russian engineer who obtained him the specimen for analysis. The mineral is also called *eytlandite.* Samarskite and yttrotantalite are now considered to be the same mineral species. The prismatic crystals of the opaque, velvety-black or yellowish-brown mineral belong to the rhombic system. E. S. Dana gave for the axial ratios of samarskite $a:b:c$ $=0·5456:1:0·5178$; and W. C. Brögger, for yttrotantalite $0·5566:1:0·5173$. Samarskite and yttrotantalite are isomorphous. K. von Chrustchoff's analysis of a specimen of samarskite from Miask, Urals, gave:

Na_2O	K_2O	MgO	CaO	MnO	FeO	ZnO	PbO	Fe_2O_3	Al_2O_3	SnO_2	ZrO_2	WO_2
0·28	0·21	0·41	0·51	0·69	11·15	0·17	0·15	2·13	0·19	0·79	1·03	1·73
SiO_2	TiO_2	Cb_2O_5	Ta_2O_5	H_2O	ThO_2	UO_3	Y_2O_3	Er_2O_3	Ce_2O_3	La_2O_3	Di_2O_3	
0·12	0·68	32·02	11·18	1·22	1·73	11·23	7·83	13·37	0·25	0·37	1·56	

Analyses of samarskite have been made by O. D. Allen, J. L. Smith, B. Szilard, M. Delafontaine, R. Hermann, H. Rose, R. J. Strutt, G. H. Williams, T. S. Hunt, C. F. Rammelsberg, G. C. Hoffmann, Y. Shibata and K. Kimura, W. F. Hillebrand, W. C. Brögger and co-workers, G. P. Tschernik, and A. Lacroix; and analyses of yttrotantalite by C. F. Rammelsberg, W. C. Brögger, and G. P. Tschernik. Yttrotantalite usually contains rather more tantalum than samarskite. C. F. Rammelsberg gave the formula $(Fe'', Ca, UO_2)_3R_2(Cb,Ta)_6O_2$, where R represents the elements of the rare earths; P. Groth regards samarskite as a *pyrocolumbate* or *pyrotantalate,* $R_4[(Cb,Ta)_2O_7]_3$, where iron, calcium, and uranium are regarded as accessory constituents. A. des Cloizeaux considers the formula indefinite. Germanium was reported in samarskite by K. von Chrustchoff; and the rare earth samaria is also found therein. The sp. gr. is 5·6–5·8, and the hardness 5 to 6. A. L. Fletcher gave 1330° for the m.p. of samarskite.

The *nohlite* of A. E. Nordenskjöld is a brownish-black massive variety of samarskite, containing about 4·6 per cent. of water, and found near Nohl, Sweden. Its sp. gr. is 5·04, and hardness 4·5 to 5·0. The *loranscite* from Imbilax, Finland, analyzed by P. Nikolaéeff; the *plumboniobite* from Morogoro, West Africa, analyzed by O. Hauser; the *rogersite* of J. L. Smith from North Carolina; the *annerödite* of W. C. Brögger from Anneröd, Norway; the rhombic crystals of *hjelmite* or *hielmite* of sp. gr. 5·82, from Kirarfvet, Sweden, and analyzed by C. F. Rammelsberg and M. Weibull; and the *ampangabeite* of A. Lacroix from Ampangabé, Madagascar, are all closely related to samarskite, or to weathered products of that mineral. The dark brown or black crystals of plumboniobite are isotropic; the formula is $(Fe, Pb, Ca, UO_2)_2Cb_2O_7R_4(Cb_2O_7)_3$, where R denotes aluminium, the yttria earth elements. The yttria earths are rich in gadolina and samaria, the ceria earths are almost absent. The sp. gr. is 4·80 4·81, and the hardness 5·0 to 5·5. Unlike samarskite, it does not glow when heated. O. Hauser found the mineral to be radioactive and to give much occluded gas, including helium, when heated with sulphuric acid. Y. Shibata and K. Kimura found a mineral at Ishikawa, Japan, which they called *ishikawaite.* It occurs in black crystals carrying 8·40 per cent. rare earths; 21·88 per cent. UO_2; 36 per cent. Cb_2O_5; 15 per cent. Ta_2O_5; etc. The axial ratios of the rhombic crystals are $a:b:c$ $=0·9451:1:1·147$, the sp. gr. 6·2–6·4, hardness 5–6.

H. L. Giesecke[12] found a mineral in the quartz near Cape Farewell, Greenland, in 1806, and later, W. Haidinger named it **fergusonite**; the same mineral was found at Ytterby, Sweden. D. Forbes and T. Dahll found a similar mineral at Hampemyr and Helle near Arendal, Norway, and called it *tyrite;* and D. Forbes found a similar mineral at Helle, Narestö, Aloe, and Askerö, Norway, which they called *bragite.* J. A. Michälson and others have shown that these minerals are probably fergusonite. In addition to the occurrences in Norway and Sweden, and Greenland, the mineral has been reported at Rockfort, Massachusetts; Burke Co. and Amherst Co., North Carolina; Llano Co., Texas; Durayakanda, Kuriwita, and

Rakivana, Ceylon; Terek, Caucasus; between Tamatave and Beforona, Madagascar; Cooglegong, West Australia. Analyses have been made by B. Szilard, V. Hartwall, H. Weber, A. E. Nordenskjöld, J. J. Berzelius, D. Forbes and T. Dahll, J. Potyka, J. A. Michälson, C. F. Rammelsberg, J. L. Smith, W. H. Seamon, W. E. Hidden and J. B. Mackintosh, G. T. Prior, G. Tschermak, W. C. Brögger, G. S. Blake, A. Lacroix, and E. S. Simpson. The following analysis is by W. C. Brögger of a sample from Rade, Norway:

BeO	MgO	CaO	MnO	FeO	SiO_2	SnO_2	Cb_2O_5	Ta_2O_5	H_2O
0·40	0·05	1·23	0·15	0·78	1·44	0·98	39·30	6·25	4·00

and traces of zirconia, together with

$(Y, Er)_2O_3$	Ce_2O_3	$(La, Di)_2O_3$	ThO_2	UO_2
35·03	0·72	2·25	2·15	4·68

The mineral may be regarded as a columbate and tantalate of the rare earth metals with uranium, iron, calcium, etc. The idealized formula is $R(Cb,Ta)O_4$, where R denotes the metals of the rare earth group—chiefly yttria earths. W. C. Brögger gives the more complex formula $(Th,U)(Si,Sn)O_4.12R(Cb,Ta)O_4$. G. Hevesy and V. T. Jantzen found no hafnia in fergusonite. M. S. Curie, and R. J. Strutt studied the radioactivity of the mineral.

The brownish-black pyramidal crystals belong to the tetragonal system with the axial ratio $a:c=1·4643$. The sp. gr. is 5·84, which is smaller with the more hydrated specimens; the hardness is 5 to 6. A. L. Fletcher gave 1300° for the m.p. of fergusonite. W. Ramsay and M. W. Travers found the mineral contains 1·3 to 1·5 c.c. of helium per gram; and when heated to 500°–600°, it glows suddenly, giving off its helium, and decreasing in sp. gr. from 5·617 to 5·375; at the same time 8·92 Cals. per gram are evolved.

The **rutherfordite** obtained by C. U. Shepard from the gold mines of Rutherford, North Carolina; the **kochelite** obtained by M. Websky, and B. Szilard from the Kochelwese, Silesia; and the **adelpholite** obtained by N. Nordenskjöld from Finland, were probably all more or less altered fergusonites. The **sipylite,** found by J. W. Mallet in Amherst Co., Virginia, in 1877, and named after Sipylus, one of the sons of Niobe in allusion to the contained niobium (columbium), is closely related to fergusonite. The idealized formula given by J. W. Mallet is $R_2O_3.(Cb. Ta)_2O_5$, where the basic elements include, besides the rare earths, iron, calcium, etc. Some tungstic oxide is also present. R. J. Strutt found the mineral also contained 4·9 per cent. of thoria, and some uranium, radium, and occluded helium. The yellowish or greenish-brown mineral **risorite,** found in the granite of Risor, Norway, is considered by O. Hauser to be an orthocolumbate, $R(Cb,Ta)O_4$, with admixed isomorphous metatitanate, $R_2(TiO_3)_3$. It differs from fergusonite chiefly in the higher proportions of titanic oxide, in a higher loss on ignition, and in the almost complete absence of uranium. The rare earths are chiefly yttria with some erbia, and a little terbia; ceria, lanthana, and didymia are also present. The mineral is radioactive, and contains much occluded helium, which is unusual with minerals containing so little uranium and thorium. It was investigated by W. C. Brogger and co-workers. The mineral is isotropic in polarized light, but no good crystals have been obtained. The hardness is 5·5; and the sp. gr. 4·179 rises to 4·678 on ignition. A. L. Fletcher gave 1720° for the m.p. of the mineral.

J. J. Berzelius [13] discovered a black mineral at Miask, Urals, which appeared to be a columbate and titanate of rare earths, and other bases; he called it **aeschynite**—*αἰσχύνη*, shame—in illusion to the inability of chemists, at the time of its discovery, to separate titanium and zirconium oxides. It also occurs at Hitteröe, Norway; and a variety described by J. J. Berzelius was called *polymignite*. This mineral occurs at Fredriksværn, Norway, and at Beverley, Massachusetts. Polymignite was shown by H. Rose to be probably identical with aeschynite. When the ceria earths are replaced by yttria earths, a similar variety is obtained resembling polycrase in composition, but W. C. Brögger named it *blomstrandine—vide infra*. Analyses of aeschynite were made by V. Hartwall, W. C. Brögger, R. Hermann, J. C. G. de Marignac, R. J. Strutt, L. Schmelck, G. P. Drossbach, C. F. Rammelsberg, and G. Tschermak. The results show that it approximates to $2R(CbO_3)_3.2ThTiO_4.TiO_2$, where R respresents the rare earth metals partially replaced by iron (ous), and thorium by iron (ous) and calcium. R. J. Strutt found it contained uranium, radium, and helium. The rhombic crystals were examined by G. Rose, H. J. Brooke, and A. des Cloizeaux. N. von Kokscharoff gave $a:b:c=0·48665:1:0·67366$ for the axial ratios. The sp. gr. is 4·93–5·17, and the hardness 5 to 6. A. L. Fletcher found the mineral melted between 1245° and 1330°.

T. Scheerer,[14] in 1839, discovered a rare mineral which he named **euxenite**—εὔξενος, a stranger—in allusion to its scarcity. It was found at Jölster, Norway; and it has since been found in various places in Scandinavia, North Carolina, South Australia, etc. Analyses have been made by C. F. Rammelsberg, L. Schmelck, H. Lange, W. A. A. Prandtl, D. Forbes and T. Dahll, A. Strecker, J. J. Chydenius, J. C. G. de Marignac, C. J. Jehn, C. W. Blomstrand, L. A. Aars, B. Szilard, R. J. Strutt, O. B. Böggild, W. C. Brögger, E. S. Simpson, O. Hauser and F. Wirth, G. T. Prior, H. Lange, A. Lacroix, K. A. Hofmann, etc. G. Tschermak gave for a sample from Caucasus:

CaO	Fe_2O_3	$(Y, Er)_2O_3$	Ce_2O_3	La_2O_3	Di_2O_3	SiO_2	TiO_2	U_2O_3	Cb_2O_5
0·44	3·24	11·20	8·53	0·55	0·48	7·03	33·31	11·11	22·20

with a trace of thoria, and 0·93 per cent. of water. This makes the mineral a titano-columbate of uranium and the rare earths, $Y_2Ti_4O_{11}.2(Ca, Fe)Cb_2O_5.(UO_2)Cb_2O_5$, or $Y_2Ti_4O_{11}.R''Cb_2O_6$. J. J. Chydenius also found thoria in a sample of the mineral, but only traces of ceria. G. Hevesy and V. T. Jantzen found no hafnia in euxenite. According to B. B. Boltwood, euxenite is usually radioactive, and contains helium. G. Krüss reported germanium in euxenite, but G. Lincio could find none. K. A. Hofmann and W. A. A. Prandtl believed that they had discovered a new element in euxenite, and named it euxenium, but O. Hauser and F. Wirth showed that in all probability some mistake had been made. The rhombic crystals, according to W. C. Brögger, have the axial ratios $a:b:c=0·3789:1:0·3527$; the sp. gr. is 4·6–5·4; the hardness, 5·0–6·5. A. L. Fletcher found the mineral melted at about 1375°. T. Scheerer discovered a related mineral in the granite of Hitterö, Norway, and near Dresden. He named it **polycrase**—πολύς, many; κρᾶσις, mixture. Analyses were made by T. Scheerer, C. F. Rammelsberg, W. E. Hidden and J. B. Mackintosh, and C. W. Blomstrand. Polycrase and euxenite are isomorphous. According to W. C. Brögger, the ratio of the acidic oxides $Cb_2O_5:TiO_2$ is nearly 1 : 2 in euxenite, but in the analyses of euxenite and polycrase this ratio ranges from 1 : 2 to 1 : 5, or, according to H. Lange, from 1 : 2 to 1 : 6. There is a continuous variation in composition between these limits, and the members of the isomorphous series are regarded as solid soln. with the unknown meta-columbate and metatitanate as end-terms of the series. W. C. Brögger suggests that the name euxenite be reserved for the minerals with the ratio $Cb_2O_5:TiO_2$ between 1 : 2 and 1 : 3, and polycrase for those with the ratio less than 1 : 4. A. L. Fletcher gave 1420° for the m.p. of polycrase. The isomorphous euxenite-polycrase series is dimorphous; and there is a parallel series of similar composition with **priorite** analogous with euxenite and **blomstrandine** analogous with polycrase. These two types were discussed by W. C. Brögger and co-workers; they belong to the rhombic system and have axial ratios $a:b:c=0·4746:1:0·6673$; the sp. gr. ranges from 4·82 to 5·00. Analyses have been made by G. T. Prior, O. Hauser and H. Herzfeld, B. Szilard, and W. C. Brögger. A bibliography has been compiled by J. Schilling.

F. Wöhler[15] found a columbate of calcium, cerium, etc., in the syenite at Fredriksvärn and Laurvig, Norway; it also occurs near Brevig, Alnö, and Sundsvall, Sweden; Tschoroch, Caucasus; and near Miask, Urals. It was named **pyrochlore**—πῦρ, fire; χλωρός, green—in allusion to its colour before the blowpipe flame. Analyses have been made by C. F. Rammelsberg, R. Hermann, F. Wöhler, B. Szilard, J. J. Chydenius, G. Tschermak, P. J. Holmquist, and K. von Chrustchoff. A sample from the Urals furnished the last-named with the analysis:

Na_2O	K_2O	CaO	FeO	TiO_2	$(Cb, Ta)_2O_5$	F
3·35	0·87	14·05	2·52	8·32	56·01	2·77

with traces of zirconia and magnesia, and the rare earths:

$(Y, Er)_2O_3$	Ce_2O_3	Di_2O_3	La_2O_3	UO	ThO_2
0·56	2·16	1·94	1·23	2·63	4·28

The presence of water is probably due to a secondary action. A. L. Fletcher gave 1340° for the m.p. of pyrochlore. R. Hermann called the varieties containing water **hydrochlore**, and those containing fluorine **fluochlore.** The brown octahedral crystals belong to the cubic system. The sp. gr. is 4·2 to 4·4; and the hardness 5·0–5·5. The thermoluminescence has been studied by W. Ramsay and T. Liebisch. P. J. Holmquist synthesized the mineral by melting together calcium chloride, columbic acid, and sodium fluoride. The crystals had the composition $NaCaCb_2O_6F$.

S. Weidman and V. Lenher found brown octahedral crystals of a mineral in the pegmatite near Wausau, Wisconsin. The mineral was named **marignacite.** The sp. gr. was 4·13; and hardness 5·0–5·5. Analysis gave:

Cb_2O_5	Ta_2O_5	SiO_2	TiO_2	Fe_2O_3	FeO	CaO	MgO	Na_2O	K_2O
55·22	5·86	3·10	2·88	0·50	0·02	4·10	0·16	2·52	0·57

Water above 110°, 5·95, and below 110°, 0·45 per cent. The rare earth contents were Ce_2O_3, 13·33; Y_2O_3, 5·07; and ThO_2, 0·20 per cent. Traces of alumina, manganese, tin, tungsten, didymia, lanthana, and erbia are reported. Marignacite thus differs from other members of the pyrochlore group in containing more cerium and yttrium and less calcium and iron; also in the presence of a little silica, suggesting a relation to the titanosilicates. The water, no doubt, represents hydroxyl, isomorphously replacing fluorine, which is here absent. It was also studied by B. Szilard. It is insoluble in acids. The **loranscite** of M. P. Meinikoff and P. D. Nikolajeff, found near Imbilax, Finland, is closely related to euxenite; it contains 3·0 per cent. of ceria, 10·0 per cent. of yttria, 20·0 per cent. of thoria earths. Its sp. gr. is 3·8 to 4·8; and the hardness 6. W. Ramsay and A. Zilliacus, L. J. Spencer, and W. Crookes referred to a mineral which H. Börgström considered as belonging to a group of minerals containing loranscite, and he called the group **wiikite.** It is a columbatotitanosilicate of iron and the rare earths. According to H. Börgström, the rhombic crystals have the axial ratios $a : b : c = 0·5317 : 1 : 0·5046$. A. L. Fletcher gave 1250° for the m.p. of wiikite.

The minerals **blomstrandite, betafite,** and **samiresite** closely resemble pyrochlore. They occur in octahedra. Blomstrandite occurs massive at Nohl, Sweden, and in crystals at Tongafeno, Madagascar G. Lindström analyzed the former, A. Lacroix the latter; *betafite,* from Ambolotora, Madagascar; and *samiresite,* from Samiresy, Madagascar, were analyzed by A. Lacroix. They contain more uranium and less alkalies than pyrochlore; otherwise their properties are similar. They contain from 0·2 to 3·0 per cent. of rare earths; up to 1·30 per cent. thoria; 18·1 to 26·6 per cent. U_3O_4; bismuth oxide, up to 0·4 per cent.; lead oxide, up to 7·35 per cent.; nearly 50 per cent. of tantalic and columbic oxides; 6·7 to 18·3 per cent. titanic oxide; up to 0·3 per cent. stannic oxide; etc. O. Hauser and H. Herzfeld, and B. Szilard studied blomstrandite. C. U. Shepard found yellow octahedral crystals of calcium tantalate and columbate in the albite at Chesterfield, Mass., and called the mineral **microlite**—μικρός, small—in allusion to the size of the crystals. Micromerite also occurs at Utö, Sweden; Amelia, Virginia; Igaliko, Greenland; and West Australia. It is a kind of pyrochlore with a high proportion of tantalic acid. It was analyzed by C. U. Shepard, A. A. Hayes, F. P. Dunnington, A. E. and G. Nordenskjöld, and E. S. Simpson. The sp. gr. is 5·405 to 5·656; and the hardness 5·5. The Virginia sample analyzed by F. P. Dunnington gave:

Na_2O	K_2O	BeO	MgO	CaO	Fe_2O_3	Al_2O_3	WO_3	SnO	$(Cb, Ta)_2O_5$
2·86	0·29	0·34	1·01	11·80	0·29	0·13	0·30	1·05	76·17

and 1·17 of water; 2·83 of fluorine; 1·59 of UO_3; 0·23 of yttria earth; and 0·17 of ceria earth. J. L. Smith, and O. D. Allen found octahedral crystals of a calcium columbate and tantalate in the mica mine, Mitchell Co., North Carolina. They called the mineral **hatchettolite.** It is closely related to pyrochlore. Its sp. gr. is 4·77–4·90; and its hardness, 5. Analyses showed 0·86 per cent. yttria earths; 7·09, calcium oxide; 15·63, uranic oxide; 1·61, titanic oxide; 67·86, of columbic and tantalic oxides; etc. A. Knop found a mineral in the limestone near Schelingen, Baden, which resembled pyrochlore but contained no titanic oxide, and little or no fluorine. He called it **koppite.** Analyses have been made by A. Knop, and G. H. Bailey. It contains 6·89–10·10 per cent. of ceria earths; 61·64–61·90, tantalic and columbic oxides; 16·00–16·61, calcium oxide; etc. The sp. gr. is 4·45–4·56. The **neotantalite** of P. Termier obtained from Allier, France, occurs in octahedral crystals and appears to be closely related to the above. The **pyrrhite**—πυρός, yellowish-red-like fire—of G. Rose, found as octahedral crystals at Alabaschka in *the Urals, is considered to be closely related with microlite.* Likewise also with the orange-red octahedral crystals—called by J. D. Dana, **azorite**—found by G. vom Rath, J. E. Teschemacher, A. Osann, and A. Corsi in the albite rock at San Miguel, Azores; by L. L. Hubbard, at Laacher See; and by W. C. Brögger at Moss and Kragerö, Norway—*vide* the zirconatosilicates.

A red silicotantalate of yttrium metals with cerium, aluminium, iron, calcium, beryllium, etc., which occurs at Ytterby, Sweden, is an amorphous decomposition product. It has been called **arrhenite,** and was investigated by A. E. Nordenskjöld, and N. Engström. It contains yttria earths, 33·2 per cent.; ceria earths, 2·6; tantalic oxide, 21·28; columbic oxide, 2·67; alumina, 3·88; ferric oxide, 1·87; silica, 17·65; zirconia, 3·42; beryllia, 0·74; calcium oxide, 5·22; and water, 6·87 per cent. Its sp. gr. is 3·68. G. Flink, and O. B. Boggild and C. Winther found in the same locality a mineral which was called **endeiolite,** it contains 4·43 of the rare earths, and 3·78 per cent. of zirconia. Its approximate formula is $RCb_2O_6(OH)_2.RSiO_3$—*vide* the columbatosilicates.

Fluorine is the only halogen which occurs in nature in combination with the rare earths. The chlorine in eudialite is probably of secondary origin, and is possibly part of the zirconyl radicle, ZrOCl. T. Scheerer[16] emphasized the fact that except in a few cases the rare earth minerals occur in igneous rocks, particularly the granites, which have undergone metamorphosis. In a few cases where erosion has occurred, the secondary formation has in all probability been derived from plutonic rocks of great age. G. Eberhard has found that the age and nature of the common rocks has no influence on the traces of the contained scandia and yttria earths; but rare earth minerals are usually very stable and have been formed by the metamorphosis of granites. The occurrence of fluorine in the rare earth minerals is also in agreement with the assumption that they have formed during the pneumatolytic metamorphism of plutonic rocks.

The mineral **yttrocerite** was discovered by J. J. Berzelius and J. G. Gahn.[17] It is found massive or granular, and coloured white, violet-blue, or reddish-brown; and it occurs sparingly in different parts of Scandinavia. G. Gibbs found it in New Jersey; C. T. Jackson in Massachusetts; and W. F. Pettard in Tasmania. Its composition corresponds with a mixture of ceria and yttria earth fluorides with calcium fluoride approximating $2CeF_3.4YF_3.9CaF_2.2H_2O$; or $5RF_3.9CaF_2.2H_2O$. Analyses were also made by C. F. Rammelsberg, and C. T. Jackson. G. Tschermak's analysis of violet-blue crystals of yttrocerite from Colorado gave:

Ce_2O_3	Y_2O_3	CaO	H_2O	F
18·19	29·36	27·61	1·96	37·69

with traces of $Al_2O_3.SiO_2$. The proportions of ceria earths range from 9·3 to 18·19, and the yttria earths from 8·1 to 29·36 per cent. Hence yttrocerite has been regarded as fluorspar in which part of the calcium has been replaced by the ceric or yttria earth metals. E. F. Glocker called it *yttrocalcite*. The hardness is about 4·5, and the sp. gr. 3·45. A. L. Fletcher found yttrocerite infusible below 1510°. The powdered mineral readily dissolves in boiling hydrochloric acid and more readily still in hot sulphuric acid. T. Vogt discovered a mineral in the pegmatite vein of Northern Norway; it is related to yttrocerite, but contains less cerium and more yttrium. Hence he called it **yttrofluorite.** It also contains less water than yttrocerite. His analysis is:

Ce_2O_3	Y_2O_3	CaO	Alkalies	H_2O	F
1·68	17·35	54·89	0·15	0·67	45·54

T. Vogt regards the mineral as an isomorphous mixture of calcium fluoride with yttrium fluoride together with cerium fluoride, where the terms yttrium and cerium represent the corresponding groups of rare earths metal. This hypothesis explains the frequency in the occurrence of the rare earths in fluorspar. The crystals belong to the cubic system. The sp. gr. is 3·5356 to 3·5572, the hardness 4·5; the index of refraction for Na-light, 1·4522–1·4572. E. Dittler also studied the mineral.

J. J. Berzelius[18] found a basic fluoride of ceria and yttria earths at Finbö and Broddbö, Sweden; and called it *basisk flussopatssyradt cerium*. W. Haidinger's term **fluocerite** is now generally employed. It contains from 81·43 to 82·64 per cent. of ceria earths, and 1·12 to 4·30 per cent. of yttria earths. M. Weibull gave the formula $(Ce, La, Di)_2OF_4$. The mineral is very scarce. It occurs in hexagonal crystals of sp. gr. 5·7–5·9, and hardness 4. A. Hadding studied the X-radiogram of fluocerite. The yellow *hydrofluorite* from Finbö is probably a weathered product containing cerium hydroxide and fluoride. F. W. Clarke,[19] and W. F. Hillebrand and W. E. Hidden described a mineral from the pegmatite of Llano Co., Texas, which they called **rowlandite.**

$(Na, K)_2O$	MgO	CaO	MnO	FeO	Fe_2O_3	SiO_2	H_2O	F	CO_2
0·28	1·62	0·50	0·67	4·39	0·09	26·04	0·24	3·87	0·34

with a trace of phosphoric oxide, uranium and titanium oxides, 0·39 per cent. of matter undetermined; and

Y-group	La-group	Ce_2O_3	ThO_2
47·70	9·34	5·06	0·59

They gave the formula $R''R_4Si_4O_{14}F_2$, where R is tervalent and R″ bivalent. W. C. Brögger gave $R''(RF)_2R_2(Si_2O_7)_2$; and P. Groth, $(Fe, Mg)(Y, Ce, La)(YF)_2(Si_2O_7)_2$.

J. J. Berzelius[20] found greyish-white, pink, or yellow crystals of *kohlensaures Cereroxydul* coating some cerite at Bastnäs, Sweden. W. Hisinger, and F. S. Beudant made some observations on the mineral; the latter called it *carbocérine.* W. Haidinger called the mineral **lanthanite.** It has also been found at Bethlehem, Pennsylvania; and at Moriah, Essex Co., New York. The mineral is essentially a carbonate of the ceria earths, chiefly lanthana. Analyses have been made by G. Lindström, J. L. Smith, F. A. Genth, and C. F. Rammelsberg. The first-named gave for the Bastnäs mineral:

Y_2O_3	$(La, Di)_2O_3$	Ce_2O_3	CO_2	H_2O
0·79	28·34	25·52	21·95	23·40

The analyses correspond with the enneahydrated carbonate, $(La, Di, Ce)_2(CO_3)_3.9H_2O$, but since P. T. Cleve, and C. Morton made the isomorphous octohydrated didymium salt, he concluded that lanthanite is octohydrated. R. Hermann, and F. A. Genth synthesized lanthanum carbonate. K. F. A. Hartmann called the mineral **hydrocerite,** and E. F. Glocker, **hydrolanthanite.** Lanthanite is usually amorphous; but tabular crystals have been examined by V. von Lang, and W. P. Blake; they are rhombic, with axial ratios $a : b : c = 0·9528 : 1 : 0·9023$. The sp. gr. is 2·6–2·7, and the hardness 2. It is readily soluble in acids.

A. F. Svanberg obtained a chalk-like alteration product, which he regarded as *kolsyrad Ytterjord*, as a thin film on gadolinite at Ytterby. J. D. Dana called it **tengerite**; it has also been called yttria spar. F. A. Genth's analysis of a sample from Llano Co, Texas, sp. gr. 3·592, is:

CaO	MnO	BeO	Fe_2O_3	$(Ce, Di, La, Y, Er)_2O_3$	SiO_2	Loss on ignition
5·58	0·22	6·03	14·53	39·20	1·03	9·30

G. Flink found crystals of a hydrated carbonate of cerium and strontium at Narsaruk' Greenland, and called it **ancylite**—ἀγκύλος, sinuous—in reference to the sinuous surface of the crystals. The analysis is:

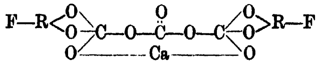
CaO	FeO	SrO	$(La, Di)_2O_3$	Ce_2O_3	CO_2	ThO_2	H_2O
1·50	0·35	21·03	24·04	22·22	23·28	0·20	6·52

with insoluble matters, 0·60; and there are traces of fluorine. The corresponding formula is $4R(OH)CO_3.3H_2O$. The brown octahedral crystals belong to the rhombic system, and have the axial ratios $a : b : c = 0·916 : 1 : 0·9174$. The sp. gr. is 3·95, and the hardness 4·5.

A brownish-yellow or red crystalline mineral found in 1835 in the emerald mines of Muso or Muzo Valley, New Granada, and in the collection of L. de Medici-Spada, was analyzed by R. Bunsen[21] in 1845. The mineral was at first called *musite* or *mussite*, but since a variety of amphibole had the same name, the mineral was designated **parisite,** from J. J. Paris, the proprietor of the mine. W. C. Brögger found it at Langesund, Norway; G. Nordenskjöld, at Narsarsuk, Greenland; S. L. Penfield, and C. H. Warren, in Ravalli Co., Montana; C. Palache, and C. H. Warren, at Quincy, Massachusetts; and G. P. Tschernik, at Mukden, Manchuria. Analyses have also *been made by A. Damour and H. St. C. Deville, S. L. Penfield and C. H. Warren,* T. Korovaeff, etc. The analysis by C. H. Warren of a specimen from Quincy, Massachusetts, is:

Na_2O	K_2O	CaO	Fe_2O_3	La_2O	Ce_2O_3	CO_2	F	Gangue
0·30	0·20	11·40	0·32	27·31	30·94	24·16	6·56	102

C. F. Rammelsberg said in 1875 that the available data do not suffice to deduce the constitution of this rare mineral. The best analyses make the mineral a fluocarbonate of calcium and the metals of the ceria earths, $CaR_2F_2(CO_3)_3$. S. L. Penfield and C. H. Warren gave the formula $2RFCO_3.CaCO_3$, or $(RF)_2Ca(CO_3)_3$, which is given graphically:



P. Groth gave $(CaF)(RF)R(CO_3)_3$; and J. Schilling, $Ce_2(CO_3)_3.CaF_2$. R. Bunsen stated that the crystals belong to the hexagonal system, and have the axial ratio $a:c=1:3·2808$; A. des Cloizeaux gave $1:3·289057$; and K. Vrba, $1:3·36456$. The crystals are now considered to belong to the trigonal system which makes the axial ratios $a:c=1:1·9425$. G. Aminoff found that the spots of the X-radiogram did not change in position after the expulsion of carbon dioxide by ignition, and he therefore inferred that there is no displacement of the atoms or distortion of the structure. The symmetry is dihexagonal, and the at. distance in the direction of the c-axis is $11·9\times10^{-8}$ cms. The sp. gr. of the specimens analyzed by the different investigations range from 4·129 to 4·358. K. Vrba obtained 4·364; the hardness is 4 to 5. The double refraction, according to A. des Cloizeaux, is strongly positive, $\omega=1·676$, $\epsilon=1·757$, and $\epsilon-\omega=0·081$. With the spectromicroscope, crystals of parisite give the characteristic absorption bands of didymium—*vide infra*—illustrated by Fig. 2.

G. Nordenskjöld described as parisite a mineral from Narsarsuk, Greenland, but G. Flink regarded it as a new species with the composition $R_2F_2Ca_2(CO_3)_4$, *i.e.* the same as parisite plus another mol of calcium carbonate; he named it *synchisite*—σύγχυσις, confusion—in allusion to its having been confused with parisite. C. Palache, and C. H. Warren noted the extraordinarily close resemblance between the physical and crystallographic properties of parisite and synchisite, and suggested that G. Flink's material must have been parisite mixed with some calcium carbonate. This mineral was investigated by G. Flink, R. Mauzelius, O. B. Boggild, etc. G. Aminoff made similar observations on the X-radiograms of synchisite as those made on parisite. E. Quercigh concluded that the sp. gr., the optical properties, and the composition of the two minerals make their identity practically certain.

G. Flink discovered at Narsarsuk, Greenland, a barium-parisite which closely resembled ordinary parisite excepting that barium replaced the calcium. It was called **cordylite**—κορδύλη, a club—in allusion to the shape of the crystals. The analysis of the yellow crystals is:

CaO	FeO	BaO	$(La, Di)_2O_3$	Ce_2O_3	CO_2	ThO_2	F	H_2O	Gangue
1·91	1·43	17·30	25·67	23·72	23·47	0·30	4·87	0·80	2·58

and the formula $(RF)_2Ba(CO_3)_3$. The axial ratio of the hexagonal crystals is $a:b:c=1:1:1·1288$, and they are isomorphous with those of parisite. The sp. gr. is 4·31; the hardness, 4 to 5; and, according to O. B. Böggild, the indices of refraction are $\omega=1·7640$, and $\epsilon=1·5762$. B. Szilard examined this mineral.

In 1838, W. Hisinger found that a mineral from Bastnäs, Sweden, corresponded in composition with a hydrated fluoride of the cerium metals, and J. J. N. Huot named it **bastnäsite**—this mineral also shows the didymium absorption bands, Fig. 1. T. Karawajeff obtained a mineral—named *kischtimite*—from the alluvial sands of the Barsorka River, near Kischtim, Urals, which he named *Kischtim-parisite* because it contained carbon dioxide in place of water given in W. Hisinger's analysis. G. Nordenskjöld showed that the loss on ignition assumed by W. Hisinger to be water was really carbon dioxide, and hence, in ignorance of J. J. N. Huot's term, he proposed to call the mineral *hamartite*—ἁμάρτω, I deceive myself. O. D. Allen and W. J. Comstock found a sample—which they called *tysonite*, after the discoverer S. T. Tyson—at Pike's Peak, Colorado. This mineral was afterwards identified with bastnäsite by W. F. Hillebrand, and F. W. Clarke. G. Nordenskjöld's analysis of a sample from Bastnäs is :

Ce_2O_3	$(La, Di)_2O_3$	CO_2	F
29·94	45·77	19·50	7·42

This agrees with the formula $RFCO_3$. Analyses made by T. Karawajeff, W. Hisinger, F. Radominsky, B. Szilard, W. E. Hidden, W F. Hillebrand, and O. D. Allen and W. J. Comstock are in general agreement ; though the ceria earths range from 64·0 to 93·5 per cent., and thoria from 0 to 10 per cent. According to A. des Cloizeaux, the prismatic crystals are hexagonal. The sp. gr. ranges from 4·784 for the sample from Kischtim ; to 4·93 for the sample from Bastnäs ; to 5·20 for the sample from Colorado. The hardness is 4 to 5. The double refraction is strongly positive. W. C. Brögger found on Oevre Arö of Langesund Fiord, Norway, a very small specimen of a mineral which he named **weibyite**—after P. C. Weibye. The imperfect analysis shows it to be a fluocarbonate of the rare earth metals with calcium, and strontium. It contains 66·96 per cent. of ceria earths. The mineral is allied to parisite and bastnäsite, and the pyramidal crystals belong to the rhombic system with axial ratios $a : b : c = 0·9999 : 1 : 0·64$.

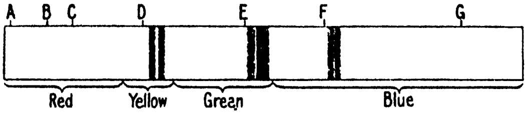


Fig. 1.—Absorption Spectrum of Monazite.

Prior to the invention of the rare earth gas-mantle in 1885, there was practically no demand for **monazite** ; the small quantity required was obtained at a high price from the deposits of Scandinavia, and the Urals. With the advent of C. A. von Welsbach's gas-mantle, there was a great demand for ceria and thoria earths, and a systematic search was made for sources of the rare earths, and it was found that these earths are not at all so rare as the name implies. From the commercial point of view, the most important source of the rare earths is monazite—μονάζω, to be solitary—so named because, when first discovered, it was considered to be of extremely rare occurrence. Although monazite is essentially an orthophosphate of the ceria earths, RPO_4, yet its commercial value depends upon the percentage of thoria present. The amount of thoria ranges up to about 20 per cent. There is some confusion in the early history of monazite because a number of minerals which were given different names were not recognized as belonging to the same mineral species.

The spelling *monacite* is but a corruption of the original. A. Lévy [22] first described a specimen from E. Turner's collection and it was labelled as a variety of sphene from Dauphiné ; A. Lévy named it *turnerite*. J. D. Dana noted the resemblances between turnerite and the mineral afterwards named monazite, and said that " they may be the same species." This hypothesis was established by F. Pisani in 1877. Meanwhile, in 1826, A. Breithaupt applied the term monazite to a mineral accompanying the zircon in a granite of Miask, Urals. The same mineral was described as *mengite* by H. J. Brooke in 1831. In 1837, C. U. Shepard described a basic sesquiphosphate of the protoxide of cerium from South Carolina, and gave it the name *edwardsite*, and another variety from Connecticut he called *eremite*—ἐρημία, solitude—in allusion to the isolated occurrence of the crystals. He found the specimens were accompanied by zirconia, alumina, and silica as impurities. G. Rose, in 1840, showed that the American minerals were the same as monazite. In 1846, F. Wöhler found acicular crystals and grains of a wine-yellow mineral in the apatite of Arendal, Norway, from which it could be separated by dissolving the latter in dil. nitric acid. The mineral was called *cryptolite*—κρυπτός, concealed. E. Mallard found the physical properties of cryptolite and monazite to be identical. A variety from Kärarfvet, Sweden, was called *kärarfvetite*. R. Hermann, 1847, called the brown mineral he obtained from the Ilem Mountains, *monazitoid* ; H. Watts, 1849, called the greyish-yellow crystalline powder which he found in the cobalt ore of Tunaberg, *phosphocerite* ; and D. Forbes and T. Dahll, 1855, called the crystalline mineral which they obtained near Nöterö, Norway, *urdite*.

J. Schilling said that monazite is one of the most widely disseminated minerals in the earth's crust. Comparatively large crystals of monazite are found embedded in the felspar of the veins of pegmatite in the Ilmen Mountains, Urals; and in several places in South Scandinavia; in the gneiss of Carolina and Georgia; etc. Small crystals occur in the crevices of some rocks. It occurs massive and granular in veins in granite associated with wolframite, cassiterite, and molybdenite on the Walsh and Tinaroo mineral fields of Queensland. Massive and granular monazite were found by F. Freise in the pegmatite veins of the granite of the Aymore Mountains, Espirito Santo, Brazil. More usually, monazite occurs in small proportions as an accessory constituent of the older crystalline rocks—granites, diorites, gneisses, etc.—belonging to the Archæan or pre-Cambrian Age, and in no rocks younger than the Mesozoic Age. The monazite may occur in the veins of crystalline matter in these rocks, or it may occur in small crystals disseminated through the whole mass of rocks. Monazite is found among the débris formed by the disintegration of the monazite-bearing rocks owing to the action of weathering and eroding agents. The unweathered fragments may have been washed away by the rivers and streams, or by the waters of the ocean. The water-borne fragments have been re-deposited so that the heavier particles with a high sp. gr. have been separated from the lighter particles of less sp. gr. The monazite grains of high sp. gr. have thus been concentrated by nature in deposits from which the water may have since receded. The grains of monazite are thus collected by nature along with the heavier constituents of the parent rock to form monazite sands which are found in the alluvial deposits of rivers, and on the sea-shore exactly like the concentration of platinum and gold in alluvial sands, or of precious stone in the so-called gem-gravels. The monazite in these sands may be in angular fragments, but it is more usually present in rounded grains—Fig. 2—showing that the grains have previously been rolled to and fro in streams of water. Monazite sands therefore represent nature's attempt to concentrate the heavier accessory constituents of the parent rock. Hence, monazite sands contain grains of zircon, rutile, ilmenite, sphene, and apatite. There are also present grains of garnet, epidote, sillimanite, tourmaline; and a number of rare earth minerals—xenotime, fergusonite, samarskite, gadolinite, and allanite. There are also present grains of ferric oxide; tin oxide; and much quartz. Often, too, the parent rocks are auriferous, and the particles of gold then accumulate with the heavier minerals. Monazite is thus almost universally present in the auriferous and gem-bearing sands and gravels.

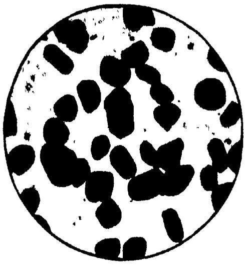

FIG. 2.—Water-worn Grains of Monazite Sand.

Monazite sands occur near Arendal, Moss, Lönneby, Dillingsö, Hvalö, etc., in Norway; Holma, Kärarfvet, etc., in Sweden; Imilaks in Finland; Miask and Batoum in the Urals; Pisel in Bohemia; Travancore in India; in the gem-gravels of Bentota, and Kudremalai in Ceylon; Mindarivo and Antyiabé in Madagascar; in the beach sands, Queensland; Emmaville and Vegetable Creek in New South Wales; Victoria; in the beach sands, the diamond-bearing sands, and the auriferous sands of Minas Geraes, Bahia, and Espirito Santo in Brazil; in the sands derived from the gneiss rocks of Carolina, and Georgia; in the auriferous sands of Idaho, Oregon, Portland in Connecticut, Amelia Co. in Virginia, and in many of the Pacific States; in the stanniferous sands of Embabaan, Swaziland; in the alluvial tinstone of Pahang, Puchong Babi, Kulim Kedah, and Kelantan, Federated Malay States; the river sands near Chiromo, Nyasaland; the river sands of Ekole, Kadera, Naraguta, Iboboto River, and Ebara River, Nigeria; Ottawa, Canada; Transvaal in South Africa; etc. The deposits of monazite sand on the coast of Brazil, North and South Carolina, and Travancore have been worked. So also have other deposits. According to E. H. Pascoe, the total production of monazite commenced in Ceylon

In 1918 to 1922, when the works closed down, was 235 tons. The exports from Brazil in 1920 was 1153 metric tons; the United States production was very small (34·7 metric tons in 1917); Travancore commenced producing in 1911, when it furnished 819 metric tons, and in 1921, 1280 tons. A great many factors determine whether a deposit can be worked profitably—transport, cost of labour, selling price of finished product, the manipulation of prices by competing syndicates, etc.

The monazite in the sands is not sufficiently concentrated for them to be used directly as a source of thoria. The sands are therefore subjected to a further washing, and magnetic or electrostatic concentration processes are applied before the chemical treatment. In some of the best of these processes, the concentrate contains 97–99 per cent. monazite. This subject has been discussed by J. H. Pratt and D. B. Sterrett. In the magnetic concentration, the sand traverses, say, four magnetic fields of increasing intensity—the first removes the magnetite, larger fragments of ilmenite and garnet; the second removes the remaining ilmenite and garnet; the third removes the coarser: and the fourth, the finer monazite; while the tailings, containing zircon, rutile, and quartz, pass on. The tailings from the Travancore sands are used in the preparation of zirconia. Efforts have been made to supersede nature's preliminary concentration of monazite, by crushing the gneiss rocks of Carolina; but even with the richest rock—containing 0·2 per cent. of monazite—the working costs are too high to compete with processes based on the concentration of the monazite sands.

Analyses of monazite have been made by C. Kersten, R. Hermann, A. Damour, C. F. Rammelsberg, C. W. Blomstrand, F. Radominsky, W. Ramsay and A. Zilliacus, K. Preis, A. Lacroix, L. A. Aars, P. Wenger and P. Christin, L. Schmelck, W. Prinz, R. J. Strutt, W. R. Dunstan, B. Szilard, F. Katzer, W. Lindgren, L. Duparc, R. Sabot and M. Wunder, E. Hussak and J. Reitinger, H. Gorceix, S. L. Penfield, F. P. Dunnington, A. Thorpe, F. A. Genth, G. P. Tschernik, A. Liversidge, J. C. H. Mingaye, C. Anderson, S. J. Johnstone, J. Bjelussoff and S. Kusnezoff, H. B. C. Nitze, C. Glaser, A. H. Church, E. S. Sperry, G. C. Hoffmann, G. P. Drossbach, R. J. Gray, O. Boudouard, O. Kress and J. F. Metzger, etc. The maximum and minimum values are calcium oxide, 0·10–1·58 per cent.; magnesium oxide, 0–0·40; manganese oxide, 0–4·89; lead oxide, 0–0·34; ferrous oxide, 0–1·10; ferric oxide, 0–5·58; alumina, 0–3·11; yttria earths, 0–7·69; lanthana earths, 6·56–40·79; ceria earths, 16·30–45·40; silica, 0·32–6·68; stannic oxide, 0–9·03; zirconia, 0–15·44; thoria, 0·46–28·20; uranium oxide, 0–1·0; phosphoric oxide, 18·89–29·92; tantalic and columbic oxides, 0–6·39; fluorine, 0–4·35; loss on ignition, 0·09–2·76 per cent. A selection of particular samples is given in Table V.

TABLE V.—ANALYSES OF MONAZITE.

The analyses can be regarded as representing only monazite plus more or less foreign inclusions. The ratio of the isomorphous ceria and lanthana earths is not *constant. The idealized mineral, as first suggested by C. U. Shepard, is considered to be an orthophosphate of ceria earths,* RPO_4. *O. Mann represents the formula by* $m\mathrm{Th}_3(\mathrm{PO}_4)_4.n(\mathrm{Ce, La, Pr, Nd})_4(\mathrm{PO}_4)_4$, where the first component is regarded as the primary constituent from which thorite is formed by weathering. F. Radominsky synthesized cerium orthophosphate, and obtained large yellow prisms; the analysis corresponded with RPO_4; if yttria and didymia be absent, the crystals are colourless. C. James has applied the bromate method to the fractionation of the rare earths derived from the monazite sands of Carolina, and found that in addition to lanthanum, cerium, praseodymium, and neodymium, these sands contain considerable quantities of samarium, gadolinium, and yttrium; small amounts of dysprosium, holmium, and erbium; and minute amounts of europium, terbium, thulium, and ytterbium. Erbium occurs in much smaller quantities than holmium and dysprosium, and this fact probably accounts for the anomalous behaviour of certain fractions which has been observed by some workers.

There has been some discussion as to the relation of thoria to monazite. F. P. Dunnington suggested that orangite, $ThSiO_4$, was mechanically mixed with the monazite, and that thoria is not an essential constituent. S. L. Penfield supported this conclusion, and claimed (i) to have detected particles of thorite or orangite microscopically, and (ii) found that the ratio $R_2O_3 : P_2O_5$ is unity—R denoted the rare earth metals—and also (iii) that the ratio of $ThO_2 : SiO_2$ is also unity. K. Preis supported S. L. Penfield's hypothesis; but C. W. Blomstrand objected. He found that silica is never absent, but its amount does not depend on the amount of thoria which is present, but rather on the amount of phosphorus pentoxide; the thoria present is combined partly with the silica and partly with the phosphorus pentoxide; and finally, the rare earths alone are not sufficient to satisfy the ratio $R_2O_3 : P_2O_5 = 1$. The thoria is therefore regarded as a primary constituent of monazite occurring as phosphate in isomorphous admixture with the cerium phosphate; the presence of silica is attributed to alteration by siliceous waters. O. Kress and F. J. Metzger also found that silica is always present, and although it usually increases with the amount of thoria, the increase is not regular; in the majority of cases, the amount of silica is quite insufficient to combine with the thoria present. They concluded that the silica which is present belongs to some unidentified silicate other than normal thorium silicate and possibly felspar. No biaxial thorite could be observed microscopically in the monazite, nor was there any evidence of a dark resinous constituent mentioned by S. L. Penfield. S. J. Johnstone showed that analyses of monazite from monazite sands are not valid in the argument owing to the risk of inclusions, and only analyses on massive monazites such as those from Ceylon can be considered; and these analyses do not support S. L. Penfield's hypothesis. There is not always sufficient phosphoric oxide to combine with the thoria and rare earths, and this does not favour O. Kress and F. J. Metzger's hypothesis. C. F. Rammelsberg, and S. J. Johnstone concluded that there is in monazite a thorium constituent which is more rapidly dissolved by nitric or hydrochloric acid than is the cerium earth constituent. For example:

	Ratio $ThO_2 : R_2O_3$ in mineral.	Ratio $ThO_2 : R_2O_3$ extracted by acid.
Nitric acid	14·03	19·7 per cent.
Hydrochloric acid . . .	14·03	17·7 ,,

B. B. Boltwood found uranium is contained in monazite, and regarded it as an essential constituent, while F. Zerban considered it to be an impurity. R. J. Strutt also found uranium in what was regarded as pure monazite, and he represented his observations by Table VI. L. Haitinger and K. Peters, J. Schetelig, B. B. Boltwood, D. O. Wood, and C. Doelter and H. Sirk also investigated the radioactivity of monazite. W. A. Tilden, and W. Ramsay, J. N. Collie and M. W. Travers observed the presence of occluded helium in monazite.

TABLE VI.—THE RADIUM, URANIUM, AND HELIUM CONTENTS OF MONAZITE.

The crystals of monazite are coloured dark brown, red, yellow, or greenish-brown. Some samples, assumed pure, are transparent, other samples are translucent to opaque. The crystals belong to the monoclinic system, and have the axial ratios $a : b : c$=0·96933 : 1 : 0·92558, and β=76° 20′; these values vary a little with variations in the composition of the specimens. The crystal habit is tabular, prismatic, or acicular. A. Hadding studied the X-radiogram of monazite. R. Scharizer has collected a bibliography of the crystallographical, optical, and chemical data. The fracture of monazite is conchoidal. The sp. gr. ranges from C. W. Blomstrand's 4·64 for a sample from Moss, Norway, to L. Duparc and co-workers' 2·2735 for a sample from Madagascar. The values for some samples from Ceylon approach 5·5; thus, S. J. Johnstone gave 5·47 for the sp. gr. of a sample from Ratnapura, Ceylon. The hardness is 5·0 to 5·5. A. L. Fletcher gave 1140° for the m.p. of monazite. H. Rosenbusch and A. E. Wülfing give for the indices of refraction of a sample from Arendal, α=1·7957; β=1·7965; γ=1·8411, and for the strong positive double refraction $\gamma-\alpha$=0·0454 to 0·0510. J. Schetelig gave:

	Li-ray	Na-ray	Tl-ray	Sr-ray
α	1·7822	1·7938	1·7997	1·8144
β	1·8388	1·8452	1·8522	1·8658

W. W. Coblentz found the ultra-red transmission spectrum of monazite shows a large band extending from 3·4μ to 5·5μ, and the mineral was opaque beyond 6·5μ. Monazite dissolves very slowly in acids. According to K. Haushofer, and H. Behrens, if a crystal be warmed with conc. sulphuric acid; the soln. evaporated to a small bulk; and a drop be mixed with a drop of a conc. soln. of sodium acetate; under the microscope, minute pointed oval crystals of sodium cerium sulphate will be observed. With the spectro-microscope, crystals of monazite give the characteristic absorption bands of didymium—*vide infra*—illustrated by Fig. 2. J. Schilling, R. Scharizer, and H. L. Bowmann have compiled bibliographies of monazite.

J. J. Berzelius[23] obtained a mineral from Hitterö and Ytterby which he regarded as yttrium phosphate—*phosphorsyrad ytterjord*—E. F. Glocker called it *yttria spar*; A. Damour, *castelnaudite*; G. S. Kenngott, *wiserine*. The present term **xenotime** appears to be the result of a misprint. F. S. Beudant apparently intended to call it *kenotime* since he gives the derivation: "κενός, vain, et τιμή, honneur." The irony is, that F. S. Beudant stated the name was intended to recall the fact that in 1815 J. J. Berzelius made a mistake in supposing the mineral to contain a new metal *thorine*—afterwards found to be a yttrium phosphate. The term *xenotime* may be derived from ξένος, stranger to; τιμή, honour, in allusion to the fact that the small crystals were for a long time unnoticed. In addition to its occurrence in Scandinavia, xenotime has been observed in Switzerland, Bohemia, Germany, Austria, Italy, France, Brazil, Canada, etc. It is also found in various monazite sands—*e.g.* those of Caroline, Georgia, etc. Xenotime is not so widely distributed as monazite, but it is not uncommon; it often occurs associated with zircon in granite rocks. Zircon is closely allied to xenotime in crystalline form, and, according to E. Hussak, in many reports of xenotime in rocks that mineral has been confused with zircon. Analyses have been reported by J. J. Berzelius, E. Zschau, W. Wartha, A. Damour, O. E. Schlötz, B. Szilard, J. L. Smith, H. Gorceix, C. W. Blomstrand, W. C. Brögger, S. L. Penfield, C. F. Rammelsberg, etc. For a sample from Narestö, Arendal, C. W. Blomstrand gave:

ThO_2	UO_3	Ce_2O_3	Y_2O_3	Fe_2O_3	Al_2O_3	CaO	SiO_2	P_2O_5	H_2O
2·43	3·48	0·96	54·57	2·01	0·28	1·09	2·36	29·23	1·77

together with MgO, 0·26; PbO, 0·68; ZrO_2, 1·11; SnO_2, 0·08 per cent. The terms yttria and ceria here refer to the corresponding groups of rare earths. The composition of xenotime closely resembles that of monazite, and it can be regarded as an orthophosphate of the yttria and erbia earths, YPO_4, just as monazite is regarded as the corresponding salt of the ceria earths, $CePO_4$. The formula has been discussed by C. F. Rammelsberg, E. H. Kraus and J. Reitinger, and W. C. Brögger. In xenotime, the ceria earths range from 0·32 to 11·03 per cent.; in monazite, 16·30 to 45·40 per cent. In xenotime, the yttria earths range from 54·13 to 59·70 per cent.; and in monazite from 0 to 7·69 per cent. W. Ramsay, J. N. Collie, and M. W. Travers found helium occluded in xenotime. B. B. Boltwood, and R. J. Strutt discussed the uranium and radium content of the mineral. Samples of xenotime with 0·75 to 2·74 per cent. of sulphur trioxide have been reported—sulphato-xenotimes. For instance, the xenotime from Bandeira de Mello, Brazil, analyzed by E. H. Kraus and J. Reitinger; from Brindletown, Burke Co., by W. E. Hidden; and from Idaho, by G. Tschermak.

In 1901, E. H. Kraus and J. Reitinger announced the discovery of a new mineral, a kind of *sulphato-xenotime* which they named *hussakite*. A sample from Sao Paulo, Brazil, contained 6·3 per cent. of sulphur, and they assigned to it the formula $3R_2O_3.3P_2O_5.SO_3$, or $6RPO_4.SO_3$. They found that the sulphur trioxide could be easily removed by the action of dil. alkalies, and inferred that xenotime is really a pseudomorph after hussakite. The sulphur trioxide was assumed to have been removed from hussakite by the alkaline water of the earth's crust. W. C. Brögger found fresh xenotime from Arö, Norway, to be quite free from sulphur trioxide, and suggested that hussakite is an independent species with the formula $5YPO_4(YSO_4)PO_3$. H. Rössler said that hussakite is common in igneous rocks and resembles zircon in appearance and properties. E. Hussak, however, showed that hussakite is not a distinct mineral species, but that it is a xenotime of prismatic habit. The report of E. H. Kraus and J. Reitinger is based on faulty analyses. The precipitate obtained by the addition of barium chloride to the acid soln. of the mineral after fusion with alkali carbonate, was assumed to be barium sulphate, whereas barium phosphate is precipitated as well. He added that the name hussakite is unnecessary and undesirable.

F. Radominsky obtained needle-like prisms of artificial xenotime by fusing yttrium phosphate and chloride. The colour of xenotime is yellow or brown. Xenotime and hussakite crystallize in the tetragonal system, and the former has the axial ratio $a : c := 1 : 0·61867$, and the latter 1 : 6208. The crystals have been studied by A. des Cloizeaux, J. D. Dana, E. Hussak, H. Rössler, and E. H. Kraus and J. Reitinger. Since tetragonal xenotime is largely yttrium phosphate, and monoclinic monazite largely cerium phosphate, and since monazite contains yttrium phosphates and xenotime cerium phosphates, it is assumed that the minerals represent the end-terms of an isodimorphous series of mixed crystals. W. C. Brögger considers that the following minerals furnish a series of the general formula $(RO)RO_3$: mossite, $Fe(CbO_3)_2$; tapiolite, $Fe(TaO_3)_2$; rutile, $TiO(TiO_3)$, or $Ti(TiO_3)_2$; xenotime, $(YO)PO_3$; and monazite, $(CeO)PO_3$, where the last three minerals are homomorphous. L. Vegard obtained X-radiograms of xenotime, and the structure appears to resemble that of rutile and other tetragonal minerals. M. L. Huggins also found the structure to resemble that of rutile (*q.v.*). The sp. gr. of the samples of xenotime which have been analyzed range from 4·40 to 5·106—the average is about 4·5; and of hussakite, 4·45 to 4·59. The hardness of xenotime is 4 to 5, and of hussakite, 5. According to H. Rosenbusch and A. E. Wülfing, the indices of refraction and the double refraction of hussakite or xenotime are positive and like that of zircon. E. H. Kraus and J. Reitinger found the following indices of refraction for hussakite:

	Li-ray	Na-ray	Tl-ray
ω . . .	1·7166	1·7207	1·7244
ϵ . . .	1·8113	1·8155	1·8196
$\epsilon-\omega$ . .	0·0947	0·0948	0·0952

H. Rössler noted the feeble pleochroism of the crystals; J. Becquerel, W. Prinz, W. Voigt, and W. M. Page examined the magnetic rotation of the ray of polarized light, and the effect of the magnetic field on the absorption spectrum.

W. G. Lettsom [24] found some samples labelled Cornish blende and described by A. Lévy as *zinc sulfuré, mameloné de Cornouailles* showed the absorption spectrum of didymium, Fig. 1; and, on analysis, gave

Fe_2O_3	Y_2O_3	$(Ce, La, Di)_2O_3$	P_2O_5	H_2O
0·25	9·93	52·82	29·10	6·86

He named the mineral **rhabdophane.** Samples from Scoville, Connecticut, named *scovillite*, were found to have a similar composition by G. J. Brush and S. L. Penfield, and W. N. Hartley; and G. J. Brush and S. L. Penfield later established the identity of the two minerals. L. de Boisbaudran found the absorption spectrum gave didymium and erbium bands. Rhabdophane is regarded as a hydrated phosphate of the rare earths, iron, aluminium, etc., with 53·8 to 57·0 per cent. of ceria earths and 2·1 to 10 per cent. of yttria earths. The idealized formula is $R_2O_3.P_2O_5.2H_2O$, or $RPO_4.H_2O$. It occurs massive, yellow or brown in colour; the sp. gr. is 3·94–4·01, and the hardness 3·5. E. Bertrand found rhabdophane is optically uniaxial. F. Henrich and G. Hiller reported a hydrated phosphate of yttrium, erbium, etc. $(Er, Y, etc.)PO_4.2H_2O$, which they termed **weinschenkite**, in the Bavarian Oberpfalz. It occurs as a white, matted, globular mass of radiating needles on brown hæmatite. Sufficient has not yet been obtained for an accurate analysis. The so-called *pseudo-wavellite* of F. Henrich is a wavellite containing 13 per cent. CaO, about 1 per cent. BaO and SrO, and 2–3 per cent. of rare earths. A. H. Church reported a hydrated calcium cerium phosphate from Cornwall which he called **churchite.** The composition approximates $CaO : Ce_2O_3 : P_2O_5 : H_2O = 1 : 1·65 : 2 : 8·5$; and C. F. Rammelsberg represents it by $3Ca_3(PO_4)_2.10CePO_4.48H_2O$. The colour is smoky-grey, or flesh-red. The doubly refracting crystals are monoclinic prisms; the sp. gr. 3·14; and the hardness 3·0–3·5. A brown, opaque, basic phosphosilicate of cerium, calcium, magnesium, etc., occurring in the pegmatite at Naujakasik, Greenland, was named **britholite**—from βρῖθος, heavy. C. Winther gives the analysis:

Na_2O	MgO	CaO	Fe_2O_3	$(La, Di, Ce)_2O_3$	SiO_2	P_2O_5	F	H_2O
1·85	0·13	11·28	0·43	60·54	16·77	6·48	1·33	1·27

According to O. B. Böggild, the crystals are hexagonal; C. Winther said rhombic with axial ratios $a : b : c = 0·620 : 1 : 0·423$. The sp. gr. is 4·446; the hardness, 5·5; and the negative double refraction weak, 0·004. O. B. Böggild obtained brown crystals of a mineral from Julianehaab, Greenland, which was named *erikite*—after Eric the Red, after whom the adjoining fiord was formerly named—with the composition:

Na_2O	CaO	Al_2O_3	$(Ce, La, Di)_2O_3$	SiO_2	ThO_2	P_2O_5	H_2O
5·63	1·81	9·28	40·51	15·12	3·26	17·78	6·28

The rhombic crystals have the axial ratios $a : b : c = 0·5755 : 1 : 1·5780$; the sp. gr. is 3·493, and the hardness 5·5 to 5·0. The mineral dissolves in acids without gelatinization of the silica. W. C. Brögger described the fluosilicate **melanocerite**, obtained from the islands of Langesund Fiord, Norway. It contains 45·05 per cent. of ceria earths; 9·17 of yttria earths; 1·66 of thoria; and 0·46 of zirconia. The tabular crystals belong to the rhombohedral system; the sp. gr. is 4·13, and hardness 5 to 6.

The mineral **fluorencite** is a cerium aluminophosphate occurring in the diamond mines at Mina Geraës, Brazil. G. T. Prior's analysis is:

CaO	Al_2O_3	Fe_2O_3	Ce_2O_3	SiO_2	P_2O_5	H_2O
1·31	32·38	0·76	28·00	0·48	25·56	10·87

The presence of fluorine is doubtful. The composition approximates $AlPO_4.CePO_4.2Al(OH)_3$, or $3Al_2O_3.Ce_2O_3.2P_2O_5.6H_2O$. The spectroscope shows only a trace of didymium. E. Hussak found that the trigonal crystals have the axial ratio $a : c = 1 : 1·1901$; the sp. gr. is 3·586, and the hardness about 3. The mineral resembles hamlinite. The isomorphism of cerium, calcium, and strontium salts has been discussed by A. Cossa, and G. Wyrouboff. The microcrystalline **gorceixite** is a barium aluminophosphate occurring in the diamond sands of Brazil. According to the analyses of E. Hussak, B. Jezek, *H. Gorceix, and A. Damour, it contains 1·55–2·57 per cent. of cerous oxide. Its composition approximates* $(Ba, Ca, Sr, Ce)O.2Al_2O_3.P_2O_5.5H_2O$. *The sp. gr. is 3·036–3·123, and the hardness 6. It has also been discussed by E. Boutan.*

H. Sjögren reported a rare earth arsenate from Moss, Norway, of the composition:

MgO	CaO	MnO	FeO	PbO	R_2O_3	As_2O_5	SiO_2	H_2O	Gangue
2·7	19·2	30·2	1·7	0·2	10·3	24·4	0·5	8·4	4·3

which he called **retzian.** *The brownish-red to wine-red mineral is pleochroic. The prismatic crystals belong to the rhombic system; the sp. gr. is 4·15; and the hardness about 4. They are readily dissolved by hydrochloric acid.*

The inseparable companionship of elements of like affinities such as nickel and cobalt, and the platinum metals, is very marked with the rare earths. This does not refer to such associations as calcium sulphate or carbonate, and sodium as chloride, but rather to co-mixtures of elements with little affinity for one another. No well-defined regularities have been observed in the nature and quantities of the members of the rare groups present in minerals, although it has been noticed that they are virtually absent from minerals which contain other elements. O. Hauser and F. Wirth[25] made some observations of the effects of titanic and tantalic acids on the occurrence of the rare earths in euxenite, samarskite, and polycrase. They found that in these minerals (i) one-third to three-sevenths of the rare earths are yttria earths containing erbia earths; (ii) as the titanic acid increases, the proportion of holmium and dysprosium increases at the expense of the erbia earths, although these earths are generally present only in small proportions; on the other hand, (iii) the proportions of scandia and yttria are relatively greater with increasing proportions of titanic acid. The relationships are more marked with the ceria earths, (iv) euxenite poor in tantalic acid, and rich in titanic acid, is free from samarium and praseodymium, but as the tantalic acid increases and titanic acid decreases, samaria makes its appearance—*e.g.* a euxenite from South Carolina, poor in titanic acid, but rich in tantalic acid, contained 2 per cent. of samaria, whilst the proportion of gadolinia was less than usual. (v) The presence of thoria in columbates also seems to depend on the presence of titanic acid, since if titanic acid is absent or present in small proportions, thoria is also absent.

G. Eberhard reported that minute traces of scandia and the rare earths are present in many of the commoner rocks and minerals. W. P. Headden found that up to 0·03 per cent. of rare earths were present in the yellow phosphorescent variety of *calcite* from Colorado; and W. Crookes observed yttria in calcite. J. Humphreys found up to 0·5 per cent. in one or two phosphorescent varieties of *fluorspar*, and traces of yttria are usually contained in fluorspar. G. Eberhard observed quite appreciable quantities of rare earths in *cassiterite*, and in *wolframite*. Thus, a specimen of wolframite from the Erzgebirge contained over 0·4 per cent. of rare earths, over half of which was scandia.

G. Woitschach reported traces of ceria and 3·47 per cent. of yttria earths in *zircon* from Schwalbenberg; H. S. Washington, 2·67 per cent. of ceria in *aegirite* from Rockall; T. Scheerer, 0·34 per cent. of yttria in *malacone* from Hitterö; and W. J. Knowlton, 1·40–2·24 per cent. of rare earths in malacone from Rockport, Massachusetts. A. E. Nordenskjöld found 1·39 per cent. of rare earths in *thorite* from Arendal; W. E. Hidden, and J. B. Mackintosh, 6·69 per cent. in thorite from Bluffton, Texas; and W. E. Hidden, 1·0 per cent. of yttria in thorite from Landbö, Norway. Up to 2·70 per cent. of ceria earths, and 10·22 per cent. of yttria earths were reported in *uraninite* and *pitchblende* by G. Lindström, C. W. Blomstrand, W. E. Hidden, and W. F. Hillebrand; 2·95 per cent. of ceria and 10·34 per cent. of yttria earths in *cleveite* were reported by A. E. Nordenskjöld, up to 0·45 per cent. of ceria, and 4·27 per cent. of yttria earths in *bröggerite* were reported by W. C. Blomstrand, W. F. Hillebrand, and K. A. Hofmann and W. Heidepriem; and 11·22 per cent. of yttria earths in nivenite were reported by W. E. Hidden. Up to 0·48 per cent. of ceria, and 4·483 per cent. of yttria earths in *columbite* were reported by R. Hermann, T. Bromeis and H. Rose, F. P. Dunnington, and F. A. Genth. 0·66 per cent. of ceria earths were found in wöhlerite by W. C. Brögger. The *zirkelite* of Sao Paulo was found by G. T. Prior to have 2·52 per cent. of ceria, and 0·21 per cent. of yttria earths. T. Scheerer found 5·0 per cent. of ceria earths in *apatite* from Snarum, Norway, and R. Weber and G. Rose, 1·79 per cent. T. L. Phipson reported 0·10 per cent. of yttria in *pyrolusite*; C. U. Shepard, 0·85 per cent. of yttria earths in *danburite* from Danbury, Connecticut; T. Thomson, 3·57 per cent. of ceria earths in *deweyhite* or *gymnite* from Emmont; W. F. Hillebrand, 0·89 per cent. of ceria, and 1·52 per cent. of yttria earths in a manganese *epidote* from South Mountain, Pennsylvania; R. Hesmann, and C. Bergemann, 2·0–5·08 per cent. of ceria earths in *felspar* from Arendal; O. Rebuffat, 3·45 per cent. ceria and 1·23 per cent. yttria earths in *guarinite* from Vesuvius; R. Hermann, 2·0 per cent. of ceria earth in *hyposclerite* (albite) from Arendal; H. Trenkler, 0·03 per cent. of ceria earths in *phonolites*, from Spitzberg, Bohemia; L. P. Lychnell, 1·25–2·24 per cent. of ceria earths in *serpentine* from Norberg, Sweden; J. R. Strohecker, 12·8 to 14·28 per cent. of ceria and 1·7 per cent. of yttria earths in *clay* from Hainstadt; T. Thomson, 25·95 per cent. of ceria earths from Suland, Norway; C. G. Mosander, 0·58 per cent. of rare earths in *titanite* from Egersund, and A. Cossa, 2·30 per cent. in titanite from Biellese; J. Renwick, 12·32 per cent. of ceria earths in *torrelite* (probably allanite) from Sussex Co., New Jersey; G. Bodenbender, 0·54 per cent. ceria earths in the *bismuthspar* from the Argentine; W. F. Hillebrand, 0·30 per cent. ceria in *wyomingite*, and 0·11 per cent. in *madupite*; and F. A. Genth and S. L. Penfield, 2·48 per cent. of ceria and 47·58 per cent. of yttria earths in a *calcium fluoride* from El Paso, Colorado.

Many of the rare earths are present in the sun and stars; thus, J. Lunt identified the spectral lines of europium in solar and stellar spectra; and H. A. Rowland mentioned the occurrence of the spectral lines of yttrium, lanthanum, neodymium (but not praseodymium), cerium, and erbium in the solar spectrum—*vide* the spectra of the individual earths. In view of the very wide distribution of the rare earths in the mineral kingdom, it would be natural to look for evidence of the occurrence of these elements in the vegetable and animal kingdoms. G. Tschermak found 10 per cent. of rare earths in the ash of a coal from Kutais, Caucasus; and smaller quantities, in the ashes of many plants. W. Crookes, and A. Cossa detected the rare earths in the ashes of rice, and tobacco. These earths also occur in the human body as shown by the fact that W. Crookes, and A. Cossa detected the rare earths in bones; and, added W. Crookes, "gorgoniæ of the species *melithæa* and *mussa sinuosa* undoubtedly remove from sea-water not merely lime, but also yttria; and other recent corals, *pocillopora damicornis* and a *symphyllia* close to the yttria-secreting mussa, separate samaria from sea-water."

§ 4. Fractional Precipitation, and Fractional Crystallization

When an acid is allowed to act upon a mixture of two bases, or a base upon a mixture of two acids, the ratio in which the acid divides itself between the two bases, or the base between two acids, depends not only upon the relative masses of the substances taking part in the reaction, but also upon the specific affinities acting between the different substances. It is assumed that the amount of single base (or single acid) is not sufficient to precipitate the two acids (or two bases) present in the system. In the same way, when a substance is added to a mixture of two or more salts of different metals, the relative amounts of salts decomposed depends upon the relative masses and specific affinities acting between the components of the system. Let only sufficient C be added partially to precipitate A and B, and let the soln. originally contain a mols of A, and b of B; let x and y denote the amounts of A and of B precipitated at the end of a certain time t, then, $a-x$ of A, and $b-y$ of B, will remain in soln.; further, let z denote the amount of C required for the precipitation of x of A, and y of B, and let c denote the amount of C added to the soln. at first. The velocity of precipitation of A and B will be $dx/dt=k_1(a-x)(c-z)$; and $dy/dt=k_2(b-y)(c-z)$, respectively. By division, and integration in the usual way:

$$\frac{k_1}{k_2}=\frac{\log a-\log (a-x)}{\log b-\log (b-y)}, \quad \text{or} \quad \left(1-\frac{x}{a}\right)^{k_2}=\left(1-\frac{y}{b}\right)^{k_1}$$

which gives the relative amounts of precipitates formed in terms of their affinity coefficients.

E. J. Mills[1] and co-workers have studied the fractional precipitation of a mixture of sulphates of different metals by means of sodium hydroxide and sodium carbonate. When sodium carbonate is added to a soln. containing mixtures of nickel and manganous sulphates, the value of k_1/k_2 is 0·34, or $k_2=2·94k_1$. This means that manganese sulphate "resists the decomposing action of sodium carbonate with a force 2·94 times greater than nickel sulphate, when both salts are simultaneously subjected to the action of the same agent." If the original soln. contains $MnSO_4 : NiSO_4=2·94:1$, and a very small fraction be precipitated, the precipitate will contain equal weights of the eq. of the two sulphates; or, if the soln. contain equal weights of the two salts, the precipitate will contain the eq. of $MnSO_4 : NiSO_4=1:2·94$. It is therefore concluded that the more k_2 exceeds k_1, the less will A tend to accumulate in the precipitate; and the more k_1 exceeds k_2, the *more* will A tend to accumulate in the precipitate. In the fractional precipitation of salts, a process commonly employed in the separation of the rare earths, the mixed metallic salts may be precipitated as nitrates, oxalates, etc. The mixed precipitate is redissolved, and again partially precipitated. By many repetitions of the process, it will be obvious that the element with the greater value of k will tend to accumulate in the precipitate, and the other element in the filtrate. In this way C. G. Mosander[2] separated the constituents of the gadolinite earths; C. A. von Welsbach, praseodymium and neodymium from the cerite earths; W. Crookes, the constituents of the yttria earths; etc.

When k_1 is nearly equal to k_2, the ratio of the quantities of A and B in the precipitate will be nearly the same as in the soln., and the process of fractionation will be a prolonged operation. This would be the case with the precipitation of a mixture of nickel and cobalt sulphates by means of sodium hydroxide, for E. J. Mills and J. J. Smith find that $k_2 : k_1=0·97:1$. Hence, the precipitate from a soln. containing equal weights would contain the eq. of $CoSO_4 : NiSO_4=1:0·97$.

---

In the limiting case, when $k_1=k_2$, the ratio of A to B in the precipitate will be the same as in the soln., and the constituents of the soln. could no more be separated by fractional precipitation than two liquids boiling at the same temp. could be separated by fractional distillation. J. C. G. de Marignac tried to prove that some common substances were homogeneous compounds by showing that fractional precipitation gave no indication of heterogeneity; but no separation would occur if the substance really did contain two components for which $k_1=k_2$, very nearly.

A little work has been done upon the subject by H. Debus on the fractional precipitation of mixtures of barium and calcium hydroxide by a soluble carbonate; by A. Chizynsky, upon the precipitation of mixtures of magnesium and calcium chlorides by ammonium phosphate; by K. von Chroustchoff, upon the composition of the precipitate from a mixture of strontium and barium chlorides after the addition of potassium sulphate, or mixtures of soluble sulphates and chromates, and soluble iodates and sulphate, by means of barium chloride; and by F. W. Küster and A. Thiel, of the precipitate from a mixture of potassium bromide and potassium thiocyanate by the addition of silver nitrate. A. Findlay studied the distribution of lead between sulphuric and hydriodic acids; R. Salvadori, lead between sulphuric and carbonic acids. The experiments of T. Paul, F. W. Küster and A. Thiel, and of A. Heintz furnish studies in the separation of the non-volatile organic acids.

In the chemical fractionation of a mixture of earths, W. Crookes separated the different components, more or less incompletely, by performing a chemical operation in an incomplete manner so that only a certain fraction of the bases was separated. As a result, he obtained part of the material in the insoluble and the rest in the soluble state. Suppose that two earths are present differing almost imperceptibly in their basicity.

Add to the very dil. soln. dil. ammonia in such amount that it can precipitate only half the bases present. The dilution must be such that a considerable time elapses before the liquid begins to show turbidity, and several hours will have to elapse before the full effect of the ammonia is complete. On filtering we have the earths divided into two parts, and we can easily imagine that now there is a slight difference in the basic value of the two portions of the earth; the portion in soln. being, by an almost imperceptible amount, more basic than that which the ammonia has precipitated. This minute difference is made to accumulate by a systematic process until it becomes perceptible by a chemical or physical test.

Other means may be employed—*e.g.* fractional precipitation with oxalic acid, formic acid, nitric acid, etc. The operations are analogous to the separation of members of a homologous series of hydrocarbons by fractional distillation. When the earths appear in the same proportion in the soln. and in the precipitate thrown down by ammonia, the precipitated earths are worked up by some other process so as to alter the ratio between them, when the previous operation can be again employed. According to W. Crookes, there are three methods of operating.

(i) In one process, one-third the eq. quantity of ammonia is added; then, after the precipitate has quite settled, it is filtered, to the filtrate one-third more ammonia is added, and the precipitate is again filtered off. The remainder of the bases present are then fully precipitated. In this way the earths are divided into three parts, which may be designated −1, 0, and +1. Each of these lots is then treated as just described, and the thirds are added to the vessel on each side. This plan is rapid in the actual separations, but probably more time is spent in the extra filterings and washings than is saved in the lessened number of operations.

(ii) C. G. Stokes recommended the following process: "Suppose the filtrate to travel to the right and the precipitate to the left. Taking the contents of any bottle, precipitate two-thirds of the whole, and advance the filtrate two places to the right and the precipitate one place to the left, and so on. Theoretically, this is the best way to operate, and I have carried on several long series with much success by its means. There is, however, a disadvantage, in that the precipitate is twice as much as the earth in soln.; and the largest part of the operation is the feeding of the filters. The reason for the selection of the two-thirds proportion is as follows:

"Suppose two earths, *a* mols. of A and *b* mols. of B, are in soln. The tendency at any moment to precipitation under given conditions is such that the proportion of the number of mols. of A to that of B, which goes down, is that of $ak_1 : bk_2$, where k_1 and k_2 are constants whose reciprocals may be considered as representing the specific affinities of the earths for the acid. Then if x and y are the numbers of the A and B mols. which have been precipitated at a given instant

$$\frac{-dx}{k_1(a-x)}=\frac{-dy}{k_2(b-y)}; \quad \text{or} \quad \left(1-\frac{x}{a}\right)^{k_1}=\left(1-\frac{y}{b}\right)^{k_2}$$

by integration. When the difference between the proportions of the two earths that are precipitated is a maximum, $dx/a=dy/b$ or $x/a=y/b$. The ratio of the number of mols. of both kinds left in the soln., $a-x+b-y$, to the total number of mols., $a+b$, then reduces to

$$\frac{ak_2+bk_1}{a+b}\left(\frac{k_1^{k_1}}{k_2^{k_2}}\right)^{\frac{1}{k_1-k_2}}$$

When k_1 and k_2 are nearly equal, the earths have nearly the same affinity for the acid, and the ratio becomes $e^{-1}=2\cdot718$ . . . This means that nearly two-thirds of the whole would be precipitated."

(iii) W. Crookes modified C. G. Stokes' plan in order to avoid as much as possible the extended manipulation by the sacrifice of a little speed : Add half the eq. amount of precipitant to the liquid, and after full settlement, filter. Starting with say 1000 grms. in the zero bottle, transfer 500 to bottle −1 and 500 to bottle +1. Then add another 1000 grms. to the 0 bottle, and repeat the operations as in the following table :

NUMBERS OF THE BOTTLES.

−6	−5	−4	−3	−2	−1	0	1	2	3	4	5	6
						1000						
					500	1000	500					
				250	500	500	500	250				
			125	250	375	500	375	250	125			
		63	125	250	375	375	375	250	125	63		
	31	63	156	250	312	375	312	250	156	63	31	
15	31	94	156	234	312	312	312	234	156	94	31	15

After the seventh fractionation the 2000 grms. of earth are spread out amongst 13 bottles in the proportions represented in the bottom line. The separation of *two* earths by either of these plans is comparatively easy. The precipitation by ammonia depends not directly on the affinities of the earths for the acid, but rather on the excess of affinity of the precipitating ammonia. For if the affinities of the two earths are represented by 100 and 101, and that of ammonia by 150, the affinities on which the precipitation depends would be represented by 150−100=50, and 150−101=49, the difference of which is 2 per cent. of the larger.

If more than two earths are present, the above processes fail, in any reasonable time, to yield practically pure specimens of more than two out of a group of closely allied earths. Thus, if there are as many as three earths, say, A, B, and C, whose positions in reference to the chemical process employed are in the order of sequence in which they are written, we may get a specimen of A as nearly as we please free from B and C, and a specimen of C as nearly as we please free from A and B, but we cannot get a specimen of B practically free from A and C. The law seems to be that *to obtain practically pure specimens of three closely allied earths, it is essential to have recourse to at least two different chemical processes.* The mere continued repetition of the same process will not do, unless indeed the operations are repeated such a vast number of times as to make the approximate expressions no longer applicable, even though the substances are chemically very close. With a greater number of earths the same law holds good ; thus with n closely allied earths to be separated, we must have recourse to $n-1$ different chemical processes. C. G. Stokes added that the number of chemical processes to be employed is not necessarily $n-1$ when one process divides the n earths into groups, and another into sub-groups, for then the earths need not necessarily be separated one at a time.

Fractional crystallization with a separating element.—Fractional crystallization has been discussed in connection with the isolation of radium. An ingenious modification was devised by G. Urbain and H. Lacombe[3] for separating two salts of the rare earths, A and C, by means of a foreign salt, B, which is isomorphous with A and C, under conditions where the binary mixture A and C separates only slowly, and where crystallization occurs with difficulty. For example, in the separation of the europium-samarium fraction, it is an advantage to introduce bismuth nitrate as the intermediary B. The solubility of the bismuth salt, B, is intermediate between the solubilities of europium and samarium nitrates, A and C. Fractionation of the mixture gives virtually pure B in several consecutive intermediate fractions; the least soluble fractions consist of AB, free from C, and the most soluble fractions consist of BC free from A. It is then possible to eliminate the bismuth by ordinary analytical processes. The separation of A from C has then been accomplished by the aid of B, so that G. Urbain and H. Lacombe called B, *l'élément séparateur*—the **separating element.**

In the mixtures of the double magnesium nitrates of samarium and europium containing neodymium, praseodymium, cerium, and lanthanum, the samarium and bismuth salts are to a large extent miscible in the solid state, whereas the neodymium salt is taken up but slightly by the bismuth salt, and the praseodymium, lanthanum, and cerium salts not at all. Hence, after the removal of the bulk of neodymium, praseodymium, lanthanum, and cerium, by ordinary methods, the use of bismuth as *un élément séparateur* rapidly eliminates these elements from samarium, and reduces the intermediate neodymium-samarium fractions to a small amount. The separation of europium and gadolinium is greatly facilitated by the use of bismuth, although here each salt is readily miscible with the separating element. G. Eberhard reported that in the separation of samarium, europium, and gadolinium by G. Urbain and H. Lacombe's process, the separation of samarium and europium is quantitative; europium may be obtained pure; samarium may be freed from europium; and gadolinium may be freed from samarium but still containing traces of europium. The process has been successfully used in separating gadolinium from terbium in mixtures containing the elements between gadolinium and celtium; and in separating the simple nitrates of gadolinium, terbium, dysprosium, etc.

Outside the rare earths themselves bismuth is the only element which has hitherto been found suitable for the purpose. One of the rare earths may act as *l'élément séparateur*. Thus, in the fractional crystallization of lanthanum, praseodymium, and neodymium double ammonium nitrates from nitric acid, the lanthanum separates fairly readily at one end before the other two elements have separated to any marked extent. When the lanthanum has separated, the other two elements crystallize very slowly and with difficulty. Hence, C. A. von Welsbach, and P. Schottländer recommended returning part of the separated lanthanum to the mother liquor and again crystallizing it out through a series of fractions. Here the lanthanum acts as a separating element. C. von Scheele found the double ammonium nitrate process gave better results with cerium as separating element. C. James used praseodymium as *l'élément séparateur* in mixtures of thulium and erbium bromates; and W. Feit and C. Przibylla, and H. Erdmann and F. Wirth used cerous magnesium nitrate as separating element with mixtures of the double magnesium nitrates of lanthanum, praseodymium, and neodymium. C. James and D. W. Bissel found neodymium acted as a separating element with mixtures of gadolinium and terbium bromates—each of the binary mixtures—gadolinium and neodymium and terbium bromates so obtained were then separated by the bismuth process.

G. Urbain and H. Lacombe found that a mixture of rare earths rich in samarium and gadolinium with much of the yttrium group does not crystallize when the magnesium nitrate process is used. The yttrium elements do not form double magnesium nitrates. By adding bismuth salts from time to time to the soluble fractions, it is possible to make the bismuth salt accumulate at the less soluble end, and carry with it practically all the samarium and gadolinium.

The controlling of the progress of fractionations.—In fractional operations it is necessary to find how the separation is proceeding, and when a direct element test is not available, as is usually the case in rare earth separations, a method dependent on some physical property is employed. Prior to the introduction of the spectroscope, about 1860, the determination of the *mean equivalent weight* was the sole *method available for controlling the fractions of the rare earths.* This is effected by converting the oxide into sulphate as employed by J. F. Bahr and R. Bunsen,[4] etc., by converting the sulphate into oxide as employed by G. Urbain, by converting the oxalate into oxide as employed by B. Brauner; and by volumetric methods, say by dissolving a known weight of oxide in an excess of sulphuric acid, neutralizing the excess of acid, precipitating the earth with an excess of a standard soln. of oxalic acid, and titrating the excess of oxalic acid with standard permanganate. This process was used by G. Krüss and A. Loose, W. Feit and C. Przibylla. In the calculations the oxide is assumed to be R_2O_3 except in the case of mixtures containing ceria, thoria, terbia, and praseodymia when the method breaks down.

The *absorption spectra* of soln. with a fixed acid radicle are useful. The reflected light from oxides furnishes a characteristic absorption spectrum called a *reflection spectrum.*[5] K. A. Hofmann and G. Bugge, A. Wägner, and G. Urbain obtained good results by this method. The *spark spectra*;[6] the *arc spectra*; and the *phosphorescent spectra,* produced by a stream of cathode rays, are employed.[7] The phosphorescent spectra have been studied by W. Crookes, G. Urbain, etc.; they are of limited application in following the course of a fractionation, but this spectrum furnishes a delicate test of the purity of a substance. The measurement of the *magnetic susceptibility* of a mixture of rare earths by means of the magnetic balance of, say, P. Curie and C. Cheveneau,[8] occupies a few minutes, and the property being strictly additive, has been employed to control fractionations by G. Urbain, R. J. Meyer and H. Goldenberg, etc.

§ 5. The General Separation of the Rare Earth Group into Chemical Individuals

> The rare earths form a group to themselves ; chemically, they are so much alike that it taxes the utmost skill of the chemist to effect even a partial separation, and their history is so obscure that we do not yet know the number of them.—W. CROOKES.

The extraction of most of the individual members of the rare earth elements from minerals is a very laborious operation, but the separation of the group from foreign elements is comparatively easy. The particular mineral selected for treatment is determined by the element which is in quest. When the proportion of the desired earth contained in the available mineral is small, it is of course necessary to treat with rather large quantities of raw material. Thorium for gas mantles is extracted on a large scale from monazite sand, and cerium for pyrophoric alloys is extracted from the residual salts. The residues were worked up by C. James[1] for yttria earths, and they furnished samarium, gadolinium, europium, terbium, dysprosium, and holmium. Monazite sand is also a convenient source of cerium, lanthanum, praseodymium, and neodymium. According to C. R. Böhm, commercial cerium oxalate, and *cerium oxalicum medicinale* are monazite residues, and when calcined, give mixtures containing about 50 per cent. of cerium. Terbia is best obtained from xenotime, euxenite, samarskite, and some columbates; and gadolinite is rich in yttria and ytterbia.

The first operation is to open up the mineral so that the desired constituents can be brought into soln. The elements so far as the hydrogen sulphide precipitates are removed in the usual manner. The rare earths are separated from the other elements by taking advantage of the insolubility of their oxalates in dil. mineral acids. E. Rimbach and A. Schubert, and B. Brauner have studied the solubilities of some of the rare earth oxalates. Table VII represents the solubilities in water, in soln. of ammonium oxalate, and in N-sulphuric acid.

TABLE VII.—SOLUBILITIES OF THE RARE EARTH OXALATES.

Oxalate.	Water grm. per litre.	Ammonium oxalate. One gram of oxalate in 38 grms. of water dissolves grm.	Normal sulphuric acid. Grms. of anhydrous oxalate per litre.
Lanthanum	0·00062	0·00023	2·56
Praseodymium	0·00074	0·00026	1·23
Neodymium	0·00049	0·00034	1·00
Cerium	0·00041	0·00042	1·64

Ytterbium	0·00334	0·02437	—
Thorium	—	0·62000	0·190

Other determinations have been made by R. J. Meyer and O. Hauser. The oxalates are slightly soluble in dil. mineral acids, and the solubility increases with the conc. of the acid and with temp. Observations have been made by O. Hauser and F. Wirth, R. J. Meyer and A. Wassjuchnoff, and B. Brauner. The results of

F. Wirth are illustrated in Figs. 3 and 4. In Table VIII, the solubility represents *grams of anhydrous oxalate in 100 grms. of sat. soln. at 25°. Excluding the erbium*

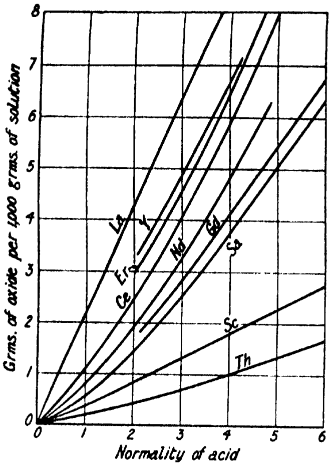

Fig. 3.—Solubilities of Some Rare Earth Oxalates in Sulphuric Acid at 25°.

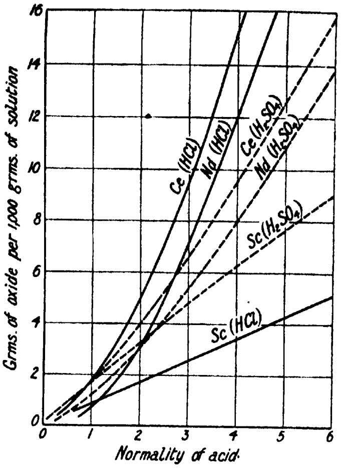

Fig. 4.—Solubilities of Cerium, Neodymium, and Scandium Oxalates in Sulphuric and Hydrochloric Acids at 25°.

oxalate curve, the more basic the rare earth, the greater is the solubility of the corresponding oxalate in the acid. The solubility in hydrochloric acid is greater than in sulphuric acid. Thus, R. J. Meyer and O. Hauser give for the number of grams of anhydrous oxalate per 100 grms. of soln. with N-hydrochloric acid at 25°:

N-	0·125	0·25	0·5	1·0	1·5	2·0	3·0	4·0	5·0

Scandium oxalate is more soluble in aq. sulphuric acid than in aq. hydrochloric acid.
32. 206, results are shown in Fig. 4. Like thorium and scandium oxalates, but unlike
News, 4nium oxalate, the oxalates of the rare earths are but very sparingly soluble in
75, 183, ln. of oxalic acid, and the addition of oxalic acid reduces the solubilities of
1889; 79. 21.

these oxalates in the mineral acids. O. Hauser and F. Wirth give for the solubilities of the oxalates in a mixture of sulphuric and oxalic acids, expressed in grams of anhydrous oxalate per 100 grms. of soln., at 25°, the results shown in Table IX.

TABLE IX.—SOLUBILITIES OF SOME RARE EARTH OXALATES IN MIXTURES OF SULPHURIC AND OXALIC ACIDS.

With more conc. acids, the solid phase changes and, as A. Job has shown, mixed oxalates—oxalato-chlorides, oxalato-nitrates, oxalato-sulphates, etc.—may be formed; or the oxalate may be converted into chloride, nitrate, sulphate, etc. The oxalates of the ceria earths are almost insoluble in soln. of the alkali oxalates, those of the yttria earths are perceptibly soluble. The order of increasing solubility of the rare earth oxalates in soln. of ammonium oxalate—Table VII.—is approximately in the order of the decreasing basicity of the corresponding oxide. Soln. of ammonium and potassium oxalates are better solvents than soln. of sodium oxalate for the yttria earth oxalates. The solubility of the rare earth oxalates is connected with the formation of complex oxalates several of which have been isolated. The whole of the third analytical group of elements, including the rare earths, can be removed from the soln. filtered from the hydrogen sulphide precipitate by treatment with ammonia; or, the rare earth group can be separated from the filtrate of the hydrogen sulphide precipitate, or from the acid soln. of the ammonia precipitate by treatment with oxalic acid. Zirconium oxalate is fairly soluble in oxalic acid and in mineral acids, so that it remains in soln. The thoria is then to be separated from the residual rare earths, and the rare earths fractionated.

The opening up of the mineral.—The mineral is very finely powdered. It may or may not be soluble in hot hydrochloric acid or in hot sulphuric acid. For example, cerite, allanite, gadolinite, thorite, and yttrialite are decomposed by treatment with hydrochloric acid; and cerite, allanite, æschynite, gadolinite, xenotime, yttrotitanite, thorianite, and monazite are decomposed by sulphuric acid. With æschynite, G. Urbain[2] recommended heating the finely powdered mineral until the excess of acid was eliminated, and after treatment with ice-cold water, allowing the liquid to stand for 24 hrs., and decanting the clear liquid from the residual titanic, columbic, and tantalic acids. The liquid was treated with ammonia, and the washed precipitate boiled with conc. nitric acid for some days, adding more acid from time to time to make good the loss by evaporation. The liquid was allowed to stand for several days, and the clear portion decanted from the last traces of titanic, columbic, and tantalic acids. With monazite sand, the excess of sulphuric acid should not be expelled so as to keep the phosphates in soln. when water is added. G. Urbain recommended decomposing monazite by fusion with sodium carbonate. In the case of fergusonite, euxenite, polycrase, samarskite, and yttrotantalite, the mineral is to be fused with sodium hydrosulphate, or sodium pyrosulphate, and the cold cake taken up with acid. L. F. Nilson and G. Krüss used the potassium salt, but it is better to use the sodium salt, because the former gives sparingly soluble complex salts under conditions where the salts given by the latter are freely soluble. The temp. is raised gradually to avoid loss by spurting. The fusion temp. is kept as low as possible in order to avoid the formation of sparingly soluble basic sulphates. C. James decomposed euxenite by heating it with an excess of sulphuric acid. Some of the columbates—*e.g.* sipylite—the tantalates, and the titanates are best decomposed by fusion with sodium hydroxide, and the cold cake taken up with acid.

H. E. Roscoe, J. L. Smith, and W. Gibbs found that it is possible to decompose minerals like fergusonite, euxenite, polycrase, samarskite, and yttrotantalite by *treatment with hydrofluoric acid.* The rare earths then remain as insoluble fluorides which can be brought into soln. by decomposition with sulphuric acid. If the fluorides be washed with dil. hydrofluoric acid, M. Delafontaine showed that columbium, tantalum, tungsten, and zirconium fluorides pass into soln. W. B. Hicks found that the mineral columbates, tantalates, titanates, etc., are decomposed by heating in a stream of sulphur chloride, S_2Cl_2 ; the chlorides of columbium, tantalum, titanium, tungsten, etc., are volatilized, while the chlorides of the rare earth metals remain. Good results were obtained with samarskite, fergusonite, æschynite, and euxenite. J. Barlot and E. Chauvenet also obtained good results by using carbonyl chloride in place of sulphur chloride.

The isolation of the rare earth group.—The acid soln. of the mineral or cold cake resulting from the fusion is taken up with water or dil. acid, and evaporated to dryness. The residue is digested in acid, and the soln. boiled for a couple of hours. Most of the zirconia and ferric oxide dissolves, while silica, stannic, tungstic, titanic, columbic, and tantalic oxides, and lead and barium sulphates remain undissolved. The soln. is allowed to stand for some hours, and filtered. The filtrate contains the rare earth oxides, uranium and thorium oxides, alumina, part of the zirconium and ferric oxides, magnesia, the alkaline earths, and alkalies. The hot acid soln. is saturated with hydrogen sulphide, and again saturated when cold. The liquid is filtered and boiled to expel hydrogen sulphide. Simplifications can be introduced when the composition of the rare earth material permits. The soln. containing the rare earths, aluminium, zirconium, uranium, etc., hydroxides or phosphates is treated with a slight excess of oxalic acid. The precipitated oxalates separate in a colloidal form, which includes some of the mother liquor. One portion of the oxalic acid should be added first, and before adding the remainder of the acid, the precipitate should be vigorously shaken until it assumes the crystalline form. The crystalline precipitate can be easily filtered and washed. The yttrium, cerium, and thorium oxalates are precipitated, while zirconium, aluminium, iron, and uranium remain in soln. According to O. Hauser,[3] the presence of uranyl salts makes the cerium oxalates very soluble, unless a great excess of oxalic acid is added. The chief source of difficulty is a fact that the acidity of the soln. requires careful adjustment, or appreciable quantities of the cerium, yttrium, and thorium oxalates will pass into soln., or else the precipitate may be contaminated with zirconium oxalate. The conditions for successful work with ceria have been investigated, but not for yttria. The best results are obtained when the ammonia precipitate is dissolved in $\frac{1}{4}$-N to $\frac{1}{3}N$-hydrochloric acid—about 50 c.c. of acid are required per gram of the earths. Add 40–50 c.c. of a 10 per cent. soln. of oxalic acid, and keep the soln. at about 60° for about 12 hrs. The precipitate is washed with warm water. The precipitate can be calcined to convert the oxalates into oxides. The precipitated oxalates are usually contaminated with small quantities of iron, aluminium, and calcium oxalates and phosphates. The precipitate is then digested with fuming hydrochloric acid, on a water-bath, and a reprecipitation made with oxalic acid.

The removal of thoria from the rare earths.—The washed precipitate of the mixed oxalates is digested on a water-bath with conc. nitric acid (sp. gr. 1·4) and one drop of $\frac{1}{10}N$-potassium permanganate, which accelerates the rate of dissolution by the nitric acid is added. The dish should be covered with a clock-glass to prevent loss by spurting. The oxalates will be decomposed in a short time. The excess of acid is removed by evaporation. The mixed oxalates can also be converted into carbonates by heating them with a 10 per cent. soln. of sodium carbonate, and a little sodium hydroxide to precipitate any of the thorium which might pass into soln. The washed precipitate is then dissolved in hydrochloric acid. Several methods are now available for removing the thoria. (1) *The hydrogen peroxide process*, studied by G. Wyrouboff and A. Verneuil,[4] P. T. Cleve, L. de Boisbaudran, etc., is based on the fact that all the thorium separates as peroxyhydroxide, $Th(OH)_4(O.OH)$, a white voluminous precipitate, when a soln. of the nitrate is treated with hydrogen peroxide. The procedure recommended by G. Wyrouboff and A. Verneuil is as follows :

Barium peroxide is stirred into a conc. acid soln. of the rare earths a little at a time until the clear liquor no longer gives a precipitate with conc. hydrogen peroxide. The filtrate contains rare earths free from thorium, the precipitate contains thorium mixed with 20–30 per cent. of the rare earths. The washed precipitate is dissolved in cold hydrochloric acid, and the barium removed by adding a slight excess of sulphuric acid so that the filtered soln. does not contain over 15 per cent. of free acid. Oxalic acid is added, and the precipitated oxalates are washed and treated with a very conc. ammoniacal soln. of ammonium carbonate. Thorium oxalate passes into soln. together with about 7 per cent. of the rare earths. The precipitate of rare earth oxalates is free from thorium. The cold filtrate is treated with sodium hydroxide, and the washed precipitate dissolved in the minimum quantity of nitric acid, and the thorium precipitated by adding an excess of hydrogen peroxide. The filtrates containing rare earths are united and precipitated with oxalic acid in a slightly acid soln. ; the precipitates of the rare earth oxalates are collected together.

Among other methods for separating thoria from the rare earths there is (2) J. J. Chydenius' *thiosulphate process*,[5] in which a boiling dil. soln. of the chlorides is treated with an excess of a conc. soln. of sodium thiosulphate. Basic thorium thiosulphate is precipitated in a flocculent mass which, after standing about 12 hrs., is easily filtered and washed. The precipitate with its filter-paper is digested in conc. hydrochloric acid, and again treated with the thiosulphate so as to get rid of all but a trace of ceria which contaminated the first precipitate. (3) J. F. Bahr's *ammonium oxalate process*.[6] Thorium oxalate is somewhat soluble in nearly neutral soln., of ammonium oxalate, and if a large excess of ammonium oxalate be used, thorium may not be precipitated at all ; but an excess is necessary to keep the zirconium oxalate in soln. Hence, some thorium may escape precipitation, and, if not separated, will, later on, appear with the zirconium precipitate. C. Glaser, therefore, recommended adding conc. hydrochloric acid to the boiling filtrate. On cooling, insoluble thorium oxalate is precipitated. The zirconium oxalate is soluble in the oxalic acid liberated by the action of the hydrochloric acid. The process may have to be repeated several times, because even with C. Glaser's improvement the separation is not sharp, for notable quantities of the rare earths—particularly the yttrium oxalates—pass into soln. As previously stated, O. Hauser added that should uranium be present the solubility of the cerium and lanthanum oxalates is increased, and the precipitation will be imperfect unless a very large excess of oxalic acid is present.

T. O. Smith and C. James,[7] and O. Knöfler recommended sebacic acid as a precipitating agent for thorium ; W. B. Giles, lead carbonate—ceric salt is also precipitated, and to prevent this, the ceric salts should be reduced to cerous salts by sulphur dioxide ; L. M. Dennis and F. L. Kortright, T. Curtius and A. Darapsky, and G. Wyrouboff and A. Verneuil, sodium azide ; F. J. Metzger, fumaric acid ; A. C. Neish, and A. Kolb and H. Ahrle, metanitrobenzoic acid ; T. O. Smith and C. James, pyrotartaric acid ; R. J. Meyer and M. Speter, iodic acid ; R. J. Carney and E. D. Campbell, pyrophosphoric acid ; M. Koss, A. Rosenheim, and F. Wirth, sodium hypophosphate ; F. Garelli and G. A. Barbieri, and C. R. Böhm, salicylic acid ; W. Muthmann and E. Baur, potassium chromate ; L. de Boisbaudran, copper and cuprous oxide ; C. R. Böhm, acetic acid ; R. Chavastelon, H. Grossmann, and A. Batek, sodium sulphite ; and F. J. Metzger and F. W. Zons, ammonium molybdate. B. L. Hartwell, and A. McM. Jefferson studied the precipitation of thorium in the presence of the rare earths by quinoline, aniline, and other aromatic bases.

After the above treatment the rare earth oxalates are supposed to have been freed from thoria, zirconia, etc. Scandia still remains. Should any thoria have escaped the extraction, and still pollute the rare earths, it will appear in one of the subsequent fractions, and if the sodium sulphate process be employed, the thoria will be found in the more soluble yttria fractions. Similarly, if traces of other elements still contaminate the rare earths, they may introduce complications in later fractions, and lead to the premature announcement of a new element. Quite a long list of pseudo-discoveries has been made both in connection with the rare earths and in connection with other elements. The *deceptio visus* is the more likely to lead one astray because **the characteristic properties of one element may be suppressed or masked in the presence of another element, so that reactions which readily occur when the element is alone do not necessarily occur when the two elements are mixed together.** For instance, W. Crookes[8] showed that titanium hydroxide is completely precipitated when a dil. soln. of titanium sulphate is boiled for some time; but if zirconium be present, there may be either an incomplete precipitation or none at all. The phenomenon is by no means uncommon. Thus, C. A. Joy found that aluminium hydroxide is dissolved by ammonium carbonate soln. in appreciable quantities when beryllium hydroxide is present, but alone, the alumina is scarcely affected. Columbium hydroxide is completely precipitated if a dil. acid soln. of the chloride be boiled, but, according to L. Weiss and M. Landecker, some columbium escapes precipitation if much titanium be present, for "it seems as if a soluble double chloride of titanium and columbium is formed and part only of the columbium separates as hydroxide." These facts also show that tables of solubilities like Table VII must be used with caution.

The resolution of the rare earths into ceria and yttria earths.—J. J. Berzelius and J. G. Gahn[9] employed potassium sulphate as a group reagent—*vide* Table I—for separating the rare earths contained in yttrocerite into the yttria and ceria groups according as they are soluble or insoluble in a cold sat. soln. of that salt. The process was employed by many of the early workers, J. J. Berzelius and W. Hisinger, J. C. G. de Marignac, C. G. Mosander, N. J. Berlin, M. H. Klaproth, etc. Most of the terbia group accompanies the sparingly soluble ceria group. The separation is not clean. The precipitate containing the double sulphates of the ceria earths is tainted with some of the members of the yttria earths; while the filtrate contains a considerable proportion of the terbia and ceria earths—more particularly with neodymia and samaria because, according to O. Boudouard, and G. Urbain, samarium and neodymium double sulphates are appreciably soluble in the presence of much yttrium sulphate, and in addition to the augmentation of the solubilities of the double sulphates of the terbium family, these salts are formed somewhat slowly. The potassium sulphate process is therefore to be regarded as a method of fractionation. C. James showed that if much of the neodymium be left in soln. only traces of the terbium and yttrium groups are precipitated. The yttrium and terbium earths in the filtrate are converted into double magnesium nitrates and fractionated. The crystals contain the cerium group up to neodymium; the mother liquor contains samarium, terbium, and yttrium.

The separation is conducted by gradually adding finely divided potassium sulphate to a soln. of the rare earth sulphates, chlorides, or nitrates. R. J. Meyer worked with a soln. which had just been raised to the b.p., and kept the soln. vigorously stirred by a jet of steam. The addition of potassium sulphate is continued until a test portion of the clear soln. shows but the faintest absorption spectrum of didymium, Fig. 1. The crystals of the cerium earth double sulphates are allowed to settle, and the soln. of yttrium earths is decanted off, and the crystals washed with a cold sat. soln. of potassium sulphate. If the potassium sulphate be added until the didymium absorption spectrum has vanished, some double sulphate yttria earths will be precipitated with the ceria earths. Many modifications have been proposed by K. A. Hofmann, L. M. Dennis and E. M. Chamot, A. Bettendorff, W. Muthmann and H. Rölig, L. de Boisbaudran, J. C. G. de Marignac, etc.

M. H. Klaproth used sodium sulphate in place of potassium sulphate in his work on ochroite, and this salt has been employed by W. Gibbs, J. L. Smith, C. James, M. Delafontaine, G. P. Drossbach, L. de Boisbaudran, C. Erk, etc. Solid sodium sulphate is stirred into a 10 per cent. soln. of the rare earth chlorides, nitrates, or sulphates until the didymium bands disappear. Special care must be taken not to use an undue excess of the sodium salt because of the formation of a sparingly soluble

yttrium sodium sulphate—Fig. 25. The double sulphates of the cerium group are filtered off and washed with sodium sulphate soln. as described below. The filtrate is treated for the yttrium group—*vide infra*.

C. James found that the sodium sulphate process does not give such good results if the cerium group predominates much in excess of the yttrium group. In that case, (1) the potassium sulphate method can be used; (2) an excess of sulphuric acid can be added; the liquid warmed so as to precipitate the bulk of the cerium group as sulphates, and the filtrate treated by the sodium sulphate process (G. P. Drossbach); (3) the bulk of the cerium group can be precipitated as double carbonates by adding potassium carbonate, and the filtrate treated by the sodium sulphate process (G. P. Drossbach); or (4) the material can be fractionated by the double magnesium nitrate process of E. Demarçay, whereby the terbium and yttrium groups collect in the more soluble portions (C. James). C. James recommended four different methods of treatment dependent upon the composition of the crude oxalates:

(*a*) If the mixture is chiefly composed of lanthanum, much cerium, praseodymium, neodymium, samarium, europium, and gadolinium, it should be converted into the neutral nitrates and boiled with potassium bromate and marble, as required for the separation of cerium—*vide infra*. (*b*) If only a little cerium is present, the oxides should be converted into double magnesium nitrates, which are then fractionated, the cerium being separated from the fractions in which it is found to occur. (*c*) Should the mixture be composed of gadolinium, terbium, dysprosium, holmium, erbium, thulium, ytterbium, lutecium, yttrium, and scandium, it is best to commence with the fractional crystallization of the bromates. (*d*) When the cerium and yttrium metals occur together, one must commence with the sodium sulphate treatment.

C. James' process for separating the ceria earths.—The precipitate obtained by the sodium sulphate process contains cerium, lanthanum, praseodymium, neodymium, samarium, europium, gadolinium, and traces of terbium, dysprosium, etc., belonging to the yttrium family. An outline of the scheme is indicated in Table X.

The separation of ceria.—The double sodium sulphates are decomposed by boiling with a conc. soln. of sodium hydroxide. Water is added, and the hydroxides filtered and washed until free from sulphates. The hydroxides are dissolved in nitric acid, and the soln. nearly neutralized. Potassium bromate is added to the boiling soln. as recommended by C. James and A. L. Pratt[10] until red fumes of bromine appear, a few lumps of marble are then added to keep the liquid nearly neutral. The liquid is boiled until a few drops of the filtered liquid fail to give the reaction for cerium with hydrogen peroxide. The lump marble is removed and the precipitate allowed to settle. The basic ceric salts are filtered, and washed with dil. nitric acid.

The precipitate of basic ceric nitrate can be purified by a repetition of the process; or it can be dissolved in conc. nitric acid by the aid of a little alcohol. The orange-red liquid is boiled with lump marble for a short time so that it does not become too alkaline. The precipitate is filtered off, and the soln. treated with potassium bromate to remove the remaining cerium. The basic salts can be further purified by dissolving the precipitate in hydrochloric acid, adding a slight excess of sulphuric acid, and heating. The crystalline cerium sulphate which separates is washed with alcohol.

The preliminary separation into four fractions.—The filtrates from the basic cerium salts can be precipitated either in the cold, with oxalic acid; or boiling, with sodium hydroxide. If a large excess of bromate has been used, much oxalic acid is consumed in reducing the bromate to bromine, etc. The oxalates are converted into oxides by ignition, and E. Demarçay's magnesium nitrate fractionation process is applied.

The oxides are dissolved in a known amount of nitric acid, an equal weight of nitric acid is neutralized with magnesia, and the two soln. are mixed. The soln. is evaporated until crystals begin to form when the surface is blown. Water is sprayed on the surface, and the whole is allowed to crystallize for about 24 hrs. The mother liquid is poured off, and further evaporated, while the crystals are dissolved by heating them with a little water. The two soln. are allowed to crystallize so that about half the solid separates on cooling. The process is now arranged so that the more soluble portions move in one direction, the less soluble fraction in the opposite direction. When the crystallization of the second series is complete, the liquid from the more soluble portion is poured off and again evaporated, while the liquid from the first fraction is used as solvent for the second fraction—adding or evaporating water as may be necessary. The least soluble portion of the first fraction is again dissolved by heating it with water. The process is repeated many times. When the fractions at either end become too small to work they should miss one series of operations and be added to the next lot. After a few series of crystallizations, the least soluble portion becomes very light coloured, later growing nearly colourless, and finally takes a faint green tinge. When the fractions at this end no longer show the characteristic absorption bands of neodymium, they should be placed aside and mixed together according to the amount of praseodymium contained therein; in other words, fractions of the same colour are united. If the liquid refuses to crystallize or a precipitate forms, it is best to dil. with water and precipitate with oxalic acid in order to separate the impurities that have accumulated and interfere with the crystallization. The insoluble oxalates are converted back to the double magnesium nitrates. The crystals are inclined to carry much mother liquid.

During the fractionation the more soluble portion changes rapidly, acquiring a yellow tint, and showing the spectra of samarium, dysprosium, holmium, and erbium. The neodymium finally becomes very weak in the mother liquor of the most soluble fraction. The soln. is then set aside to be treated for samarium, europium, and gadolinium. The more soluble portion of the remaining fractions soon becomes an amethyst-blue colour, and it is set aside as crude neodymium. After fractionating for some time longer, the material will have been resolved into the following four groups of double magnesium nitrates—commencing with the least soluble: (i) Lanthanum and praseodymium; (ii) Praseodymium and neodymium; (iii) Neodymium; and (iv) Samarium, europium, and gadolinium together with the simple nitrates of terbium, dysprosium, holmium, yttrium, etc.

(i) *Isolation of lanthanum.*—The fraction containing lanthanum and praseodymium can be treated by the metanitrobenzenesulphonate or the bromate process. C. James recommends C. A. von Welsbach's process involving the fractional crystallization of the double ammonium nitrates.

The rare earths are separated from the double magnesium nitrates, by adding oxalic acid to the aq. soln. of the magnesium double salts, and igniting the washed and dried oxalates. The resulting oxides are dissolved in the required amount of nitric acid, and for every three parts of acid required by the oxides, two additional parts are neutralized by ammonia. The resulting soln. are mixed, filtered if necessary, and evaporated until small crystals appear when the surface is blown. A little water is sprayed on the surface of the hot soln. and the whole is allowed to crystallize for 24 hrs. The process of fractional crystallization is allowed to proceed as in the case of the double magnesium nitrates.

(ii) *Isolation of praseodymium.*—Praseodymium is obtained from the mother liquor remaining after the separation of lanthanum, and from the second fraction of the double magnesium nitrate process. The fractionation of the double ammonium nitrates is continued until no more lanthanum ammonium nitrate separates at the less soluble end of the series. The praseodymium accumulates at the more soluble end of the series. The mixture of praseodymium and neodymium magnesium nitrates is then treated by H. Lacombe's process involving the fractional crystallization of the double manganese nitrates from dil. nitric acid.

The rare earth oxides are extracted from the magnesium double nitrates as indicated above. The oxides are dissolved in nitric acid, and an equal amount of nitric acid is neutralized by manganese carbonate. Any peroxide remaining undissolved can be brought into soln. by the addition of a few drops of dil. oxalic acid soln. to the hot double nitrates. The manganese double salts are crystallized from nitric acid having a sp. gr. 1·3.

The fractionation is continued until the spectrum of neodymium disappears, even when a conc. soln. is examined in thick layers. The double ammonium or manganese nitrate is then dissolved in water and precipitated with oxalic acid. The oxalate is free from the other rare earth metals excepting perhaps a trace of cerium. The cerium can be removed by C. James and A. L. Pratt's process—*vide supra*—or by means of the potassium permanganate process—*vide infra*.

(iii) *Isolation of neodymium.*—Neodymium is obtained from the mother liquors of the double manganese nitrate and the third fraction from the double magnesium nitrate process. The fractional crystallization of the respective mixtures can be continued until the most soluble fraction assumes a lilac-blue colour, with marked absorption bands in the blue. The pure oxide is blue.

(iv) *Isolation of samarium and europium.*—The fourth fraction from the double magnesium nitrate process contains samarium and europium as well as large quantities of gadolinium, yttrium, dysprosium, and erbium. The double magnesium salts are fractionally crystallized from 30 per cent. nitric acid. The least soluble fractions soon acquire a yellow tint as the samarium accumulates, while the most soluble fractions begin to crystallize badly as the yttrium earths accumulate. G. Urbain and H. Lacombe's *l'élément séparateur* in the form of bismuth magnesium nitrate may now be advantageously employed. This rapidly removes all the europium from the yttrium earth nitrates. After many crystallizations, the mother liquor shows a strong spectrum of dysprosium, holmium, and erbium, and it is put on one side. The series is allowed to expand to about 20 fractions. After a large number of crystallizations, samarium is removed from the least soluble end, when it is considered certain that all the europium has passed along the series. As soon as the gadolinium fractions, next to the samarium, show a fine sharp absorption band in the blue, due to europium, 50 per cent. nitric acid is used as solvent. Most of the samarium of a high degree of purity will now have been removed, and in addition, nearly all the yttrium, dysprosium, and erbium earths, together with quantities of gadolinium from the opposite end. As the work proceeds, the europium band grows stronger in the fractions between samarium and gadolinium; later two green bands appear. The fractions become smaller and smaller since all the mother liquors beyond one or two that give no europium spectrum, have been removed Only traces of samarium are left. Finally, the samarium bands disappear and the remaining fractions contain only bismuth magnesium nitrate. The fractions containing no gadolinium are mixed, diluted, and the bismuth precipitated with hydrogen sulphide; the clear filtrate is treated with oxalic acid, and the europium oxalate is collected, washed, and dried.

(v) *Isolation of gadolinium.*—All the more soluble portions of the preceding operations consisting of gadolinium, yttrium, etc., are collected together; converted into oxalates; ignited to oxides; and dissolved in nitric acid. The simple nitrates are then fractionated from conc. nitric acid. The first crystals contain gadolinium and terbium; the intermediate crystals contain dysprosium, holmium, and yttrium; and yttrium, erbium, etc., collect in the mother liquor. The last is added to soln. of yttria earths derived from the first sodium sulphate precipitation. The middle fraction containing dysprosium, holmium, and yttrium is added to a later fraction employed for dysprosium. The least soluble nitrates of gadolinium and terbium cannot be purified by the fractional crystallization of the double magnesium nitrates, likewise the simple nitrates fractionate very slowly, but G. Urbain fractionated the double nickel nitrates and obtained a white gadolinium salt which readily crystallizes from nitric acid of sp. gr. 1·3. Terbium collects in the more soluble crystals.

C. James' process for separating the yttria earths.—The fraction of the rare earths soluble in a sat. soln. of sodium sulphate, consists of dysprosium, holmium, yttrium, erbium, thulium, ytterbium, lutecium, celtium, and small quantities of gadolinium, terbium, and scandium. The soln. is acidified, and the rare earths are precipitated by oxalic acid. The oxalates are heated with conc. sulphuric acid until fumes of sulphuric acid cease to be evolved. An outline of the scheme of separation is indicated in Table XI.

The preliminary separation into five fractions.—The sulphates are dissolved in cold water, and the conc. soln. gradually added to finely divided barium bromate covered with a layer of water; the mixture is heated and stirred until decomposition is complete. This is shown by the absence of a precipitate when a little of the clear liquor is diluted and boiled with a soln. of barium bromate. The mixture is filtered, and the barium sulphate well washed. The clear filtrate is evaporated until a drop removed on the end of a glass rod nearly solidifies when rubbed on a watch-glass. A little water is then sprayed on the surface, and the contents allowed to crystallize. The mother liquor and crystals are fractionally crystallized. The absorption spectrum soon shows that a change rapidly occurs. The products (i) samarium, gadolinium, terbium, neodymium, and europium which collect at the less soluble end. This mixture is fractionated as indicated in connection with Table X for the more soluble earths derived from the samarium-europium fraction (iv). (ii) The second raction is yellow, and contains dysprosium, holmium, and yttrium, with small quantities of terbium. (iii) The third fraction consists almost entirely of yttrium contaminated with small quantities of dysprosium, holmium, and erbium. iv) Practically the whole of the erbium is contained in the fractions more soluble than yttrium ; the erbium spectrum is very marked, and the soln. is rose-red. (v) The mother liquor is nearly colourless or it has a faint pink colour. The absorption spectrum shows a feèble erbium spectrum and an intense thulium spectrum. This raction consists almost entirely of ytterbium, lutecium, and celtium.

Traces of scandium in the mineral are usually lost in the oxalate precipitations, owing to the slight solubility of scandium oxalate, particularly in the presence of free acid. During the fractional crystallizations, the scandium accumulates in the mother liquid and in the erbium, and dysprosium fractions.

(i) *Isolation of terbium.*—The mother liquor from the gadolinium nickel nitrate fractionation contains terbium, as well as dysprosium, and gadolinium. The less soluble portion of the next fractionation also contains terbium and dysprosium. The collected mixture can be fractionated by crystallization of the simple nitrates, as the ethyl sulphates, or it may be fractionally precipitated by ammonia which concentrates the terbium in the portions more basic than dysprosium. The simple nitrates are fractionally crystallized using bismuth nitrate as a separating element. (i) Bismuth nitrate accompanied by terbium collects in the middle fraction ; (ii) gadolinium collects with the least soluble fraction ; and (iii) the dysprosium in the mother liquor is passed on to the dysprosium fraction. The bismuth is removed from the middle fractions by hydrogen sulphide, and the terbia precipitated by oxalic acid ; and the oxalate ignited for terbium oxide which appears as a black powder. In the ethyl sulphate fractionation, terbium comes between gadolinium and dysprosium.

(ii) *Isolation of dysprosium.*—Most of the dysprosium in the original material collects in the intermediate fraction from the gadolinium nitrate fractionation, the second fraction from the preliminary separation of the ytrria fraction, and the mother liquor from the terbium fractionation. The earths in this fraction are separated by the ethyl sulphate process advocated by G. Urbain. The earths are first converted into ethylsulphates either by the action of the rare earth sulphates on barium ethylsulphate or by mixing alcoholic soln. of the rare earth chlorides with sodium ethylsulphate. In the former process, there is a loss of rare earth sulphates entrained with the barium sulphate, and the filtration is difficult ; the latter process gives the best results when hot conc. soln. are used. The collected fractions are treated with oxalic acid, the oxalates converted to oxides, and the oxides dissolved in hydrochloric acid, adding a slight excess of oxide so as to keep the soln. slightly basic. The soln. is evaporated until it solidifies on cooling. Before the soln. has cooled sufficiently to solidify it is poured into 95 per cent. alcohol, and the turbid soln. cleared by adding hydrochloric acid drop by drop. A hot conc. alcoholic soln. of sodium ethylsulphate is then added, with vigorous stirring. The mixture is heated on the water-bath for a short time, filtered, washed with hot alcohol, and the filtrate allowed to crystallize. The mother liquid is poured off and the crystals well drained. Liquid and crystals are then fractionally crystallized for a long time. (i) Terbium with a little dysprosium collects in the first few fractions ; (ii) dysprosium alone comes next ; (iii) then follows dysprosium and holmium ; and (iv) the most soluble portion contains holmium and yttrium.

(iii) *Isolation of holmium.*—Holmium has not been prepared of a high degree of purity. The small quantities available may be freed from dysprosium, but the fractions so obtained are rich in yttrium, and carry a little erbium. Fractionation by the fusion of the nitrates as described in connection with yttrium should give a basic holmium nitrate, but too little holmium is usually available.

(iv) *Isolation of yttrium.*—The best sources of yttrium are the third fraction of the preliminary fractionation of the yttria earths soluble in sodium sulphate, and also the less soluble fraction after the separation of erbium. Several methods are available for the purification of the crude yttrium. The chromate process of W. Muthmann and C. R. Böhm gives good results, particularly if terbium is present, and not much material is available.

The oxides are dissolved in a soln. of chromic acid so that about 40 grms. of the rare earth sesquioxide is contained in a litre. C. James said that the soln. obtained by adding potassium dichromate to a soln. of the rare earth nitrates can also be used. The liquid is treated with a 10 per cent. soln. of potassium chromate until it becomes cloudy, and heated in a retort while agitated by a current of steam. The retort is fitted with a cork and separating funnel so that potassium chromate can be added from time to time to keep the vol. of soln. in the retort constant. The precipitate is collected in a series of fractions. The first and second fractions are obtained by using 10 per cent. potassium chromate, and about four fractions by using a 5 per cent. soln. The best fraction is virtually pure yttrium chromate in the form of minute deep-red prisms.

C. James recommends the fused nitrate process of A. Damour and H. St. C. Deville for purifying large quantities of yttrium material. If terbium be present, pure white yttria cannot be obtained. The result of the operation furnishes yttrium nitrate of a high degree of purity, and a less basic portion which is worked up for erbia. He said:

When working on a large scale, porcelain dishes are used, while casseroles are found very convenient for smaller amounts. During the decomposition, the evolution of red fumes is allowed to proceed until the surface assumes a glazed appearance. This point is easily ascertained by experience. The decomposition should never be allowed to advance so that the mass becomes of a thick creamy nature. The best method for obtaining a soln. of the melt is to pour the fused mass into a sufficient quantity of cold water. Great care, however, is required and stirring usually aids the operation very much. A large amount of cold water must be avoided, since it is desired that the soln. should be concentrated after about five minutes' boiling. As the fused nitrate is gradually added to the water, the temp. rapidly rises and the whole suddenly begins to boil violently. When the dish, which contained the melted salt, has cooled sufficiently, a little water is added and the whole heated until the glassy mass has disintegrated, after which it is added to the main bulk. The latter is then boiled for five minutes and set aside to cool. Under the best conditions the entire mass goes into soln.; especially is this true of the yttrium end of the series. Upon cooling, it will be found that the basic nitrate separates in a crystalline form. At the opposite end, the least basic portion of the fractions, there always remains an insoluble basic nitrate, unless the decomposition is stopped at an earlier stage, *i.e.* when there is a copious evolution of red fumes. In case a precipitate remains, it is highly important that it be well agitated by thoroughly boiling. After cooling, the precipitate (fraction B) is filtered off, redissolved in nitric acid, and again fused. The filtrate (fraction A) is also boiled down and fused. The second series gives two filtrates and two precipitates. The filtrate from fraction B is mixed with the precipitate from fraction A, with the result that the second series contains three fractions, etc.

(v) *Isolation of erbium.*—The less basic fraction obtained from the purification of the yttria by the fused nitrate process, and the fourth fraction in the preliminary separation of the rare earth sulphates which are soluble in a sat. soln. of sodium sulphate, contain practically the whole of the erbia present in the raw material. Some yttrium is present along with traces of scandium, thulium, and holmium. According to C. James, yttrium is best separated by fractionally decomposing the nitrate by fusion. Since erbium nitrate decomposes easily, the temp. is not raised quite so high as in the case of nearly pure yttrium. The least basic portion obtained after a large number of series, consists of erbium basic nitrate. During conc., the material rapidly becomes less, the erbium soln. becomes more rose coloured, and the absorption spectrum appears very intense. The yttrium concentrates in more basic fractions, which, when united, are worked up for yttria as described above. The best method for removing scandium is to crystallize the nitrates from nitric acid (fairly strong). Holmium and thulium are separated, if still found contaminating the material, by converting back to the bromate and employing fractional crystallization from water. This last method also causes yttrium to pass into the less soluble crystals.

(vi) *Isolation of thulium.*—Thulium is so scarce that only small quantities can be obtained from large quantities of material. The most soluble portion obtained in the preliminary fractionation of the yttria earths soluble in a sat. soln. of sodium sulphate is employed. This fraction contains thulium, ytterbium, lutecium, and celtium, it shows the absorption bands of thulium, and mere traces of those of erbium. As a rule ytterbia largely predominates in this fraction. The thulium is separated by continuing the fractionation of the bromates at a temp. of about 16° ; at higher temp., the soln. employed are so conc. that they solidify on cooling. The soln. are very liable to supersaturation, and crystallization has to be started by seeding. C. James found that during the first few series, erbium rapidly separates in the least soluble portion, after which the other fractions become coloured greenish. As soon as the mother liquors fail to give any thulium absorption bands, when examined in a sat. soln. of about 10 cms., they are placed aside for the separation of ytterbium, etc. Thulium is found to collect in the fractions between erbium and ytterbium. The soln. become coloured a faint bluish-green and show a very intense absorption spectrum consisting of three bands. If very great care be taken, dil. alcohol can be used as solvent for a short time—best towards the end of the work. However, it soon shows signs of being attacked by the bromate.

(vii) *Isolation of ytterbium and lutecium.*—These three elements are contained in the mother liquor remaining after the separation of thulium. This can be fractionated by continuing the bromate process, provided the soln. do not become basic. G. Urbain fractionated the nitrates from nitric acid. Lutecium is more soluble than ytterbium. Lutecium salts have not yet been obtained of even a moderate degree of purity.

§ 6. The Processes Employed in Resolving the Rare Earths into their Component Earths

C. R. Böhm, in his *Die Darstellung der seltenen Erden* (Leipzig, 1905), reviews the methods which have been employed in resolving the rare earths into their components. He classifies these methods: I. Separation by fractional crystallization—*A*, simple salts; *B*, complex salts. II. Separation by fractional precipitation—*A*, basic salts; *B*, hydroxides and salts. III. Separation by oxidation processes—*A*, in the dry way; *B*, in the wet way. IV. Separation by physical methods. The following outline is based on that of C. R. Böhm.

Since fractional crystallization or precipitation usually involves the frequent repetition of the same operations, it is important to reduce the necessary operations to a minimum; not only because of the need for economizing time, but also to lessen the risk of accidents and the frittering away of the material by small losses. Large quantities of materials have usually to be handled in the initial operations in order to get relatively small amounts of the finished product. Expensive materials are often ruled out. Except in very special cases, it is well to avoid methods where troublesome precipitates have to be washed and ignited, or where tedious evaporations have to be made. As C. James[1] has said: " Fractional operations to be of value, must be very rapid."

I. Fractional crystallization.—Processes for the fractional crystallization of the rare earths are mainly dependent upon the fact that corresponding salts can form isomorphous or mixed crystals. The fractional crystallization of salts which are not isomorphous usually results in the separation of the least soluble or the most abundant component of the mixture; but the members of an isomorphous series of salts can usually be separated in the order of their solubilities. According to G. Urbain and H. Lacombe,[2] the usual order of separation is: La, Ce, Pr, Nd, Sa, Eu, Gd, Tb, Dy, Ho, Y, Er, Tm, Yb, Lu, *i.e.* with the exception of yttrium in the order of increasing at. wt. This is generally assumed to be the order of the solubilities. C. James, however, has shown that this does not always follow, because praseodymium bromate is rather more soluble in water than yttrium bromate, and yet when the mixed bromates of yttrium, praseodymium, erbium, and thulium are fractionated, praseodymium bromate accumulates in advance of the yttrium salt. Usually lanthanum furnishes the least soluble salt of the series, but in some cases the order is changed and lanthanum furnishes the most soluble salt. If the salts be not all isomorphous and of the same type, it is easy to understand how fractional crystallization may alter the order of separation. Thus, the bromonitrobenzenesulphonates studied by S. H. Katz and C. James, fall into three groups with different degrees of hydration, and each group has its own order of solubility as illustrated by Fig. 5. The order may be modified even in cases where the salts are isomorphous. Water is the most convenient solvent. The salts should have a high solubility in the hot solvent, and separate on cooling in compact crystalline masses so that the only operations involved are the dissolution of the crystals, the concentration of the soln., and the decantation of the mother liquors. The operations involved are outlined in connection with the extraction of radium chloride—**3.** 26, 2. It is a matter of opinion whether some processes should be classed with fractional crystallization or with fractional precipitation.

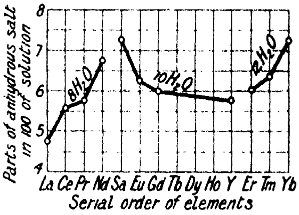

FIG. 5.—Solubilities of the Rare Earth Bromonitrobenzenesulphonates.

1. *Fractional crystallization of the halides.*—The action of alkali fluorides is described in connection with fractional precipitation—*vide infra.* C. Baskerville and R. Stevenson[3] also fractionally precipitated the chlorides by saturating a soln. of the chlorides with hydrogen chloride. P. H. M. P. Brinton and C. James obtained good results in the fractional crystallization of the rare earth chlorides from hydrochloric acid (1 : 1).

2. *Fractional crystallization of the bromates.*—C. James[4] and co-workers introduced a method for the separation of the yttria earths by the fractional crystallization of the bromates. The following method was recommended by C. James:

The rare earth material, generally in the form of the oxalates, is mixed into a paste with sulphuric acid and the temp. raised until the fumes of sulphuric acid cease to be evolved. The residue is then finely powdered, dissolved in ice-cold water, and the resulting soln. poured over an excess of barium bromate. This operation is best carried out in a large evaporating dish placed on the water-bath, care being taken to keep the mass well stirred. After a time the precipitate is allowed to settle and some of the clear liquid taken up by means of a pipette and added to a warm soln. of barium bromate; if no precipitate is obtained the liquid is filtered off. Sometimes, however, a precipitate is formed which consists of barium bromate: and, therefore, it is best to dilute with water and boil. If the precipitate persists, either more stirring or more barium bromate may be required. When the double decomposition is complete a little bromine is often liberated. This is evidently due to the fact that a small amount of bromic acid is formed by the action of a trace of free sulphuric acid accompanying the rare earth sulphates. The latter should, therefore, be well ignited. The filtered liquid is evaporated until a drop, removed on the end of a glass rod, nearly solidifies when stirred on a watch-glass. Under these conditions just about half of the substance in soln. crystallizes out on cooling. After a little experience there is absolutely no difficulty in judging the most convenient concentration. If the fractionation is carried out in porcelain dishes a little water should be sprayed on the surface so as to prevent the top from solidifying to a crystalline mass. Very often, but usually when working with small quantities, the liquid refuses to crystallize or else the crystals separate out as a fine feathery mass, so that it is quite impossible to pour off the mother liquor. If it does not crystallize, the best procedure is to add a trace of the solid, when the whole immediately solidifies, forming the feathery type of crystals as mentioned above. The mass is then carefully heated so as to dissolve all but a very little, which will start the crystallization as the liquid cools. An even better plan is to commence the operation by the addition of a crystal while the liquid is still quite hot. After about twenty crystallizations, the least soluble fraction is colourless and consists of the desired bromate with traces of dysprosium, samarium, holmium, and terbium; the next fractions are yellow, and show the spectral lines of dysprosium and holmium; the next fractions are pink, and they show the erbium lines; there is one fraction mainly thulium; and finally, a very soluble fraction, chiefly ytterbium.

The solubilities of the bromates increase in the following order: Sa, (Eu, Gd), Tb, Y, Dy, Ho, Er, Tm, Yb, similar to the order of the solubilities of the oxalates in ammonium oxalate. The order of separation with the bromates decreases with increasing at. wt. from lanthanum to europium, and thereafter increases with increasing at. wt.—*confer* Fig. 6 for the analogous behaviour of the nitrates. By the bromate process, C. James obtained thulium and yttrium bromates of a high degree of purity; L. Jordan and B. S. Hopkins separated terbium from samarium and europium; and H. C. Kremers and C. W. Balke, dysprosium and holmium from yttria earths.

3. *Fractional crystallization of the simple sulphates.*—The method depends on the fact that the sulphates of the rare earths are less soluble in hot water than in cold water, but to varying extents with the different earths. Consequently a sat. soln. of the dihydrated sulphate, made in ice-cold water, furnishes crystals of one or more of the hydrates, $M_2(SO_4)_3.nH_2O$, as the temp. is raised to 30°-40°. C. G. Mosander [5] used the process to separate lanthana and ceria, and didymia from lanthana, and it was used by J. C. G. de Marignac, M. Holzmann, C. Czudnowicz, R. Bunsen, C. Wolf, H. Robinson, P. Schützenberger, O. Boudouard, R. H. F. Manaske, etc. W. Muthmann and H. Rölig employed it to separate praseodymium and neodymium. Thorium is easily freed from the rare earths by this method, although the ceria earths are not so readily freed from thorium.

4. *Fractional crystallization of the double sulphates.*—The use of potassium and sodium sulphates as grouping agents for the rare earths has been described in previous sections. Nearly all investigators [6] on the rare earths have employed one or other of these agents; for cerium, thorium, and zirconium salts give precipitates with potassium sulphate, and the different solubilities of the double potassium sulphates is after used as a means of separating the rare earths from one another. The use of potassium sulphate in separating the ceria and yttria earths dates from M. H. Klaproth's work on ochroite; W. Hisinger and J. J. Berzelius worked simultaneously and independently on the same subject, and J. J. Berzelius later made observations on zirconia and thoria. The rare earths form double sulphates with sodium sulphate, and those formed with the ceria earths are very sparingly soluble in a sat. soln. of alkali sulphate. As indicated in the preceding section, sodium sulphate has been used by M. H. Klaproth, C. Erk, and many others. W. Gibbs, and C. H. Wing tried a number of sulphates other than those of the alkalies, and obtained the best results with luteocobaltic and roseocobaltic ammoniosulphates. The double sulphates are less soluble and crystallize better than those formed with the alkali sulphates. W. Gibbs found that the sulphates of the alkaloids offer no advantages. T. Scheerer, F. Wöhler, R. Hermann, N. Engström, L. F. Nilson, C. Schmidt, H. Rose, W. Gibbs, H. Bührig, J. L. Smith, A. Loose, F. M. Stapff, R. Fresenius and E. Hintz, etc., utilized the solubility of the double alkali sulphates in dil. acids; W. Hisinger and J. J. Berzelius, and R. J. Meyer and E. Marckwald,

n conc. nitric acid; G. Urbain, L. M. Dennis and E. M. Chamot, W. Muthmann, I. Rölig, and L. Stützel, in soln. of ammonium acetate.

5. *Fractional crystallization of the ethylsulphates.*—In 1898, G. Urbain[7] described method for the separation of the yttria earths by the fractional crystallization f the ethyl sulphates. The earths separate in the order terbia, yttria, holmia, ysprosia, erbia, and ytterbia. No free acid should be present, for ethylsulphuric cid is then readily hydrolyzed. The solubilities of the ethylsulphates of the rare arths decrease with increasing at. wt. from lanthanum to neodymium and thereafter ncrease—*confer* Fig. 6 for the analogous behaviour of the nitrates. The application f the process has been described in the previous section. By its means, G. Urbain eparated dysprosium from a mixture of yttrium, terbium, and dysprosium. . von Scheele separated lanthanum and praseodymium. K. A. Hofmann and . Burger obtained erbium from an admixture of thulium, holmium, dysprosium, nd erbium; and H. C. Kremers, C. W. Hopkins, and E. W. Engle, dysprosium from mixture of neodymium, praseodymium, and terbium, but it did not separate satisfactorily holmium and dysprosium. W. Muthmann and E. Baur employed the process for fractionating yttria earths. G. Urbain recommended separating the rare earths into three groups—ceria, terbia, and yttria earths—by means of the thylsulphate process in preference to the potassium sulphate process.

6. *Fractional crystallization of the nitrates.*—In 1896, E. Demarçay[8] separated gadolinium and samarium by crystallization of the nitrates from conc. nitric acid of sp. gr. 1·30 to 1·54. The method gives good results with earths of at. wt. less than that of dysprosium (162·5). This is due to the fact that the solubilities of the nitrates in nitric acid decrease with increasing at. wt. as shown diagramatically in Fig. 6, until gadolinium nitrate is reached, when after that, the solubilities increase with increasing at. wt. up to a maximum with ytterbium nitrate. E. Baur and R. Marc obtained good results with gadolinium and ytterbium; J. Blumenfeld and G. Urbain obtained ytterbium of a high degree of purity after 4000 fractionations; and with 15,000 fractionations of the ytterbium nitrate, G. Urbain separated it into lutecium and ytterbium, and from the mother liquor he obtained celtium. K. Bröckelmann obtained a didymium preparation which could not be fractionally crystallized by the usual methods, but with alcohol as solvent furnished scandium and yttrium. O. L. Barnebey fractionated the basic nitrates from acetone soln. and obtained cerium in the first fraction, didymium in the last one.

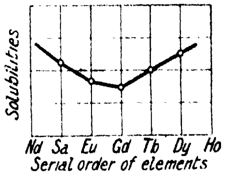

Fig. 6.—Solubilities of the Rare Earth Nitrates (Diagrammatic)

7. *Fractional crystallization of the double nitrates.*—(i) *The double ammonium nitrates*, $R(NO_3)_3.2NH_4NO_3.4H_2O$, were first used by D. I. Mendeléeff for the separation of lanthanum and didymium; and C. A. von Welsbach subsequently modified the process by crystallizing from nitric acid instead of from aq. soln. The method has been outlined in the previous section, and it has been extensively employed. C. James and others have used it in separating lanthanum and praseodymium; M. Esposito, lanthanum, praseodymium, and neodymium, etc. C. von Scheele modified the process by using ceria as *l'élément séparateur.*

(ii) C. A. von Welsbach, and C. von Scheele tried substituting sodium nitrate for ammonium nitrate, for separating lanthanum and praseodymium from neodymium, but the *double sodium nitrate* method was not economical or efficient since the separation is too slow.

(iii) E. Demarçay employed a process based on the fractional crystallization of the *double magnesium nitrates*, $2R(NO_3)_3.3Mg(NO_3)_2.24H_2O$, from nitric acid of sp. gr. 1·3. The process has been described in the preceding section. According to W. Muthmann and L. Weiss,[9] with the yttria earths the separation from water is in the order: La, Pr Nd, Sa, Eu. Er, Gd, Y, and the remaining yttria earths.

G. P. Drossbach used the process for the separation of neodymium and praseodymium; W. Feit, for the separation of terbium from monazite; and C. James, for the initial separation of the ceria earths.

(iv) G. Urbain and H. Lacombe[10] employed a process based on the fractional crystallization of the *double bismuth nitrates.* The bismuth also acts as *l'élément séparateur.* The process has been outlined in the preceding section. G. Urbain and H. Lacombe applied the process to the separation of gadolinium from the yttria earths; G. Urbain, to the separation of lanthanum and cerium from a mixture of ytterbium, lanthanum, lutecium, and cerium; G. Urbain and H. Lacombe, C. James and J. E. Robinson, and G. Eberhard, to the preparation of europium; and G. Urbain to the separation of terbium and gadolinium.

(v) G. Urbain[11] fractionally crystallized the *double nickel nitrates,* $2R(NO_3)_3.3Ni(NO_3)_2.24H_2O$, in order to separate traces of europium and terbium from gadolinium as indicated in the preceding section. When the soln. of the mixed earths is treated with nickel nitrate, the nickel gadolinium salt separates in a high degree of purity. The continued fractionation of the mother liquid furnishes terbium also of a high degree of purity.

(vi) H. Lacombe,[12] and C. James found that when the *double manganese nitrates,* $2R(NO_3)_3.3Mn(NO_3)_2.24H_2O$, are fractionally crystallized a good separation of neodymium and praseodymium from each other, and from lanthanum and samarium, is obtained, and this more quickly than with E. Demarçay's process—*vide supra.* The fractionation is best carried out in nitric acid of sp. gr. 1·3; the volume of the mother liquid should be maintained almost constant, and be very small in comparison with the bulk of crystalline matter separated. The formation of crystals may be initiated by a nucleus of the isomorphous bismuth manganese nitrate. C. James also recommended the process for the separation of neodymium and praseodymium.

8. *Fractional crystallization of the formates.*—Like the double potassium sulphates, the formates serve for separating the terbia earths. The formates of the ceria earths are much less soluble than those of the yttria earths. P. T. Cleve[13] gave 1 : 421 for the solubility of lanthanum formate in water; 1 : 360 for cerium formate; and 1 : 220 for didymium formate—J. C. G. de Marignac gave between 1 : 128 and 1 : 160 for the latter. According to B. Brauner, when a soln. of the rare earth formates is evaporated, the formates of the ceria earths separate first, then follow those of the terbia earths, while those of the yttria earths remain in soln. M. Delafontaine applied the method to the terbia earths and obtained *philippia* from the mother liquor. G. Urbain separated neodymium and praseodymium formates; A. Bettendorff separated the yttria earths into three groups; and J. Sterba-Böhm removed the last traces of ytterbium from scandium by the fractional crystallization of the formates. G. Urbain showed that philippia is a mixture of terbia and yttria which cannot be completely separated as formates—*vide* fractional precipitation.

9. *Fractional crystallization of the acetates.*—N. J. Berlin[14] observed that by the repeated crystallization of the so-called yttrium acetate, the rose-coloured crystals became colourless. J. F. Bahr and R. Bunsen also found that by the fractional crystallization of the acetates of erbium and yttrium the first crop of crystals was richer in erbium than the later crops. O. Popp, M. Delafontaine, C. Benedicks, and others made observations on this subject. The yttrium acetates are less soluble than those of the cerium group. K. T. Postius separated mixtures of yttria and terbia earths by the fractional crystallization of the acetates.

10. *Fractional crystallization of the acetylacetonates.*—G. Urbain[15] showed that the acetylacetonates of the rare earths, $R[CH(COOCH_3)_2]_3$, crystallize well, and he applied the fact to the purification of thoria. The mixed hydroxides were first dissolved in nitric acid, and the soln. evaporated to dryness on a water-bath, the residue was dissolved in water, and treated with sodium acetylacetonate, and again evaporated to dryness. The residue, crystallized from its soln. in chloroform, furnished thoria of a high degree of purity. G. Urbain also fractionated the rare

earths from monazite by this process using absolute alcohol as solvent. K. A. Hofmann likewise separated erbium from holmium and dysprosium; and R. J. Meyer and A. H. Winter, scandium from the rare earths in wolframite.

11. *Fractional crystallization of the dimethylphosphates.*—J. C. Morgan and C. James [16] found that with dimethylphosphoric acid the rate of separation of the rare earths is vastly greater than with that of practically all the methods given up to the present time. Lanthanum, cerium, praseodymium, neodymium are left at once in the mother liquor. Samarium, europium, and gadolinium are much less soluble than those previously mentioned, while they are more soluble than terbium, dysprosium, and holmium. Erbium, thulium, yttrium, ytterbium, etc., collect in the least soluble portions. Since the solubilities of these compounds are the reverse of the usual type, they may be used for the rapid purification of many of the rare earths. For instance, we can easily remove traces of neodymium from samarium by this means, as the samarium dimethyl phosphate separates before the neodymium compound. It is necessary to state that there is some inconvenience when working with the salts of dimethyl phosphoric acid, since they undergo a very gradual decomposition. A gelatinous precipitate is formed, very slowly, in the case of the rare earths, which filters with difficulty.

12. *Fractional crystallization of the picrates.*—L. M. Dennis [17] and co-workers recommend crystallization from a hot soln. of the hydroxides in picric acid for separating erbia and holmia from the didymia and yttria earths previously freed from ceria and thoria. It is also said to be an "excellent means of effecting a rapid concentration of praseodymium and neodymium practically free from erbium and holmium, and the concentration of erbium and holmium with but a relatively small amount of the members of the didymium group." P. S. Willand and C. James found that for the separation of erbia from yttria, the method does not compare favourably with other processes.

13. *Fractional crystallization of the* m-*nitrobenzenesulphonates.*—O. Holmberg [18] found that the *m*-nitrobenzenesulphonates of the cerium earths crystallize very well, and he successfully separated and purified neodymium as *m*-nitrobenzenesulphonate. C. Garnier also found this a speedy method for separating neodymium from mixtures with samarium and praseodymium. P. S. Willand and C. James tried the diphenylmonosulphonates for separating erbia from yttria, but no special advantages were observed.

14. *Fractional crystallization of sulphanilates.*—L. Stützel [19] separated neodymium from praseodymium by the fractional crystallization of soln. of the oxides in sulphanilic acid. K. T. Postius also removed the last traces of didymia from erbia by this means. This method has nothing to recommend it in preference to other more efficacious processes.

II. Separation by fractional precipitation.—In these methods the mixed earths are dissolved and then gradually concentrated by precipitation in stages as indicated in the preceding section.

1. *Fractional precipitation by ammonia.*—The method was employed by J. J. Berzelius,[20] C. G. Mosander, M. Delafontaine, O. Popp, P. T. Cleve, W. Crookes, B. Brauner, L. de Boisbaudran, etc.—*vide supra*. K. A. Hofmann and O. Burger used the same method for removing traces of thulium, holmium, and dysprosium from erbium. Ammonia effects a separation strictly in the order of the basicity of the bases. Starting with the weakest, *i.e.* the base first to be precipitated, the order is Zr, Th, Ce (ous), Sc, Yb, Tm, Er, Ho, Dy, Tb, Y, Sa, Gd, Nd, Pr, Ce (ic), La. There are, however, considerable differences of opinion in detail. R. Marc, P. Truchot, L. de Boisbaudran, A. Bettendorff, C. Benedicks, K. T. Postius, C. G. Mosander, G. Krüss and K. A. Hofmann, A. Loose, R. Hermann, G. Urbain, and W. Muthmann and co-workers give a different order. W. A. A. Prandtl and J. Rauchenberger show that the reaction $RCl_3+3NH_3+3H_2O\rightleftharpoons R(OH)_3+3NH_4Cl$ is reversible. W. A. A. Prandtl and co-workers examined the effect of cadmium and cobalt on the basic precipitation.

2. *Fractional precipitation by alkali hydroxides.*—The main features of the process are the same as those with the ammonia precipitation. A dil. soln. of sodium hydroxide was found by G. P. Drossbach[21] to give good results in separating didymium from lanthanum, and in fractionating a mixture of the erbia earths which had been previously treated by the magnesia process. B. Brauner and F. Pavlicek used it for purifying lanthanum earths, and H. Behrens, for cerium earths.

3. *Fractional precipitation by organic bases.*—In this connection *aniline* has been used more than the other organic bases. In applying the process, a neutral soln. of the chlorides in 50 per cent. alcohol, at say 90°, is treated with a 2 per cent. soln. of aniline in 50 per cent. alcohol. The method was used by K. A. Hofmann and O. Burger[22] for separating holmium, thulium, and dysprosium from erbium; by G. Krüss for fractionating holmia earths; and by A. Kolb for purifying thoria. A. Loose tested didymium for homogeneity by fractional precipitation with aniline. A number of other bases—*o-toluidine, xylidine, dimethylaniline, diethylaniline, benzylamine, pyridine, quinoline, piperidine, phenylhydrazine, dimethylamine, triethylamine, diphenylamine, naphthylamine,* m-*chloro-aniline, benzidine, picoline,* etc.—have been tried by A. McM. Jefferson, B. L. Hartwell, G. Krüss and co-workers, and K. A. Hofmann. Some might give good results in special separations.

With respect to cerium, lanthanum, neodymium, praseodymium, thorium and zirconium, B. L. Hartwell found (i) *benzylaniline, dimethylnitrosamine, dipropylnitrosamine, o-, m-* and *p-nitroaniline, p-nitrophenylhydrazine, o-chloro-aniline, piperidine, succinimide, and tetranitromethylamine* precipitated none of the six bases from their soln.; (ii) *Allylamine, benzylmethylamine, bornylamine, camphylamine, diamylamine, dibenzylamine, diethylamine, dimethylamine, dipropylamine, ethylenediamine, heptylamine, hexylamine, isobutylamine, isotributylamine, isodibutylamine, monoamylamine, monoethylamine, monomethylamine, monopropylamine, neurine, normal butylamine, normal dibutylamine, propylenediamine, tetraethylammonium hydroxide, tetramethylammonium hydroxide, triethylamine, trimethylamine, tripropylamine,* give precipitates with salts of all six earths; and *benzidine, m-bromo-aniline, p-bromo-aniline, p-bromo-phenylhydrazine, p-chloro-aniline, isoquinoline, α-picoline, p-toluidine, m-toluylenediamine, tribenzylamine,* give precipitates only with thorium and zirconium salts. The chloro-anilines and hexamethylene-tetramine appeared the most suitable of the bases tried for the separation of thorium from zirconium, whilst *p*-toluidine gave promising results in the separation of zirconium and thorium from lanthanum, neodymium, and praseodymium. J. Köppel[23] dissolved a mixture of rare earths in a soln. of hydrogen chloride in methyl alcohol, and added pyridine. Crystals of cerium pyridine chloride, $(C_5H_5NH)_2CeCl_6$, separate, and they can be purified by recrystallization from a mixture of alcohol and ether.

4. *Fractional precipitation by magnesia.*—C. Czudnowicz[24] tried to fractionate the ceria earths by boiling the nitrate with magnesia. G. P. Drossbach suggested using magnesia in place of ammonia or alkali hydroxide, and he found that the earths are precipitated in the order of their different basicities. Magnesia is gradually added to a boiling soln. of the nitrates, until the filtrate no longer shows the spectral bands of didymium. W. Muthmann and H. Rölig thus separated lanthanum from didymium in a single operation, but the yield was poor. The precipitation can be conducted in a series of stages whereby the least basic element will be found in the first fractions, and the most basic element in the last fraction. G. P. Drossbach separated yttria from the yttria earths by this process.

5. *Fractional precipitation by cuprous oxide.*—L. de Boisbaudran[25] claimed to separate thoria from the other rare earths by the following process:

Boil for a few minutes the soln. mixed with copper turnings and acidified with a few drops of hydrochloric acid, so as to reduce the weakly basic ceric salt to the strongly basic cerous salt. Add a slight excess of finely powdered cuprous oxide, and boil the mixture for an hour.

The precipitated thoria contains a little ceria which can be removed by two or three repeated [illegible] of the process. The copper is removed by hydrogen sulphide.

G. P. Drossbach, P. Schützenberger and O. Boudouard, and G. Urbain examined the process. The latter found that cuprous oxide does not precipitate all the thoria from the soln.

6. *Fractional precipitation by basic oxides.*—C. A. von Welsbach[26] devised an important process—*Welsbach's basic oxide process*—in which the oxides of the rare earths themselves act as basic oxide, like the magnesia in the above-described process, and so hasten the formation of sparingly soluble basic salts of elements of weakened basicity. The process differs in details according to the particular mixture employed. For the mixed ceria and yttria earths, the process is conducted as follows:

Dissolve, say, 100 grms. of the mixed ceria and yttria earth oxides in the minimum quantity of nitric acid for dissolution; and add gradually a paste made from another 100 grms. of the same oxides. Care must be taken that at no point is all the oxide dissolved. The soln. should have a syrupy consistency and contain some undissolved oxide; it also becomes hot owing to chemical action. On cooling, most of the yttrium and erbium will be found as basic nitrate in the crystalline precipitate. Enough nitric acid is added to change the colour of the soln. red, and to dissolve all the residual oxide and carbonate. The basic nitrates are insoluble. A rose-coloured precipitate forms in a few hours, and sets to a hard mass. The mother liquid is decanted off, and the residue extracted with alcohol to remove normal nitrates from the basic nitrates containing the erbia group, some scandia, and some ytterbia; the soln. contains nitrates of yttrium and ceria earths. The ceria can be removed by the basic nitrate process. The separation of the yttria earths can be continued by repeating the process.

G. P. Drossbach used the process for the yttria earths; P. Schottländer for the ceria earths; and G. P. Drossbach, H. Behrens, W. Muthmann and L. Weiss, P. Schottländer, and C. R. Böhm for separating lanthana and didymia. It has also been described in the preceding section.

7. *Fractional precipitation by alkali azides.*—L. M. Dennis[27] and co-workers added a 0·3 per cent. soln. of potassium or sodium azide to a cold soln. of earth containing thoria, and on boiling found thoria to be precipitated as hydroxide: $Th(NO_3)_4+4NaN_3+4H_2O=Th(OH)_4+4NaNO_3+4HN_3$; but G. N. Wyrouboff and A. Verneuil did not get the same results.

8. *Fractional precipitation by sulphurous acid or sulphites.*—M. H. Klaproth,[28] and N. J. Berlin utilized the fact in analytical work that sulphurous acid or soluble sulphites give precipitates with some metal salt soln., and P. Berthier first applied the reaction to salts of the rare earths. When a sat. soln. of sodium sulphite is added to neutral soln. of rare earths and thoria, the ceria and yttria earths are precipitated, but thoria remains in soln.; on the contrary, sodium hydrosulphite precipitates thoria from a cold soln., but does not precipitate the ceria earths. J. P. Bonardi and C. James precipitated the yttria earths from boiling soln. mixed with potassium sulphite. The reactions have been utilized by H. Grossmann, and A. Batek for purifying thoria, and separating thoria from ceria earths. The reaction has also been applied by R. Hermann, W. Henneberg, C. Erk, C. Baskerville, W. Buddäus and co-workers, H. Geisow and P. Horkheimer, and R. Chavastelon.

9. *Fractional precipitation by sodium thiosulphate.*—N. J. Berlin[29] found that the yttria earths are not precipitated from their soln. by sodium thiosulphate; F. Chancel, R. Hermann, F. Stromeyer, M. Weibull, K. Rördam, and P. T. Cleve found that zirconia is precipitated under these conditions; and W. C. Brögger, and O. Boudouard used the process to separate zirconium from titanium. J. J. Chydenius found that when a soln. of sodium thiosulphate is added to a soln. of the rare earths, thorium thiosulphate is precipitated when the soln. is boiled, while the rare earths remain in soln. W. Crookes noted that some yttria is carried down with the precipitate. P. T. Cleve found that scandia is readily but not completely precipitated under these conditions; samaria is not precipitated. R. Bunsen, and G. Urbain have utilized the reaction to separate thoria from the rare earths—*vide supra*. P. H. M. P. Brinton and C. James did not recommend the basic thiosulphate process for the separation of the erbia earths.

10. *Fractional precipitation as fluorides or fluosilicates.*—J. J. Berzelius,[30] and J. J. Chydenius noted that the addition of hydrofluoric acid or of normal or acid alkali fluorides to thorium salts gives a gelatinous precipitate of thorium fluoride.

The precipitation is almost quantitative. J. J. Chydenius, and A. Rosenheim and co-workers studied zirconium fluoride. While the rare earth fluorides are insoluble in an excess of hydrofluoric acid or soln. of alkali fluorides, zirconium fluoride is readily soluble under these conditions. When hydrofluoric acid or potassium fluoride is added to a soln. of salts of the rare earths containing zirconium and titanium the fluorides of these elements are all precipitated; and when fused with potassium hydrofluoride, and the cold cake extracted with water, the zirconium and titanium are dissolved while the rare earth fluorides remain as a residue. The solubility of the rare earth fluorides in a large excess of conc. acid increases with the electropositive character of this metal, the fluorides of the more negative elements being least soluble. Hence, thoria and scandia may be conc. to a large extent by repeated precipitation with hydrofluoric acid in acid soln. As shown by F. Stolba, the fluosilicates of the rare earths form gelatinous precipitates when hydrofluosilicic acid or alkali fluosilicate is added to a boiling neutral soln. of the rare earth salt. In the presence of mineral acids, the precipitation does not occur in the cold. The cerium fluosilicate is hydrolyzed to the fluoride; the yttrium elements are held in soln. by the mineral acid; the scandium salt is precipitated. R. J. Meyer used this process for separating scandia from the rare earths—*vide* scandium. J. Sterba-Böhm used ammonium fluoride to separate scandia from the hydrochloric acid soln. of wolframite residues.

11. *Fractional precipitation of the chlorides and oxychlorides.*—J. J. Berzelius[31] noted the hydrolysis of a soln. of zirconium chloride, and on boiling a basic chloride was precipitated. G. H. Bailey separated iron from zirconium by boiling the mixed chlorides; zirconium oxychloride is precipitated and the iron remains in soln. G. Krüss and L. F. Nilson, F. P. Venable, O. Hauser, and J. M. Matthews also studied the reaction with zirconium. G. P. Drossbach dissolved the mixed erbia and yttria earths in hydrochloric acid, and added more of the mixed oxides until the soln. showed no more erbium spectral bands. The mixture was heated some hours on a water-bath, mixed with a large proportion of boiling water, and allowed to settle. The precipitate contained all the erbia, and it was repeatedly boiled with a soln. of ammonium chloride to remove traces of entrained yttrium. The same method was used for separating praseodymium and neodymium. J. C. G. de Marignac found that when a mixture of the lanthanum, didymium, etc., chlorides is heated some of the earths form oxychlorides, others not. When the residue is treated with water, the earths can be separated. P. H. M. P. Brinton and C. James did not recommend the *basic chloride process* for the separation of the erbia earths. M. Fronstein and J. Mai used the process for the initial separation of the monazite earths. The process has been modified by H. Behrens, F. Frerichs, etc. C. James and co-workers tried the process for the separation of erbia from yttria earths. C. Baskerville and R. Stevenson fractionally precipitated neodymium and lanthanum by passing hydrogen chloride into the soln. W. Gibbs tried *bromides* in place of chlorides.

12. *Fractional precipitation with iodates.*—N. J. Berlin[32] observed that yttria earths are precipitated as an amorphous white powder by alkali iodates; and P. T. Cleve noted that zirconium and thorium are likewise precipitated quantitatively as iodates under similar conditions. When calcined, the iodates pass into oxides. R. J. Meyer and J. Wuorinen, and H. C. Holden and C. James found that on the addition of a soln. of potassium iodate, drop by drop, to a hot soln. of the nitrates, acidified with nitric acid, yttrium iodate is precipitated last; and when iodic acid is added to a soln. of scandium and thorium salts, most of the thorium is precipitated, while the scandium remains in soln.

13. *Fractional precipitation by ammonium or alkali carbonates.*—In 1802, M. H. Klaproth[33] showed that white yttria earths are precipitated from soln. of their salts by potassium, sodium, or ammonium carbonate, and the precipitate is soluble in an excess of the reagent. The precipitate with dil. soln. of carbonate is a simple rare earth carbonate, but with a conc. soln., a double carbonate is produced:

$K_2CO_3.R_2(CO_3)_3.12H_2O$; $3Na_2CO_3.R_2(CO_3)_3.(20-24)H_2O$; $(NH_4)_2CO_3.R_2(CO_3)_3.(4-6)H_2O$. The potassium salt is the most soluble in water. The double carbonates of the cerium group are least soluble, those of the yttrium group come next, and the double thorium carbonate is most soluble. R. J. Meyer used the reactions for separating lanthanum and praseodymium ; A. Damour, for separating thoria from the ceria earths ; and R. J. Meyer and A. H. Winter, for separating scandia and thoria.

14. *Fractional precipitation with barium carbonate.*—According to J. C. G. de Marignac, when barium carbonate is added to a soln. of thoria and the rare earths, thoria and ceria earths are precipitated, but not the yttria earths. O. Popp, C. Erk, and C. Schmidt applied the reaction to the separation of these earths.

15. *Fractional precipitation by chromic acid or the chromates.*—N. J. Berlin[34] observed that a soln. of yttrium chromate dissolves yttria, forming a basic salt. M. M. Pattinson and J. Clark heated a mixture of ceria earth chromates to 110°, and found that the cerium chromate becomes insoluble, while the congener earths are not changed. A. Brauell, and L. M. Dennis and B. Dales founded analytical methods on the reaction. G. Krüss and A. Loose, and W. Muthmann and C. R. Böhm found that potassium chromate precipitates the ceria earths in the order : La, Pr, Nd, and Sm ; and the yttria earths in the order : Tb, Yb, Er, Y, and Gd. J. E. Egan and C. W. Balke separated yttria from terbia and gadolinia by this method, but B. S. Hopkins and C. W. Balke found that erbia and holmia cannot be completely separated from yttria by the chromate method, but the other yttria earths can be separated. According to C. James, the method is valuable for rapidly preparing yttria of a high degree of purity from the crude yttria earths freed from ceria earths and terbia—*vide supra.*

16. *Fractional decomposition of the carbides.*—H. Moissan[35] found that the carbides of zirconium, iron, etc., are not decomposed by water, while the carbides of thorium, the rare earth metals, calcium, etc., are decomposed by water. They are made by heating the metal oxides with carbon in the electric arc furnace. When the finely powdered carbides of the ceria earths are treated with very dil. nitric acid, and the soln. evaporated to dryness, and ignited, white cerium oxide is said to be formed, B. Brauner showed that the white colour may be taken to indicate that much thoria was present. H. Moissan and F. Lengfeld converted zircon into a form susceptible to attack by acids by converting it into carbide ; and W. Muthmann and co-workers treated monazite in a similar way.

17. *Fractional precipitation with potassium ferrocyanide.*—N. J. Berlin[36] obtained a white precipitate by the addition of potassium ferrocyanide to a soln. of yttria earths ; L. T. Lange, A. Brauell, and P. T. Cleve obtained a non-crystalline precipitate with soln. of salts of ceria earths, and with thorium ; and H. Rose, H. Sjögren, and R. Hornberger obtained precipitates with soln. of zirconium salts. H. A. Rowland, H. Behrens, W. Crookes, A. Bettendorf, etc., recommended fractionally precipitating a neutral soln. of the mixed earths by means of a sat. soln. of potassium ferrocyanide, so as finally to concentrate all the erbium in the first fraction. P. S. Willand and C. James tried potassium ferrocyanide for the separation of erbia from yttria earths. J. P. Bonardi and C. James effected a rapid separation of yttrium from yttria earths by precipitation with *potassium cobalticyanide.* They say that the method is without doubt one of the most rapid known. P. S. Willand and C. James also tried the same reagent for the separation of erbia from yttria earths.

18. *Fractional precipitation as basic nitrates and sulphates.*—C. G. Mosander[37] found that when ceric sulphate is largely diluted with water, a yellow basic salt is deposited, owing to the hydrolysis of the ceria salt. R. Hermann applied the reaction to the purification of ceria. According to the former, the mixed oxides are digested with conc. nitric acid, and the insoluble portion is dissolved in conc. sulphuric acid. An excess of acid is avoided. The two soln. are mixed, largely diluted with water, and boiled—basic ceric sulphate is precipitated. The washed

precipitate is redissolved in sulphuric acid, and reprecipitated. B. Brauner preferred to work wholly with nitric acid because an excess is not so harmful as is the case with sulphuric acid, since ceric nitrate is more easily converted into the basic salt than is the case with ceric sulphate. C. G. Mosander's method of purifying ceria was for a long time considered the best; it was employed by M. Holzmann, C. F. Rammelsberg, C. Czudnowicz, R. Hermann, T. Lange, C. Wolf, C. H. Wing, C. Erk, H. Bührig, R. Bunsen, J. C. G. de Marignac, etc. The properties of the salt have been studied by B. Brauner and co-workers, R. J. Meyer and co-workers, W. Muthmann and H. Rölig, etc. The formation of a basic zirconium sulphate was observed by J. J. Berzelius, H. Endemann, S. R. Paykull, O. Hauser, etc.

R. Bunsen evaporated a nitric acid soln. of the mixed earths to a syrupy consistency and poured the product into a large vol. of water slightly acidified with nitric acid, the precipitate of basic ceric nitrate was washed and dried. B. Brauner said the ceria formed by the ignition of the basic nitrate is practically pure, but H. Behrens stated that it contains both neodymium and samarium. The basic ceric nitrate process has been used by R. Hermann, C. Czudnowicz, C. F. Rammelsberg, H. Zschiesche, G. Krüss and L. F. Nilson, G. P. Drossbach, R. J. Meyer, W. N. Hartley, H. Robinson, etc. The process of G. N. Wyrouboff and A. Verneuil, and J. Sterba is as follows :

The mixed oxides are gradually added to about four times their weight of cold, conc. nitric acid, and warmed to 50°–60° towards the end of the operation. The dark red soln. is allowed to stand for 24 hrs.; decanted from any insoluble residue; and evaporated on a water-bath until the syrupy liquid solidifies on cooling. The product is dissolved in an amount of water equal to 10–30 times the weight of the oxides used; a gram of ammonium chloride per litre of liquid is added, and the soln. boiled for a quarter of an hour. The pale, greenish-yellow precipitate so obtained is a mixture of basic ceric nitrate and sulphate. The precipitate is washed in a dil. soln. of ammonium nitrate and sulphate. The precipitate contains nearly all the cerium, but a little may still be present in the filtrate. This can be removed by the hydrogen dioxide or by the ammonium sulphate process described below. J. Sterba modified the method by oxidizing the cerous nitrate to ceric nitrate by means of a current of about 0·7 amp. and 2 volts, the liquid containing about 1 per cent. of nitric acid. The ceric oxide is precipitated with ammonia and a small quantity of ammonium sulphate, and the precipitate washed with water containing 5 per cent. of ammonium nitrate and 1 per cent. of ammonium sulphate. The process is repeated until the substance shows no absorption spectrum of impurities.

N. J. Berlin[38] found that the nitrates of the different rare earths decompose at different temp., and the work of J. C. G. de Marignac, P. T. Cleve, L. F. Nilson, G. Krüss, O. Boudouard, G. and E. Urbain, etc., has shown that the order of decomposition is the same as the order of their basicity; and, commencing with the least basic and most readily decomposed, this order is: Zr, Th, Ce (ic), Sc, Yb, Tm, Er, Ho, Tb, Sa, Gd, Nd, Pr, La. The mixture of nitrates is ignited at a relatively low temp., cooled, and extracted with hot water; the nitrate decomposed to form a basic nitrate remains undissolved. The filtrate is evaporated to dryness, and the operation repeated. Details are described in the preceding section. The method has been very frequently employed. By this process, A. Bettendorf, and A. Damour and H. St. C. Deville separated lanthanum and didymium; and J. C. G. de Marignac was led to the discovery of ytterbium; and L. F. Nilson, to that of scandium. H. C. Kremers and C. W. Balke found that holmium and yttrium cannot be separated, but if samarium be present, the separation is easy and rapid. This is the so-called basic nitrate process. P. H. M. P. Brinton and C. James obtained good results by this process in separating the erbia earths.

H. Debray[39] fused the mixed earths with 8 to 10 times their weight of potassium nitrate at 300°–350° for some hours; the cerium nitrate was alone decomposed, and on extraction with water remains insoluble, while lanthanum and didymium nitrates pass into soln. This is the so-called *Debray's basic nitrate process*. L. M. Dennis and W. H. Magee showed that the temp. of fusion of the nitrate used by H. Debray, *viz.* 325°, is so near the decomposition temp. of didymium nitrate (300°) that the basic cerium nitrate is contaminated with basic didymium nitrate. They preferred to work with an equimolar mixture of sodium and potassium nitrates, fusing at 231°, and so bring the m.p. above the decomposition temp. of cerium nitrate, *viz.* 200°, and below that of didymium nitrate.

19. *Fractional precipitation with alkali nitrates.*—The alkali nitrates were found by H. Erdmann,[40] and L. Pissarjewsky to precipitate thorium hydroxide from soln. of its salts ; and with neutral soln. of zirconium salts, the precipitation of zirconium hydroxide is complete. G. Krüss and A. Loose found that the reaction with the rare earths is not suited for the separation of ytteria and ceria earths. C. James and co-workers found that if the yttria earths be dissolved in nitric acid, diluted, boiled, and mixed with a boiling soln. of sodium nitrite, the yttrium concentrates in the later fractions, and the isolation of yttria is effective and rapid if terbium be absent. B. S. Hopkins and C. W. Balke also found that yttria is rapidly separated from holmium and erbium earths by this process. K. A. Hofmann and O. Burger evaporated to dryness a soln. of sodium nitrite with thulmium, holmium, dysprosium, and erbium nitrates. When the dry residue was extracted with water most of the erbium oxide remained insoluble.

20. *Fractional precipitation by the acids of phosphorus, arsenic, and vanadium.*—W. Hisinger and J. J. Berzelius,[41] and J. C. G. de Marignac found that phosphoric acid precipitated the ceria earth phosphates from soln. of the salts ; L. N. Vauquelin, and R. Hermann, that it precipitates zirconium and thorium phosphates ; but, according to L. N. Vauquelin, yttria earth phosphates are not precipitated under like conditions. P. T. Cleve, G. Wyrouboff and A. Verneuil, and C. Volck found that with thorium salts the precipitation by orthophosphoric acid is quantitative. L. N. Vauquelin showed that all the rare earths are precipitated by sodium phosphate ; and, added A. Loose, secondary sodium phosphate precipitates the primary phosphate of yttrium. H. C. Holden and C. James tried fractionally precipitating the yttria earths with ammonium phosphate, monomethylphosphate, and dimethylphosphate. P. S. Willand and C. James tried sodium phosphate for the separation of erbia from yttria earths. J. C. Morgan and C. James found the solubilities of the dimethylphosphates expressed in parts of salt per 100 parts of water at 25°, to be :

La	Ce	Pr	Nd	Sa	Gd	Y	Er	Yb
103·7	79·6	64·1	56·1	35·2	23·0	2·8	1·78.	1·2

The subject was also investigated by L. Jordan and B. S. Hopkins. P. T. Cleve showed that pyrophosphoric acid gives a voluminous precipitate with soln. of thorium salts. A. Rosenheim and T. Triantaphyllides found that both cerium and thorium pyrophosphates are precipitated by sodium pyrophosphate, but the former is alone dissolved by hydrochloric acid. O. Kauffmann noted that thorium salts are precipitated by *hypophosphorous acid.* F. Wirth found that when this acid or sodium hypophosphite is added to a soln. of the rare earths in hydrochloric acid, thoria is alone precipitated as hypophosphite. With soln. of the earths in sulphuric acid sodium cerium earth sulphates are precipitated as well. This is avoided by preparing the hypophosphoric acid in soln. either by the oxidation of yellow phosphorus, or by the anodic oxidation of copper phosphide. O. Kauffmann obtained a white precipitate by treating thorium salts with *phosphorus or hyphosphorous acid.* H. C. Holden and C. James tried fractionally precipitating the yttria earths with sodium phosphite, and with sodium hypophosphite.

21. *Fractional precipitation with arsenates and vanadates.*—W. Hisinger and J. J. Berzelius[42] obtained no precipitate by adding arsenic acid to soln. of ceria earth salts, but J. C. G. de Marignac found that when arsenic acid is boiled with didymium salts a precipitate is produced which does not dissolve readily in acids. M. H. Klaproth, and N. J. Berlin found that potassium arsenate gives an insoluble gelatinous precipitate with yttria earths. J. J. Berzelius obtained a similar precipitate with thorium salts. G. Krüss and A. Loose separated samarium, lanthanum, and didymium salts from scandium, ytterbium, erbium, and terbium salts by

fractional precipitation with this reagent; and H. C. Holden and C. James tried sodium arsenate as a fractional precipitant for the yttria earths. G. Krüss and A. Loose obtained poor results with *potassium arsenite.*

J. J. Berzelius noted that neutral alkali *vanadates* give a precipitate with soln. of the yttria earths while acid vanadates give no precipitation; neither neutral nor acid vanadates give a precipitate with zirconium salts; and thorium salts behave like the yttrium salts. C. Volck found thorium salts are quantitatively precipitated by salts of metavanadic acid.

22. *Fractional precipitation with tungstates and molybdates.*—N. J. Berlin[43] found that sodium tungstate with soln. of yttria earths gives a white sparingly soluble precipitate; F. Frerichs and F. Smith, A. Cossa, M. Zechini, and F. R. M. Hitchcock obtained similar results with cerium, lanthanum, neodymium and praseodymium salts. J. J. Berzelius found thorium salts behave similarly, while zirconium hydroxide dissolves in a boiling soln. of potassium paratungstate. W. Gibbs stated that the precipitates given by soln. of the rare earth salts with phosphotungstic acid are probably simple tungstates. J. P. Bonardi and C. James obtained poor results in trying sodium tungstate for separating the yttria earths.

N. J. Berlin found that an alkali molybdate with soln. of yttria earths gives a curdy precipitate insoluble in water. W. Hisinger and J. J. Berzelius, and A. Cossa obtained similar results with soln. of ceria earths; and F. R. M. Hitchcock with neodymium and praseodymium. J. J. Berzelius, and J. J. Chydenius found thorium salts behave similarly. W. Gibbs also stated that phosphomolybdic acid probably precipitated simple molybdates.

23. *Fractional precipitation with formates.*—J. J. Berzelius[44] found that thorium formate which is soluble in alcohol and in hot water, is decomposed by cold water (the hot soln. does not become turbid), and M. Delafontaine could not purify the salt by recrystallization. L. Haber found that sodium formate could be used as a precipitating agent in the purification of thoria. When zirconium salt soln. are boiled, hydrated zirconia is precipitated; with cerium, sparingly soluble salts are formed in cold and hot water. H. Behrens found ammonium formate precipitated the ceria earths but not the yttria earths. K. Postius did not get good results by the fractional soln. of the finely divided earths in dil. formic acid.

24. *Fractional precipitation with acetates.*—Unlike the salts of most tervalent metals, the addition of an alkali acetate to a soln. of a rare earth salt gives no precipitate when the soln. is boiled; so that the hydrolysis of the rare earth salts under these conditions is relatively small. In this respect, too, the salts of the rare earths differ from the salts of tetravalent cerium, thorium, and zirconium for the salts of these tetravalent elements, when boiled with sodium acetate give sparingly soluble basic acetates. O. Boudouard[45] claimed to confirm P. Schützenberger's observation that ceria is complex, by fractionally precipitating thoria-free cerium sulphate as acetate, but G. Wyrouboff and A. Verneuil showed that a mistake had been made. N. A. Orloff also claimed to purify ceria in the form of its acetate. Even sparingly soluble salts of the rare earths usually dissolve when digested with a soln. of ammonium acetate. G. Krüss examined L. de Boisbaudran's method of separating erbia, holmia, thulia, and ytterbia earths based on the retarding action of ammonium acetate on the precipitation of the rare earths by ammonia, but obtained unsatisfactory results. M. Delafontaine investigated the action of ammonia on yttrium acetate. The solubility of thorium oxalate in soln. of ammonium acetate was noted by R. Finkener, H. Rose, G. P. Drossbach, C. Glaser, and E. Benz; the solubility of the double potassium sulphate, by G. Urbain, L. M. Dennis and E. M. Chamot, and L. Stützel; and H. Bäckström, and P. T. Cleve noted that titanium and zirconium oxides are precipitated when soln. containing ammonium acetate are boiled. O. Popp, and R. J. Meyer and M. Koss noted the quantitative precipitation of ceric oxide from neutral soln. by sodium acetate, while didymium and lanthanum remain in soln. L. M. Dennis and B. Dales, C. G. Mosander, and G. Krüss fractionally precipitated the yttria earths by adding dil. acetic acid drop

by drop to a soln. of the hydroxides in ammonium carbonate. Terbia and yttria accumulate in the first fractions, holmium, thulium, and dysprosium in the middle fractions, and erbium and ytterbium in the last fractions.

25. *Fractionation by precipitation with stearic acid.*—C. W. Stoddart and C. W. Hill[46] found that the yttria earths can be separated from monazite, gadolinite, and samarskite by the addition, drop by drop, of a 50 per cent. hot alcoholic soln. of potassium stearate to a cold vigorously stirred soln. of the neutral nitrates and in quantity sufficient for the precipitation of a fractional portion of the earths present. The more basic earths precipitate first. It is said that the precipitate formed is easily filtered and washed, the precipitant cheap, the separation sharp and distinct. For the preparation of pure yttria from monazite it is decidedly the best method known, and yttria is one of the most difficult rare earths to separate pure. Only one reagent is necessary, and few fractionations are required, thereby saving a great amount of time, as well as of material, in a large number of manipulations.

26. *Fractional precipitation with oxalic acid or the oxalates.*—C. G. Mosander[47] introduced a method for the separation of the rare earths based on the varying solubilities of the oxalates in water. The details of the original method have undergone many modifications; and advantage has been taken of the varying solubilities of the rare earth oxalates in dil. mineral acids in oxalic acid, and in soln. of alkali or ammonium acetate and of alkali or ammonium oxalate—*vide supra.* In one method the boiling soln. of the nitrate, just acidified with nitric acid, is treated with oxalic acid added drop by drop until a slight permanent precipitate is formed; the soln. is allowed to cool, and the precipitated nitrato-oxalate filtered off. The filtrate is again treated as before. The ceria earths and thoria are precipitated in the order: Th, Sa, Nd, Pr, Ce, La; and in the case of the yttria earths, in the order: Tb, Eu, Gd, Dy, Ho, Tm, Er, Sc, Yb, and Y. In this way J. C. G. de Marignac, B. Brauner, and R. Bunsen separated lanthanum from didymium; neodymium has likewise been separated from samarium and the yttria earths, and ytterbium from erbium. The method was modified by F. Wirth by precipitating all the earths as oxalates, and fractionally dissolving the precipitate in sulphuric and oxalic acids; B. Brauner found the solubility of the oxalates in ammonium oxalate to be in the relative order: Th (2663), Yb (104), Y (10·99), Ce (1·8), Nd (1·44), Pr (1·13), and La (1·0), and he separated thoria from ceria by this means. C. A. von Welsbach separated a mixture of dysprosium, holmium, erbium, and ytterbium; and N. A. Orloff separated cerium and thorium from the other ceria earths. C. James found the elements separated from a hot ammoniacal soln. of ammonium carbonate in the order: Tb, Y, Dy, Ho, Er, Tm, Yb, Lu, and in this way rapidly separated erbium from dysprosium, holmium, and terbium. M. Esposito separated lanthanum from didymium by using nitric acid as solvent; C. G. Mosander used potassium hydroxalate for separating ceria and yttria earths; and M. Delafontaine used the method for separating the gadolinia earths. A. J. Grant and C. James tried 20 per cent. soln. of the amine oxalates as solvents, but the solubilities of the various oxalates were too close together for successful applications. P. S. Willand and C. James tried ammonium oxalate for the separation of erbia from yttria earths.

27. *Fractional precipitation with succinates.*—According to A. G. Ekeberg,[48] yttria earths are not precipitated by alkali succinates, while beryllia earth is precipitated. This does not agree with the observations of others. N. J. Berlin stated that yttria earths are not precipitated at once by sodium succinate, but after a few minutes, the liquid becomes turbid, and a fine crystalline powder is deposited, but M. H. Klaproth said no precipitate is formed and the mixture dries to a viscid mass. J. P. Bonardi and C. James precipitated yttria earths from boiling soln. mixed with sodium tartrate. T. Thomson, and H. Behrens found that, like oxalic acid, succinic acid produces a crystalline precipitate with soln. of cerium salts and the precipitate is not soluble in excess; ammonium succinate precipitates soln. of cerium chlorides or nitrates. W. Hisinger and J. J. Berzelius found that acetates are not precipitated by ammonium succinate, and hence they recommended this

agent for separating iron from these earths. J. J. Berzelius, O. Kauffmann, and J. Schilling found that thorium is quantitatively precipitated by ammonium or potassium succinate, but that only 99·5 per cent. is precipitated by sodium succinate. V. Lehner, and R. C. Benner found that if a soln. of sodium succinate be added drop by drop to a one or two per cent. soln. of the nitrates of the yttria earths, a fraction containing terbia, holmia, europia, with some yttria is precipitated, while europia, yttria, samaria, and small quantities of holmia remain in soln. P. S. Willand and C. James tried ammonium succinate for the separation of erbia from yttria earths.

28. *Fractional precipitation with tartaric acid and the tartrates.*—N. J. Berlin [49] observed the formation of an insoluble white precipitate when alkali tartrates are added to soln. of yttria earths; and H. Rose, A. Brauell, and R. Fresenius and E. Hintz found that this behaviour is characteristic of the yttria earths in contrast with the other rare earths. The precipitate obtained by adding ammonium tartrate to a neutral soln. of the rare earths is readily soluble in acids, and in an excess of the precipitant. According to W. Hisinger and J. J. Berzelius, M. H. Klaproth, A. Brauell, and T. Thomson, in the presence of tartaric acid, the precipitation of the earths by sodium hydroxide is completely inhibited; potassium hydroxide under these conditions gives a precipitate with the yttria earths when the soln. are boiled, and ammonia gives a precipitate with the yttria earths even in the cold. L. Haber, and A. Rosenheim and co-workers showed that the precipitates are double alkali tartrates. The ceria earths give no precipitates under these conditions. J. J. Chydenius, P. T. Cleve, L. Haber, and O. Kauffmann studied the precipitation of soln. of thorium salts by tartaric acid; and J. Schilling, by ammonium tartrate; M. H. Klaproth, L. N. Vauquelin, R. Hornberger, and L. Haber, the precipitation of zirconium salts by tartaric acid, and the alkali tartrates. Zirconium tartrate is soluble in soln. of potassium hydroxide, sodium tartrate, and sodium acetate. According to F. P. Venable and A. W. Belden, zirconium hydroxide is soluble in ammonium tartrate. H. Behrens said that soln. of cerium salts give a curdy precipitate with soln. of ammonium pyrotartrate, which is readily dissolved by free acids. O. L. Barneby fractionated an acetone soln. of the rare earths by a soln. of tartaric acid in the same solvent—erbium, holmium, and dysprosium are precipitated with the first fractions, and yttrium last; cerium concentrates with the first fraction, and didymium with the yttrium. O. L. Barneby, and P. S. Willand and C. James tried the process for the separation of erbia from yttria earths, but the latter found it not suitable.

29. *Fractional precipitation with citric acid and the citrates.*—N. J. Berlin [50] and J. P. Bonardi and C. James found that alkali citrates precipitate the yttria earths from soln. of their salts; at first, the white precipitate dissolves as it is formed, but later, it remains permanent. Yttrium citrate is soluble in an excess of sodium citrate, especially when freshly precipitated, and undried; the soln. is not precipitated by alkali carbonates or hydroxides, but it is by potassium oxalate. The presence of citric acid hinders the precipitation of the rare earths by ammonia, or alkali hydroxides. M. H. Klaproth, W. Hisinger and J. J. Berzelius, and L. Haber found the ceria earths are not precipitated by citric acid, but if the oxide be treated with citric acid, insoluble compounds are formed which do not dissolve in an excess of the acid. C. Baskerville purified praseodymium by precipitation as citrate. J. J. Chydenius, L. Haber, O. Kauffmann, C. Baskerville, H. Erdmann, L. Pissarjewsky, E. Benz, and J. J. Berzelius studied the precipitation of thoria by citric acid and the citrates; and L. N. Vauquelin, L. Haber, and H. Harris, the precipitation of zirconia by the same reagents.

30. *Fractional precipitation with organic salts.*—G. Urbain [51] tried a number of salts like the *acetates*, *chloroacetates*, *butyrates*, etc., but noticed no special advantages over the ordinary methods. A. Mandl found that salts of (i) *formic*, *acetic*, *mono-*, *di-*, *and tri-chloroacetic*, *acetoacetic*, *succinic*, *fumaric*, *tricarballylic*, *aconitic*, *benzoic*, *m- and p-oxybenzoic*, *trimesic*, *or benzoylformic acid* gives a precipitate with zirconium nitrate soln.; (ii) *glycollic*, *ethylenelactic*, *glyceric*, *tartronic*, *malic*, *tartaric*, *saccharic*,

mucic, trioxybenzoic (gallic), dioxybenzoic (resorcylic), citric, phenylglycollic, or quinolic acid gives a precipitate which dissolves in excess and ammonia gives no precipitation ; (iii) *o-oxybenzoic (salicylic), o-phthalic, or benzalmalonic acid* gives a precipitate when warm, but no precipitation occurs with ammonia in the cold ; (iv) *oxalic, malonic, maleinic, or maleic acid* gives no precipitate, but the clear soln. gives a precipitate with ammonia. H. Erdmann and T. Nieszytka obtained precipitates with soln. of cerium salts and *sodium naphthalenemonosulphonate, naphthalene disulphonate, naphthalene trisulphonate, naphthosulphonate, chromotropate, or anthraquinesulphonate.* H. Erdmann and F. Wirth studied the action of the *hydroxynaphthalene sulphonic acids* on the rare earths.

A. Rosenheim and co-workers, and L. Haber showed that ceria earths are not precipitated, but that thoria is precipitated from soln. of their salts by malic acid ; N. J. Berlin said that alkali malates precipitate the yttria earths if an excess of the precipitant be not added. H. Behrens said *ammonium malonate* gives a flocculent precipitate with soln. of cerium salts. J. B. Trommsdorff said that the zirconium salt of *valeric acid* appears to be insoluble, and L. L. Bonaparte found that if this acid be added to a mixed soln. of cerium and didymium nitrates, pure cerium valerate is precipitated, whilst didymium with a little cerium remains in soln. According to H. Behrens, *ammonium lactate* can be used in place of the double sulphate or ammonium carbonate methods of separating the ceria and yttria earths. The thoria and the ceria earths remain in soln., while zirconium and yttrium lactates are precipitated. Soln. of ceria earths in lactic acid give no precipitate with ammonia. A. Brauell noted the formation of a sparingly soluble, non-crystalline, basic ammonium cerium lactate. W. Gibbs, and P. Waage also made observations on the action of lactic acid on soln. of salts of the rare earths. O. Kauffmann found thorium salicylate is precipitated by *potassium salicylate* ; and H. Behrens found that soln. of salts of cerium earths, thorium, and zirconium give precipitates with ammonium salicylate, while salts of the yttria earths are not precipitated. L. A. Pratt and C. James studied the action of salicylic acid on yttria.

C. James and co-workers [52] found that thoria is completely precipitated from the rare earths by adding a boiling soln. of *sebacic acid* to a hot neutral soln. of the earths. The other earths are not precipitated even when the soln. is boiled for a long time. Yttrium can be separated quantitatively from the alkali metals by means of ammonium sebacate. T. O. Smith, C. F. Whittemore and C. James found that on fractionally precipitating a soln. of yttrium, holmium, and dysprosium chlorides with *sodium cacodylate,* the yttrium was conc. in the earlier fractions, while the holmium and dysprosium collected in the later ones ; with the cerium group, neodymium collected in the more soluble fractions, and samarium and gadolinium in the less soluble ones. C. James and co-workers studied the action of cacodylic acid on samaria and neodymia. R. J. Meyer and J. Wuorinen found that with *phthalic acid,* the most positive elements remain longest in soln., and the weakly basic ones accumulate in the first precipitates, and they were able to separate the members of the yttria group with good results. A. Kolb and H. Ahrle showed that *m-nitrobenzoic acid* precipitates thoria and ceria salts, but not cerous salts and those of lanthanum and didymium. The precipitation of thoria is more complete in the presence of a little aniline. J. P. Bonardi and C. James did not get useful results with *sodium m-nitrobenzoate* and the yttria earths, and they also tried the *sodium phenoxyacetate, sodium camphorate, sodium azobenzenesulphonate,* but with poor results. C. James and co-workers studied the effect of *methylsulphonic, methylenedisulphonic, methanetrisulphonic, ethylsulphonic, propylsulphonic, isobutylsulphonic, camphorsulphonic, methoxysulphonic, methanetrisulphonic, phthalic, phenylacetic, phenoxyacetic, ethylenedisulphonic, m-xylenesulphonic, citraconic, sulphoacetic, hydroxyethanesulphonic, m-sulphobenzoic, quinic, anisic,* and *oxanilic acids,* and *ethyl glycollate,* on yttria, samaria, and neodymia. P. S. Willand and C. James tried *malonic acid* in acetone soln., and with *sodium diphenylmonosulphonate* for the separation of erbium from yttrium, but the results were not satisfactory. H. Erdmann and

F. Wirth found that malonic acid gives no precipitates with the rare earths, but they prepared a number of rare earth malonates. P. S. Willand and C. James found that with *picric acid* the erbium accumulates at the more soluble end of the series, but the results are not good. G. Jantsch and A. Grünkraut fractioned the rare earths from xenotime by *glycollic acid.* They found that yttrium glycollate is least soluble, then follow the salts of lanthanum, cerium, praseodymium, neodymium, samarium, and gadolinium. L. Jordan and B. S. Hopkins found that sodium glycollate is useful in removing the last traces of samaria from gadolinia. C. James and co-workers also studied the action of glycollic acid on yttria, samaria, and neodymia.

N. J. Berlin[53] found that *alkali benzoates* do not give an immediate precipitation with soln. of the yttria earths; but one forms if the mixture is allowed to stand for some time in a warm place. H. Behrens found *ammonium benzoaté* gives a precipitate with cerium salts. The action of *benzoic acid* was studied by W. Hisinger and J. J. Berzelius, T. Thomson, and A. Brauell, the acid gives no precipitate with cerium salts. O. Kauffmann found that thorium and zirconium salts give a gelatinous precipitate with alkali benzoates.

III. Separation by fractional oxidation.—These methods are mainly directed to the separation of cerium from the other rare earth elements, and they are based on the fact that, unlike the other elements of the family, cerium forms a strongly basic trioxide, $Ce(OH)_3$, and a feebly basic tetrahydroxide, $Ce(OH)_4$. The basicity of cerium tetroxide is very near that of thorium hydroxide, $Th(OH)_4$. Mixtures of the rare earths containing over 50 per cent. of ceria are usually only partially soluble in hydrochloric or nitric acid; but if digested with an excess of sulphuric acid, ceric sulphate is produced. This is insoluble in the excess of sulphuric acid. The mixed sulphates are dissolved in cold nitric acid, and when the soln. is boiled with alkali hydroxide, the rare earth hydroxide is formed. This is readily soluble in nitric acid. G. N. Wyrouboff and A. Verneuil,[54] and G. von Knorre showed that rare earths containing over 50 per cent. ceria are dissolved when heated with nitric acid if hydrogen peroxide be added from time to time. The soln. contains cerous nitrate. R. Bunsen showed that the mixture of rare earths is also dissolved by conc. hydrochloric acid if ammonium or potassium iodide be present. Iodine is liberated, and cerous chloride is formed. R. J. Meyer obtained a similar result with a mixture of hydriodic and conc. nitric acids.

1. *Fractional oxidation by roasting.*—When the rare earth carbonates, oxalates, nitrates, etc., are ignited, oxides are formed—cerium and thorium salts give dioxides, and the other rare earths, sesquioxides. When treated with dil. nitric acid, cerium dioxide is either insoluble, or very sparingly soluble dependent on the amount of lanthana or didymia which may be present. C. G. Mosander[55] used this method and separated lanthana and didymia from what was considered to be pure ceria. H. Zschiesche explained the brown colour of ceric oxide as a result of the combination of ceria and didymia. T. Kjerulf, B. Brauner, C. A. von Welsbach, P. Schottländer, P. Mengel, R. J. Meyer and M. Koss, etc., explained the great tendency of ceria to be contaminated by didymia and lanthana to the formation of compounds of ceria oxide with the tervalent earths analogous to manganites and chromites. H. Zschiesche found some cerous oxide was always dissolved by the nitric acid. C. F. Rammelsberg, and F. M. Stapff, in order to ensure the complete oxidation of the ceria. fused the earths with potassium chlorate; and F. Frerichs and F. Smith repeatedly calcined the oxide moistened with nitric acid. P. Schottländer, however, showed that cerium dioxide, like lead dioxide, manganese dioxide, etc., develops some oxygen with nitric acid, or chlorine with hydrochloric acid; and when dissolved in conc. nitric acid, a little of the ceric oxide is always reduced to cerous oxide.

2. *Fractional oxidation by chlorine or bromine.*—C. G. Mosander[56] purified cerium by suspending the mixed oxides in a soln. of potassium hydroxide, and passing in a rapid stream of chlorine for a few hours. This converts all the

rare earths except cerium into soluble chlorides. The cerium remains undissolved as a light yellow powder of hydrated ceric oxide. R. Bunsen, T. Kjerulf, S. Jolin, L. M. Dennis and co-workers, L. Haber, G. Krüss, K. Brockelmann, O. Pettersson, L. Stützel, P. Mengel, O. N. Witt, etc., found that a repetition of the process for a number of times is said to effect a complete separation of the cerium. J. L. Smith used the chlorine process for the separation of thorium which is precipitated with the cerium. L. M. Dennis and F. L. Kortright also used it for separating thorium from thorite. O. Popp, R. Fresenius and E. Hintz, and G. P. Drossbach used sodium or calcium hypochlorite in place of chlorine. P. E. Browning and E. J. Roberts found that the hydroxide of lanthanum passes into soln. more rapidly than that of didymium. P. E. Browning, L. Haber, and W. Muthmann and H. Rölig, found that bromine can be more conveniently added than chlorine. With bromine, the hydrobromic acid produced towards the end of the operation does not act on the ceric oxide the same as does the hydrochloric acid produced when chlorine is employed. Iodine was also tried in place of chlorine.

3. *Fractional oxidation by potassium permanganate.*—F. M. Stapff,[57] and W. Gibbs oxidized soln. of cerous sulphate, nitrate, and chloride with potassium permanganate; but the oxidation was incomplete. C. Winkler found that the oxidation was completed in the presence of mercuric oxide, and hence the reaction: $3Ce_2O_3+2KMnO_4+H_2O=6CeO_2+2KOH+2MnO_2$, could be employed for the quantitative determination of cerium. F. Stolba substituted zinc oxide for mercuric oxide, and founded a volumetric process on the reaction; and the method was successfully employed by W. Muthmann and H. Rölig, C. James, G. P. Drossbach, P. E. Browning, etc. If zinc oxide and potassium permanganate be employed for precipitating ceric oxide from soln. of the rare earths, the zinc salt is troublesome to remove, and C. R. Böhm accordingly substituted the alkaline earths, or magnesia; and R. J. Meyer and A. Schweitzer recommended sodium carbonate which is now generally employed. E. J. Roberts recommends the following procedure:

The rare earth soln., which should not contain salts other than nitrates, is heated to boiling in a large porcelain dish, and, if not already neutral, is neutralized with the sodium carbonate soln. The soln. of permanganate is added in small quantities until the red colour begins to be permanent, and the mixed soln. of permanganate and alkali is then added very slowly, with constant stirring, the liquid being kept nearly at the b.p. during the whole process. A faint colour of permanganate is maintained all the time in the liquid, a little of the pure permanganate soln. being added if at any time the colour be entirely bleached. This is important, as the constant acidity of the liquid is thereby insured. When the cerium is nearly all precipitated, the colour is bleached more slowly after each addition of the precipitant, and the effervescence is less noticeable. The acidity of the liquid should now be tested from time to time, which may be done with litmus-paper if only a slight excess of permanganate be present. Small amounts of the mixed soln. or of sodium carbonate are added, until the liquid is nearly neutral to litmus, but still is faintly coloured with permanganate. The whole is heated, and stirred for about ten minutes, and filtered hot. The precipitate is washed with boiling water till the washings give no precipitate with ammonia. If the liquid at the end of the precipitation be faintly acid, the filtrate usually contains a trace of cerium giving a faint yellow colour with ammonia and hydrogen peroxide, while from the precipitate a preparation of cerium chloride may readily be obtained which shows no absorption bands in a thickness of 15 cms. of very conc. soln. The presence of a little cerium in the filtrate, where the earths in the latter are to be subjected to fractional crystallization, is usually not objectionable.

4. *Fractional oxidation by lead dioxide or bismuth tetroxide.*—In 1864, W. Gibbs[58] introduced a method of separating ceria from the rare earths which was based on the oxidation of cerous salts by boiling them with lead dioxide and nitric acid; H. Zschiesche used red lead in place of the dioxide; and in 1894, W. Gibbs suggested using bismuth tetroxide in place of lead dioxide. W. Gibbs' lead dioxide process is as follows:

Boil a mixture of the rare earth sulphates, with lead dioxide and nitric acid until a drop of the clear liquid gives no precipitate with lead acetate. Small quantities of lead dioxide and nitric acid are added from time to time as the reaction proceeds. The soln. is boiled for an hour and a half longer, adding nitric acid from time to time to replace that

lost by evaporation. After cooling and settling, the clear soln. is decanted off, and the lead sulphate is digested several times with hot nitric acid so as to remove any rare earths entrained with the precipitate. The main soln. and washings are concentrated to a syrupy liquid, on a water-bath, and poured into ten times its vol. of water, when basic ceric nitrate is precipitated. This is well washed with water, treated with conc. sulphuric acid, and heated to remove the excess of acid. The mass, digested in ice-cold water, gives a soln. of cerous sulphate of a high degree of purity.

The process was used by H. Bührig, P. Mengel, H. Robinson, etc.; and the reaction was applied to the detection of small quantities of cerium by W. Gibbs, L. M. Dennis and W. H. Magee, G. Krüss and L. F. Nilson, G. von Knorre, R. Fresenius and E. Hintz, etc. G. von Knorre tried oxidizing cerous salts by boiling them with manganese dioxide and nitric acid, but the result was not satisfactory. C. H. Wing treated a soln. of a cerous salt with lead dioxide and sulphuric acid, so as to form the ceric salt. This was mixed with luteocobaltic sulphate, *i.e.* luteocobaltic tetramminotrisulphate, when crystals of the double salt, $[Co(NH_3)_6](SO_4)_3.H_2O$, are formed. The product contains a little didymium.

5. *Fractional oxidation by hydrogen, sodium, or barium dioxide.*—G. H. Bailey[59] found that a soln. of zirconium sulphate or acetate gave with hydrogen dioxide a precipitate of zirconium peroxide, Zr_2O_5, under conditions where titanium, columbium, iron, and aluminium salts gave no precipitation. The reaction was investigated by H. Geisow and P. Horkheimer, who found that in dil. soln. in the presence of hydrogen peroxide, iron hydroxide but not zirconium hydroxide is precipitated by alkali hydroxide. P. T. Cleve, and L. de Boisbaudran then found that in the presence of ammonia or the hydroxides of the alkaline earths, a thorium persulphate is precipitated. This reaction was studied by G. Wyrouboff and A. Verneuil as a method of separating thoria from the rare earths. In applying the process, it is advisable to remove most of the ceria and yttria earths before applying the hydrogen dioxide process to avoid the entraining of these earths with the precipitated thoria. It is also necessary to use hydrogen dioxide free from phosphoric acid. E. Wedekind found that the presence of tartaric acid hinders the precipitation. G. Wyrouboff and A. Verneuil use the process in the following manner:

To obtain thorium free from cerium, the soln. of the nitrates is mixed with an excess of ammonium carbonate, and a small quantity of ammonium hydroxide added; all the thorium remains in soln. whilst the greater part of the other metals is precipitated. The soln. is neutralized as exactly as possible with nitric acid, mixed with excess of hydrogen peroxide, and heated to 60°; all the thorium is precipitated, and if the precipitate be dissolved in nitric acid, evaporated to dryness, redissolved in water, and the treatment with hydrogen peroxide repeated, very pure thorium is obtained. In the presence of large quantities of cerite earths, three or four precipitations may be necessary. The formation of the compound, $Th_4O_7.N_2O_5$, by the action of hydrogen peroxide constitutes a delicate and characteristic test for thorium, and can be used for its quantitative estimation. The oxynitrate cannot, however, be heated or dissolved in acids without loss, and the following method is recommended. The soln. of nitrates containing not more than 0·5 grm. of oxide is evaporated to dryness, mixed with 100 c.c. of water and 10 c.c. of hydrogen peroxide, heated for a short time, and filtered. The precipitate, after washing, is transferred to a flask and dissolved in hot water containing ammonium iodide and hydrochloric acid, the soln. is precipitated with ammonium hydroxide, and the precipitate dried and heated. If the precipitate of oxynitrate be not white, it must be redissolved in nitric acid, evaporated to dryness, and the process repeated.

G. and E. Urbain used the method to separate thoria from ytterbia. If a boiling soln. of lanthanum and didymium in the presence of sodium acetate be treated with hydrogen peroxide, a peroxidized didymium acetate is precipitated which redissolves on cooling; this reaction enables didymium to be separated rapidly from lanthanum, which is not precipitated. The basic ceric acetate is less soluble than the didymium salt.

P. Mengel found that an ice-cold soln. of sodium peroxide added to a soln. of the rare earths, oxidizes and completely precipitates the cerium as hydrated ceric oxide. The precipitate is well washed with cold water, dried at 120°–130°, redissolved, and again precipitated. The product has a high degree of purity. H. Geisow and P. Horkheimer studied the process. G. Wyrouboff, and C. G. Mosander noted that *barium dioxide* gave a precipitate with soln. of cerium salts, and A. Verneuil used this reagent for the approximate separation of thoria from the monazite earths.

6. *Fractional oxidation by ammonium or potassium persulphate.*—G. von Knorre[60] oxidized the cerous salts in a boiling neutral soln. of the rare earths by the addition of potassium or ammonium persulphate: $K_2S_2O_8+H_2O=K_2SO_4+H_2SO_4+O$. The soln. must be kept neutral during the reaction, and this was done by allowing the reaction to proceed in the presence of barium or calcium carbonate. G. Wyrouboff and A. Verneuil removed the last traces of cerium from ceria earths by this reaction, but instead of using an alkaline earth carbonate to keep the soln. neutral, they boiled the soln. with a mixture of sodium acetate and ammonium persulphate. If thorium be present, the soln. should be dil. enough to prevent the precipitation of thorium sulphate. O. N. Witt and W. Theel replaced the sodium acetate by precipitated calcium carbonate.

7. *Fractional oxidation with potassium bromate.*—C. James[61] used potassium bromate for removing cerium from the rare earths. He boiled a neutral soln. of the nitrates mixed with potassium bromate, in the presence of some marble. The cerium was precipitated as basic ceric nitrate as described in the previous section. Ceria can thus be obtained free from other earths.

IV. Separation by physical processes.—In a rigid system of classification, some of the basic salt processes would be more correctly described as cases of fractional dissolution or decomposition by heat. K. A. Hofmann and G. Krüss[62] suggested a possible means of fractionating the rare earths by shaking a soln. of one of their salts with charcoal free from phosphates because he found that the charcoal adsorbs the weaker bases first. About 0·5 grm. is adsorbed by 8 grms. of charcoal from 2 grms. of the mixture.

1. *Fractional distillation, or sublimation.*—J. J. Berzelius and W. Hisinger[63] separated iron chloride from cerium chloride by *fractional sublimation,* the iron chloride volatilizes while cerium chloride remains. G. P. Drossbach passed a current of chlorine gas over a heated mixture of the rare earths from monazite sand and charcoal. Thorium chloride volatilizes, and the less readily volatile chlorides of the ceria earths remain. O. Pettersson studied the volatility of the rare earth chlorides, but his attempt at the fractional distillation of the anhydrous chlorides gave negative results. R. J. Meyer and A. H. Winter showed that scandium can be freed from thorium by the fractional sublimation of the anhydrous chlorides. G. T. Morgan and H. W. Moss showed that scandium and thorium can be separated by the distillation of their acetylacetonates, for, at 8–10 mm. press., thorium acetylacetonate begins to sublime at 160°, while the scandium salt sublimes at a lower temp., and, at atm. press., scandium acetylacetonate sublimes undecomposed between 210° and 260°, while at 260° the thorium salt decomposes into a brown charred mass. G. Urbain and co-workers found the method to be of use in separating small quantities of lutecium chloride from the less volatile neoytterbium chloride. Scandium and thorium chlorides are also more volatile than lutecium chloride.

2. *Fractional electrolysis.*—In 1879, L. de Boisbaudran[64] separated didymium from the samarskite earths by electrolysis. G. Krüss stated that when a soln. of a chloride of a rare earth behaves upon electrolysis like a soln. of an hydroxide in dil. hydrochloric acid, chlorine and hydrogen are set free at the electrodes, the soln. loses more and more hydrochloric acid, and as the amount of the solvent diminishes, the hydroxide of the earth is precipitated in increasing amount. In this manner the rare earths can be removed from chloride soln. of mixtures of the earths, the amounts thus precipitated depending upon the strength of the current and the duration of the electrolysis. It is to be expected that those bases which are the weakest toward hydrochloric acid will first be precipitated as hydroxides as

soon as a part of the hydrochloric acid is decomposed by the electrolysis. The stronger bases will remain in soln. as the more stable chlorides. In order to remove the hydrochloric acid uniformly from all parts of the soln. of the chlorides of the rare earths, electrodes of large surface were employed. E. F. Smith found that on electrolysis didymium is not precipitated either as nitrate or acetate although a partial precipitation takes place at the positive pole. B. Brauner, in the course of his study of peroxides, electrolyzed a soln. of didymium acetate with platinum electrodes and obtained on the negative pole a pale red crystalline crust containing didymium and acetic acid; while soln. of the nitrate and sulphate gave similar products. He observed no peroxide formation. G. Bricout, J. Šterba, and G. von Knorre studied the anodic oxidation of cerous salts. A. Classen separated iron from zirconium by the electrolysis of a soln. of ammonium zirconium oxalate. L. M. Dennis and B. J. Lemon electrolyzed neutral soln. of the rare earth nitrates using a mercury cathode and platinum anode, without a diaphragm, and found that with a neutral soln. of the nitrates of neodymium, praseodymium, lanthanum, and samarium, the lanthanum collects in the last fractions, and can thus be separated from the other earths of the didymium group. Lanthanum can be satisfactorily separated from praseodymium by this method. On the fractional electrolysis of the earths from xenotime, erbium collects in the early fractions and yttrium in the later fractions. In order to test if the fractional precipitation were caused by the ammonia formed in the cathodic reduction of the nitric acid, L. M. Dennis and P. A. van der Meulen employed a diaphragm cell, and fractionally electrolyzed a soln. of the chlorides and the nitrates of yttria earths from which nearly all the ceria and didymia had been removed. They found that the coloured earths concentrated in the earlier fractions, yttrium in the last fractions. The rate of separation is about four times as great with the nitrates as with the chlorides. No ammonium salts were produced. L. M. Dennis and A. B. Ray found that a vigorous stirring of the liquid about the cathode accelerates the segregation of earths of higher at. wt. in the early fractions and gives a better conc. of the earths of lower at. wt. in the last fractions. In the fractional electrolysis of mixtures of thorium and the rare earth nitrates, thoria concentrates in the early fractions.

§ 7. The Occurrence and Isolation of the Cerium Family of Rare Earths

The cerium family of elements is arbitrarily taken to include: cerium, Ce; lanthanum, La; neodymium, Nd; praseodymium, Pr; and samarium, Sa or Sm. As previously indicated, the criterion of this classification is the sparing solubility of the double sodium or potassium sulphates. The oxides are strongly electropositive, and form a series of sesquioxides of the type R_2O_3, in which the element R is tervalent. The strongly basic oxides form a series of well-defined salts. Cerium furnishes a well-defined dioxide, CeO_2, which is also basic, forming a series of ceric salts. Praseodymium forms an analogous oxide, PrO_2, and neodymium an unstable dioxide. The basicity of ceric oxide, CeO_2, is much less than that of the sesquioxide cerous oxide, Ce_2O_3. A number of intermediate cerosoceric oxides have been prepared. Still higher oxides of the different members of the family have also been reported. Samarium forms a series of salts of the type SaX_2 which correspond with the unknown monoxide, SaO. The high basicity of the rare earth sesquioxides is illustrated by the relatively large heats of dissociation of the sulphates as calculated by L. Wöhler and M. Grunzweig,[1] indeed, these values are the greatest hitherto observed for tervalent sulphates, and indicate that the rare earths belong to the strongest bases. These values ranged in the order of decreasing basicity furnish the series: La, Pr, Nd, Sa, Ce, while the series:

La, Ce(ous), Pr, Nd, Sa, Ce(ic)

is derived from (i) the order in which the hydroxides are precipitated from soln. by alkali hydroxides or aq. ammonia; or from (ii) the order in which the nitrates are decomposed by heat; or from (iii) the electrical conductivity of aq. soln. of the chlorides.

The occurrence of the ceria earths.—Cerium occurs in a large number of widely distributed minerals, orthite or allanite, cerite, æschynite, yttrocerite, parisite, lanthanite, and a number of others which have been previously described. Monazite is almost exclusively the source of cerium products on a commercial scale. The cerium earths are really a by-product remaining after the extraction of thorium from monazite. Allanite and cerite are used to a very small extent on a manufacturing scale. It is not alone the relative richness of the minerals in the cerium earths that determines its availability as raw material for the manufacture of cerium, but rather its relative abundance. Allanite and cerite are comparatively scarce minerals. Only a small proportion of the ceria earth by-products obtained in the manufacture of thoria from monazite are manufactured into pure cerium salts.

Lanthanum is found in all the minerals containing cerium, and it occurs to the largest extent in lanthanite and beckelite; it is also in moderate proportions in allanite, cerite, and samarskite. Praseodymium and neodymium occur in all the minerals which contain cerium and lanthanum, but to a smaller extent. The term *didymium* is often used as a grouping term to include both neodymium and praseodymium; the group was formerly supposed to be one element. It is curious that the ratio of Pr : Nd in minerals is very nearly constant 1 : 2, so that neodymium appears to be twice as abundant as praseodymium. Samarium also accompanies cerium, in the cerium earths; and when samarium itself is desired, the usual sources are cerite, allanite, samarskite, and euxenite. For the occurrence of these elements in the sun and stars, *vide infra*, spectrum.

The preparation of ceria.—Among the rare earth elements cerium is unique in readily forming a series of quadrivalent ceric compounds which are easily hydrolyzed, forming sparingly soluble hydrated oxides or basic salts. In the ceric form, cerium behaves in many respects like thorium and zirconium, and as if it did not belong to the rare earth family; and in this form cerium can be isolated without the need for elaborate processes of fractionation. Ceria is obtained by the extraction of the roasted mixture of salts with very dil. mineral acids or a boiling soln. of ammonium chloride; by the extraction of the partially roasted nitrates or chromates; with acids by the oxidation of cerium salts with chlorine, lead dioxide, potassium bromate, potassium permanganate, hydrogen dioxide, sodium dioxide, and potassium or ammonium persulphate; by anodic oxidation; by the hydrolysis of oxidized soln.; by treating the carbides with dil. acid; by precipitation with *o*-toluidine, pyridine, or quinoline hydrochloride; by a sulphate, chromate, acetate, or valerate; by precipitation as potassium cerium sulphate or ceric ammonium nitrate; and by the partial solubility of the oxalate. These methods have been described in the preceding section. The most expeditious and efficient methods are the basic nitrate process, the bromate process, the permanganate process, and the pyridine hydrochloride process—*vide* thoria. W. Prandtl[2] described a process based on the use of cadmium nitrate as separating element.

The purification of ceria has been discussed by J. Sterba, G. Wyrouboff and A. Verneuil, G. P. Drossbach, R. J. Meyer, B. Brauner, A. Batek, C. C. Kiess and co-workers, A. C. Neish, etc.—*vide* at. wt. of cerium. Conc. aq. soln. of cerous salts should show no signs of the didymium spectrum, Fig. 1, when viewed in layers 10–12 cms. thick. The colour of the ignited oxide should be pale yellow when cold, and show no signs of a salmon, red, or brown tint. H. Bührig showed that the methods published prior to 1875 did not give pure ceria. W. Gibbs first purified cerium to pass the spectroscopic test. Ceria can be purified by dissolving the impure oxide in conc. nitric acid, and evaporating the soln. to a syrupy consistency. The cold mass is then dissolved in cold water, and boiled for 10–15 mins. so as to precipitate the basic nitrate according to the process previously described. J. Sterba found that four precipitations as basic nitrate suffice to eliminate the last traces of other rare earths from ceria. Another method is to apply the ammonium ceric nitrate process four or five times, but this does not get rid of the other rare earths. The salt can also be freed from thoria by the recrystallization of cerous sulphate a number of times. The thoria can also be removed by adding hydrogen dioxide to a hot, neutral, or feebly acid soln.

The preparation of lanthana.—According to H. Zschiesche,[3] prior to W. Gibbs' discovery of the lead dioxide test for ceria in 1864, and the application of spectroscopic tests, the methods of detecting ceria in the rare earths were so inadequate that it is almost certain that all the preparations were more or less ceriferous. The preparation of highly purified lanthana is a far more serious undertaking than is the case with ceria. Lanthana has been obtained from the ceria earths, after the removal of cerium, by fractionation with ammonia, alkali hydroxide, magnesia, and aromatic bases; by extracting the roasted oxides with mineral acids; by the extraction of the partially roasted nitrates or chlorides with acids; by precipitation as oxalates or chromates; by the action of sodium acetate and hydrogen peroxide; by electrolysis; by the fractional crystallization of the nitrates, the double ammonium, sodium, magnesium, or manganese nitrates, double potassium carbonates, the sulphates, the ethylsulphates, the chlorides, the bromates, *m*-nitrobenzene sulphonates, and the picrates. These methods have been described in the preceding section. The order of separation with the nitrates, ethylsulphates, bromates, and oxalates is Nd, Pr, La; with the double nitrates, double carbonates, and *m*-nitrobenzene sulphonates, La, Pr, Nd; and with the sulphates, La, Nd, Pr. The more expeditious methods for the purification of lanthana are the fractional crystallization of the double *magnesium nitrate, and the double carbonate processes as recommended by* R. J. Meyer. W. Prandtl and J. Rauchenberger used the basic ammonia process. The last traces of praseodymia are retained very tenaciously. C. James' process of purification has been previously described. Purified lanthana is white, and a thick layer of an aq. soln. of the chloride or nitrate should not show *the praseodymium absorption bands.*

The preparation of neodymia.—*Although didymium no longer appears in the list of elements, it is often convenient to prepare first what was formerly regarded as didymia before proceeding to separate it into its components neodymia and praseodymia.* The fractionation methods employed for the preparation of crude lanthana also yield didymia. The separation of didymia into its components is more difficult than the preparation of lanthana; and neodymia is more difficult to purify than is the case with praseodymia. The fractionation of the double ammonium nitrates from nitric acid for the separation of neodymium has been previously described, and it was the method employed by C. A. von Welsbach[4] in his demonstration of the complex nature of didymia. W. Muthmann and L. Weiss recommend the double magnesium nitrate process, and W. Feit and C. Przibylla say that better results are obtained by using cerium as *l'élément séparateur.* According to E. Demarçay, samarium can be eliminated from neodymium by the double magnesium nitrate process continued for four days' working with four fractions; it can also be removed by the double ammonium nitrate process; or perhaps, best of all, by the double manganese nitrate process. The elimination of praseodymium is tedious. After ignition, purified neodymia has a blue colour which is not affected by a few tenths of one per cent. of praseodymia. If samaria and praseodymia be present, the blue absorption bands are less sharply defined than when these impurities are absent. G. P. Baxter and co-workers separated samaria and praseodymia by the fractional crystallization of the nitrate from conc. nitric acid. The bromate fractionation also collects the praseodymium in the more soluble fractions. C. Baskerville and R. Stevenson recommended fractional precipitation by passing hydrogen chloride into a soln. of the chlorides. O. Holmberg, and C. Garnier purified neodymia by fractionating the *m*-nitrobenzene sulphonates. The subject has been discussed by C. C. Kiess and co-workers.

The preparation of praseodymia.—The preparation of praseodymia naturally follows as a sequel to the preparation of its congener neodymia by the double ammonium nitrate or the double magnesium nitrate process. The product may contain lanthana and neodymia. W. Feit and C. Przibylla[5] eliminate the last traces of lanthana by crystallization of the ethylsulphates, bromates, or simple nitrates from nitric acid. G. P. Baxter and O. J. Stewart used the double ammonium nitrate process in their work on the at. wt. of praseodymium. M. Esposito crystallized the oxalates from nitric acid. B. Brauner found that pure praseodymium dioxide, PrO_2, separates when the nitrate is fused at 440°. N. A. Orloff purified praseodymia from lanthana by boiling it with a soln. of potassium permanganate and mercuric oxide, to which a soln. of cerium chloride is then gradually added. The precipitate obtained consists of the higher oxides of cerium and praseodymium, whilst the lanthanum remains in soln. The praseodymium is then separated from the cerium by any of the usual methods. C. Baskerville and J. W. Turrentine said that praseodymia containing not more than 10 per cent. of lanthana, can be purified in one operation by precipitating the hydroxides with ammonia, washing the precipitate free from ammonia, dissolving it in a sat. soln. of citric acid, and filtering the soln. When heated to 100°, normal praseodymium citrate separates as an amorphous green powder which can be washed with water. R. J. Meyer could not support this claim. The last traces of neodymia can be removed from praseodymia by the fractional crystallization of the double potassium carbonate, or the double ammonium, magnesium, or manganese nitrate.

The preparation of samaria.—The samaria will be found in the mother liquors from the didymia extractions, and it will also be found with the less soluble portion of the earths which are not insoluble in a sat. soln. of sodium sulphate. The more soluble fractions from the double ammonium nitrate, the ethylsulphate, or the bromate process, are converted into double magnesium nitrates, and again fractionated from nitric acid of sp. gr. 1·3 as recommended by G. Urbain,[6] E. Demarçay, and C. James and co-workers. The fractionation should be continued until the samarium has been eliminated from the more soluble fractions, and the less soluble fractions do not show the europium absorption bands. Crystals of magnesium nitrate are apt to separate during this fractionation since the single nitrate is less soluble than the double salt, it is therefore considered best to seed the supersaturated soln. with small crystals of bismuth magnesium nitrate. G. Urbain and H. Lacombe recommended the fractional crystallization of the double magnesium nitrates to which a little bismuth nitrate has been employed as separating element.

§ 8. The Preparation of the Metals of the Cerium Family

A few of the metals of the rare earths have been isolated, but usually in an impure state. All the metals of the cerium family of earths have been obtained more or less impure.

The preparation of the cerium metals.—C. G. Mosander[1] obtained cerium, lanthanum, and didymium by reducing the anhydrous chloride with heated sodium or potassium; A. Beringer, and F. Wöhler also made cerium in this way; J. C. G. de Marignac, didymium; and C. A. Matignon, and M. A. Hunter, neodymium. The yield is poor. The metal appears in the form of a large number of fine globules which give it the appearance of a powder. It is difficult to remove the alkali chloride which is produced; and the metal is liable to be alloyed with a little sodium or potassium. M. Moldenhauer reduced cerium fluoride by heating it with an excess of calcium, or aluminium. The cerium was always alloyed with the reducing agent. *Thus, the product with calcium contained* 12 per cent. of *calcium, and 86 per cent. of cerium. It* is necessary to cover the contents of the *crucible with a layer of calcium* fluoride in order to prevent oxidation during the reaction. *If the* cerium fluoride be mixed with ferric oxide, a cerium-iron alloy is produced. M. Moldenhauer said that cerium oxide is not reduced by applying the thermite process, using aluminium, magnesium, or calcium as a reducing agent. C. A. Winkler reduced lanthana and ceria by means of magnesium; and H. Holm, and C. A. Matignon reduced the ceria by the same agent. C. A. Matignon, E. C. Schiffer, W. Muthmann and L. Weiss, and A. Hirsch reduced cerium oxide with aluminium; K. A. Kühne used the thermite process; and A. Hirsch used calcium, carbon, or silicon. The last-named found that with carbon, and silicon, the products are carbides or silicides, and with the other three metals, alloys are produced. C. A. Matignon made praseodymium by reducing the oxide with magnesium. E. W. von Siemens and J. G. Halske obtained cerium by heating the nitride or other compound of cerium with the elements of the nitrogen family, in the absence of air. G. Siebert and E. Korten obtained the metal by heating the halides at a high temp. in the presence of a reducing agent—*e.g.* carbon.

W. F. Hillebrand and T. H. Norton[2] prepared the metals cerium, lanthanum, and didymium in a coherent form by the electrolysis of the fused chlorides covered by a layer of ammonium chloride, and contained in a porous cell surrounded by a mixture of molten sodium and potassium chlorides, contained in a porcelain crucible. The anode was thin sheet iron, and the cathode iron wire. W. Muthmann and co-workers electrolyzed a fused mixture of 90 per cent. of cerous chloride, and 10 per cent. of potassium and sodium chlorides in a water-cooled copper vessel. A current of 30–40 amps. and 12–15 volts was used, and the electrodes were carbon. They also electrolyzed a soln. of cerium oxide in molten cerous fluoride using a current density of 8–10 amps. per sq. cm. at the cathode, and 3 amps. per sq. cm. at the anode. The yield of metal corresponded with 57 per cent. of the current used. They showed that the materials employed should be free from silica or the metal will be contaminated with silicide: potassium fluoride, calcium fluoride, or cryolite cannot be employed with success in place of cerium fluoride. The electrolysis of a molten soln. of ceric oxide in cryolite yields an alloy of cerium and aluminium. If the electrolysis be conducted in the presence of carbon, cerium carbide is formed. According to A. Hirsch, cerium is best prepared by dehydrating ceric chloride in an atm. of hydrogen chloride, and electrolyzing the fused chloride in an iron crucible, which serves as cathode, with a graphite anode. Sodium chloride, potassium fluoride, and barium chloride are added in small quantities to the electrolyte to increase the resistance of the bath and check decomposition. The cerium thus obtained contains about 2 per cent. of impurities, consisting of iron and of cerium oxide and carbide. It may be purified by amalgamating with boiling mercury, skimming off the undissolved impurities, and distilling in a vacuum in a quartz vessel lined with magnesia.

W. Muthmann and co-workers found that since lanthanum, neodymium, and praseodymium melt at a higher temp. than cerium, while their chlorides melt at a lower temp., a higher temp. about the electrodes is required for the preparation of these metals by the electrolysis of the anhydrous chlorides in order to avoid the formation of a neutral regulus. This was secured by using very slender carbon electrodes, or by using an iron rod to which sticks of carbon were fastened. Lanthanum was obtained by using a current of 50 amps. at 10–15 volts; while with neodymium a current of 90–100 amps. at 16–22 volts was employed. In the case of praseodymium, it was necessary to avoid the formation of the dioxide and consequently a maximum current of 70 amps. was used. The metals were purified by remelting them in crucibles made from purified magnesia, and covered by a layer of barium chloride. Ordinary crucibles must not be used since lanthanum, neodymium, and praseodymium attack the silicates. Metallic samarium was obtained with difficulty by the electrolysis of the fused anhydrous chloride mixed with one-third its weight of barium chloride, using a current of 100 amps. and a small carbon cathode. The metal is deposited on the carbon from which it is separated by a layer of golden-yellow carbide. H. C. Kremers and R. G. Stevens prepared lanthanum by the electrolysis of the fused chloride mixed with variable amounts of potassium fluoride and sodium chloride. The metal prepared by the use of a tungsten cathode did not contain tungsten; metal prepared in iron cells was always contaminated with iron.

§ 9. The Physical Properties of the Cerium Family of Metals

According to W. Muthmann and L. Weiss,[1] polished surfaces of cerium, lanthanum, neodymium, and praseodymium are very similar, but exhibit minute differences in **colour.** Lanthanum has the whiteness of tin, cerium that of iron; neodymium has a yellow tinge, which is still more marked in the case of praseodymium. Samarium is a pale grey lustrous metal. The interior of a bar of cerium is highly crystalline, but attempts by A. Hirsch to make definite crystals by fusion below molten lithium chloride were not successful. According to A. W. Hull, the **X-radiogram** of cerium corresponds either with a hexagonal close-packing with side 3·65 A., and the closest approach of the atoms, 3·64 A.; or with a face-centred cube with side 5·12 A., and the closest approach of the atoms as before; while E. E. Schumacher and F. F. Lucas found that the metal crystallizes in the cubic system. A. Hirsch gives 6·920 for the **specific gravity** of cerium; and J. F. Bahr and R. Bunsen give 6·628. W. Muthmann and L. Weiss give for the sp. gr. of cerium, 7·0424; lanthanum, 6·1545; neodymium, 6·9563; praseodymium, 6·4754; and samarium, 7·7 to 7·8. The **atomic volumes** are cerium, 19·917; lanthanum, 22·547; neodymium, 20·765; praseodymium, 21·709; and samarium, 19·36. On plotting the at. vol. against the at. wt., Fig. 7, cerium, not lanthanum, occupies an exceptional position. H. C. Kremers and R. G. Stevens gave 6·1598 for the sp. gr. of lanthanum at 15°. The **hardness** is in the order: Pb, Sn, Ce, La, Zn, Nd, Pr, Sa, so that while cerium is nearly as soft as lead, and can be cut with a knife, samarium has the hardness of steel. H. C. Kremers gave 37 for Brinell's hardness (599 kgrms.); F. Hanaman gave 28. Samarium is very brittle, while, according to A. Hirsch, the **ductility** and **malleability** of cerium resemble those of lead; lanthanum is malleable, and it

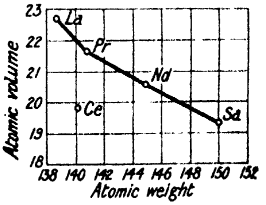

FIG. 7.—Atomic Volumes of the Cerium Metals.

is ductile enough to be hammered into foil, or drawn into wire. Cerium can be machined fairly well although it has a tendency to buckle. The **tensile strength** is 9 kgrms. per sq. mm. According to P. W. Bridgman, the **compressibility** of cerium represented by $\delta v/v$, where v denotes the vol. of cerium at $\theta°$ and atm. press., and the change in vol. δv, given by $\delta v/v \times 10^7$ at 30° is $-35{\cdot}74p+19{\cdot}0\times10^{-5}p^2$; and at 75°, $-35{\cdot}80p+19{\cdot}7\times10^{-5}p^2$.

The **melting point** of cerium given by W. Muthmann and L. Weiss is 623°; lanthanum, 810°; neodymium, 840°; praseodymium, 940°; while samarium melts at 1300°–1400°. F. Hanaman estimates the m.p. of cerium to be 720°. W. Guertler and M. Pirani gave for cerium 700°; lanthanum, 810°; praseodymium, 940°; neodymium, 840°; samarium, 1300°. H. C. Kremers and R. G. Stevens gave 826° for lanthanum. W. R. Mott gave 645° for the m.p. and 1400° for the **boiling point** of cerium; and 810° for the m.p. and 1800° for the b.p. of lanthanum. J. J. von Laar estimated the **critical temperature** to be 3580°, and the **critical pressure,** 560 atm. D. I. Mendeléeff gave for **specific heat** of cerium, 0·05; W. F. Hillebrand, 0·0448 between 0° and 100°; and A. Hirsch, 0·05112 between 20° and 100°; the average at. ht. is 6·82, an unusually high value. J. Dewar gave 0·0330 for the sp. ht. of cerium and 0·0322 for that of lanthanum at a temp. between the b.p. of hydrogen and oxygen. W. F. Hillebrand gave 0·449 for the sp. ht., and 6·23 for the at. ht. of lanthanum. G. W. Lewis and co-workers, and E. D. Eastman found the **entropies** of lanthanum and cerium to be respectively 13·7 and 13·8 at 25° and atm. press. A. Hirsch found qualitatively that the **thermal conductivity** of cerium is high, and that the latent **heat of fusion** is high. R. Pohl and P. Pringsheim prepared mirrors by condensing the vapour of cerium on glass plates. W. Muthmann and L. Weiss gave 1603·15 cals. for the **heat of combustion** of a gram of cerium burning to ceric oxide; and the **heat of formation** of the oxide given by A. Hirsch is $\frac{1}{4}CeO_2=56{\cdot}1$ Cals. W. Muthmann and L. Weiss give for the heats of combustion of a gram of metal to the sesquioxide—lanthanum, 1602·1 cals.; neodymium, 1506·0 cals.; and praseodymium, 1476·8 cals. The high values of the heats of combustion suggest that since a mixture of the cerium and yttrium metals can be easily obtained, the alloy might be useful as a reducing agent. The heat of formation of lanthana, $\frac{1}{6}La_2O_3=74{\cdot}1$ Cals., is greater than that of alumina; this makes it doubtful if lanthana can be reduced by aluminium, unless the heats of combustion alter at higher temp. The heat of formation of praseodymia, $\frac{1}{6}Pr_2O_3=68{\cdot}7$ Cals.; and of neodymia, $\frac{1}{6}Nd_2O_3=72{\cdot}5$ Cals. H. C. Kremers and R. G. Stevens gave 1645 cals. per gram for the heat of combustion of lanthanum.

It will be observed that praseodymium and neodymium present an exception to the rule that there is a regular change in the properties of a sequence of elements in a given family with change in the at. wt. Thus:

	La	Pr	Nd	Sa
At. wt.	139	140·9	144·3	150·4
M.p.	810°	940°	840°	1300°–1400°
Heat of formation, cals. per eq.	74·1	68·9	72·5	—
Heat of combustion, cals.	1602·1	1466·8	1506	—

There are therefore four pairs of such anomalies presented by argon and potassium, tellurium and iodine, cobalt and nickel, and praseodymium and neodymium, and, as A. Werner pointed out, these anomalies occur in periods in which six to seven elements occur between the first and last pairs.

The lines in the **spark spectrum** of cerium were first measured by G. Kirchhoff,[2] and compared with Fraunhofer's lines of the solar sprectrum. Many observers—R. Thalén, J. H. Pollok and A. G. G. Leonard, B. Brauner, F. Exner and E. Haschek, O. Lohse, F. L. Cooper, R. Bunsen, A. Hagenbach and H. Konen, etc.—have studied the spark spectrum. G. Meyer and M. Greulich found that with a soln. containing 0·01 mgrm. of cerium per c.c. the lines λ=3940·89 and 4166·75 are visible. They also examined the influence of various other salts when admixed with the cerium salt. A. Bakowsky, F. L. Cooper, J. M. Eder and E. Valenta, C. C. Kiess and co-workers, F. Exner and E. Haschek, etc., studied the lines in the **arc spectrum** of cerium. The spectrum of this element is one of the richest in lines; A. Bakowsky measured between 2800 and 2900 of them. The most intense lines in the arc spectrum are 4150·11, 4186·78, 4222·78, 4296·88, 4337·96, 4382·32, 4386·95, 4460·40, 4479·52, 4487·06, 4527·51, 4528·64, in the violet; 4539·90, 4562·52, 4572·45, 4594·11, 4628·33, in the blue; and 5512·27 in the green. W. J. Humphreys measured the effect of press. on the lines; H. Geisler studied the anomalous dispersion; and P. G. Nutting, the structure of the lines. R. Bunsen observed no spectrum in the Bunsen flame. W. Huggins obtained a continuous spectrum with the oxide in the oxyhydrogen flame, but J. N. Lockyer observed the lines 5273 and 5160. W. N. Hartley noted that special spectra are furnished by cerium oxide and salts under these conditions. G. Kirchhoff, and J. N. Lockyer observed two of Fraunhofer's lines corresponded with the spectral lines of cerium; H. A. Rowland found 33 coincidences; and A. Bakowsky, several hundreds.

The lines in the spark spectrum obtained from aq. soln. of salts of the rare earths gradually weaken and vanish at different rates as the conc. of the soln. is diminished. J. H. Pollok, A. G. G. Leonard,[3] W. N. Hartley, and A. de Gramont have studied this question in the case of cerium, lanthanum, and yttrium. The most persistent lines—*i.e.* those which remain longest when the soln. is diluted—are called ultimate or residual lines. The lines which show in a 0·001 per cent. soln. are called the ω-lines; with a 0·01 but not in a 0·001 per cent. soln., the ψ-lines; those in a 0·1 per cent. but not in a 0·01 per cent. soln., the χ-lines; those in a 1·0 per cent. but not in a 0·1 per cent. soln., the ϕ-lines; and those in a more conc. soln. σ-lines. Lines given by sparks from the solid but not by an aq. soln., are called the τ-lines. Assuming that with the same conditions, the same lines disappear at the same dilutions, the observations become quantitative. G. Meyer found 0·01 mgrm. per c.c. to be the minimum conc. for the spectroscopic detection of cerium, lanthanum, and didymium.

G. Kirchhoff,[4] R. Thalén, P. T. Cleve, J. H. Pollok and A. G. G. Leonard, B. Brauner, A. Bettendorff, E. Demarçay, O. Lohse, F. Exner and E. Haschek, S. Forsling, J. M. Eder and E. Valenta, A. Hagenbach and H. Konen, etc., have studied the spark spectrum of lanthanum. G. Meyer and M. Greulich found that with a soln. containing 0·006 mgrm. of lanthanum per c.c., the line λ=3949·22 can be detected. They also examined the effect of various other salts admixed with the lanthanum salt soln. H. A. Rowland and C. N. Harrison, R. J. Meyer, C. C. Kiess and co-workers, F. Exner and E. Haschek, A. Hagenbach and H. Konen, J. Kellner, E. Wolff, M. Bertram, etc., have investigated the arc spectrum. The most intense lines in the arc spectrum are 3949·27, 3988·69, and 4238·55 in the violet; 4333·98 in the blue; and 6250·14, 6262·52, and 6394·46 in the red. There are also bands in the arc spectrum studied by J. Kellner, J. Okubo, E. Wolff, and A. Hagenbach and H. Konen. R. Bunsen found lanthanum salts do not show a spectrum in Bunsen's flame. W. N. Hartley and H. Ramage observed that the spectrum of the oxide in the oxyhydrogen flame exhibits a number of bands. W. J. Humphreys studied the effect of press.; H. Ebert, the anomalous dispersion; J. N. Lockyer, the enhanced lines; and W. M. Hicks, and E. Paulsen, their regularities in the spectral lines. H. A. Rowland observed lines of lanthanum in the solar spectrum.

C. A. von Welsbach,[5] the discoverer of neodymium and praseodymium, made some observations on the spark spectra of these elements; and further observations were made by S. Forsling, O. Lohse, F. Exner and E. Haschek, A. Hagenbach and H. Konen, C. C. Kiess, J. M. Eder and E. Valenta, etc. G. Meyer and M. Greulich found that with soln. containing 0·01 mgrm. per c.c. the Nd-lines λ=4061·27 and 4325·80 or the Pr-lines λ=4206·81 and 4429·41, could be detected; and they examined the effect of other salts admixed with the neodymium or praseodymium salt soln. The arc spectra were examined by A. Hagenbach and H. Konen, J. M. Eder and E. Valenta, etc. F. Exner and E. Haschek observed 2014 lines in the spark spectrum and 1294 in the arc spectrum of neodymium, and 2490 lines in the spark spectrum of praseodymium; and M. Bertram reported 1954 lines in the arc spectrum of neodymium, and 1500 lines in that of praseodymium. The most intense lines in the arc spectrum of neodymium are 3863·52, 3951·32, 4061·32, 4274·54, 4282·67, 4325·87, 4375·11, 4385·81, 4400·96, 4446·51, 4451·71, 4463·09, 4920·84, 5293·35, 5319·98, 5594·58, 5620·75, 6310·69, 6314·69, and 6385·32; while with praseodymium, the most intense lines are: 4100·91, 4118·70, 4143·33, 4179·60, 4189·70, 4206·88, 4223·18, 4225·80, 4241·20, 4305·99, 4429·28, 4496·60, and 4510·32. H. Auerbach observed no spectrum with praseodymium salts in Bunsen's flame, or in the oxyhydrogen flame; W. N. Hartley and H. Ramage said that in the oxyhydrogen flame neodymium gives a band spectrum. L. Haitinger noted a flame spectrum with praseodymium, and C. A. von Welsbach, L. Haitinger, K. Schaum and H. Wüstenfeld, and C. Anderson noted the flame spectrum of neodymium. The flame spectra are of little or no help in the detection of these earths. The flame spectra vary with temp., and C. Anderson found that the bands occupy the same position in the flame and **reflection spectra** of neodymium when examined at the same temp., and W. Muthmann and co-workers and P. Joye examined the reflection spectra of neodymium and praseodymium; and K. A. Hofmann and K. Höschele, the reflection spectrum of the same two elements. Neodymium mixed with alumina was found by L. Haitinger to give a discontinuous spectrum in Bunsen's flame, and this spectrum is almost identical with the reversed absorption spectrum. H. A. Rowland attributed a number of Fraunhofer's lines in the solar spectrum to neodymium and to praseodymium. G. Hofbauer noted that 140 neodymium lines and 110 praseodymium lines corresponded with lines in the solar spectrum.

The spark spectrum of samarium was examined by R. Thalén,[6] A. Bettendorff, F. Exner and E. Haschek, A. Hagenbach and H. Konen, C. C. Kiess, E. Demarçay, J. M. Eder and E. Valenta, etc.; and the arc spectrum by F. Exner and E. Haschek, J. M. Eder and E. Valenta, A. Hagenbach and H. Konen, C. Rütten, etc. The most intense lines in the spark spectrum are: 3739·30, 4152·38, 4203·18, 4225·48, 4229·83, 4236·88, 4256·54, 4319·12, 4329·21, 4334·32, 4347·95, 4391·03, 4420·72, 4421·32, 4424·55, 4434·07, 4434·52, 4452·92, 4454·84, 4458·70, 4467·50, 4519·80, 4524·08, 4544·12, 4566·38, 4577·88, 4642·41, and 4674·79. The flame spectrum of samarium was examined by L. de Boisbaudran, and A. Bettendorff; and the reflection spectrum, by K. A. Hofmann and K. Höschele. Samarium chloride or nitrate was found by E. Demarçay, and L. de Boisbaudran, to give a yellow phosphorescent *spectre de reversement* or **reversion spectrum**; there are three bands with maxima of wave-length 6440, 6000, 5640. H. A. Rowland could identify no samarium lines in the solar spectrum, but G. Hofbauer reported that 125 lines of the samarium spectrum probably coincided with lines in the solar spectrum.

Unlike the salts of a great number of elements with a colourless acid, soln. of the salts of many of the rare earths show a characteristic **absorption spectrum** which exhibit a number of bands some of them remarkably narrow and intense. The aq. soln. of cerous and lanthanum salts are devoid of absorption spectra in the visible region, but soln. of praseodymium, neodymium, and samarium have well-defined absorption spectra. The blue and red ceric salts also show absorption bands at the violet end of the spectrum. The width of the bands is increased by augmenting the conc. of the soln. or the depth of the soln. through which the light passes; the edges of the bands are also more or less hazy, hence, it is usual to state the position of maximum absorption, *i.e.* the so-called head of the band, than to state the limits of the region included by the band. The head of a band is usually independent of the conc., but one band may have two or more maxima. The intensity of the absorption is increased by increasing the conc. of the soln., or the depth of the liquid through which the light passes; and, as H. C. Jones[7] and co-workers have shown, in accord with Beer's law. With a constant depth of soln., broad bands shown in conc. soln. may be resolved by dilution into two or more narrower bands; and eventually as dilution proceeds, the bands disappear—*cf.* Fig. 8. The conc. at which the bands cease to be visible is different for different bands. As in the case of the arc and spark spectra, estimates of the conc. of a soln. can sometimes be made from the bands which are present or absent. J. Becquerel, R. W. Wood, and G. J. Elias found that in the vicinity of the absorption bands, aq. soln. exhibit anomalous magnetic rotatory dispersion. Absorption spectra are assumed to be produced by molecules of the solute, or by combinations of the molecules of the solute with those of the solvent. The absorption spectrum may therefore be considerably modified by variations in the nature of the solvent. This subject has been discussed by H. C. Jones and co-workers. W. N. Hartley, G. D. Liveing, and H. C. Jones, etc., have studied the effect of temp. on the absorption bands. Usually, a rise of temp. intensifies the absorption, and broadens some of the bands, while lowering the temp. narrows the bands. H. C. Jones and W. W. Strong showed that in the presence of calcium chloride, the absorption bands of aq. soln. of neodymium chloride decrease in intensity with rise of temp., and the heads of the bands are slightly displaced.

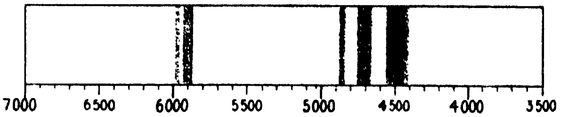

FIG. 8.—The Absorption Spectrum of Aqueous Solutions of Praseodymium Chloride

Thin slices of crystals of minerals and salts may also show absorption bands which are not the same as those obtained with soln. although a certain family likeness can often be detected. R. Bunsen[8] noted that the crystals of didymium sulphate are pleochroic. H. Becquerel, H. Dufet, G. H. Bailey, etc., have also studied the phenomenon with a number of minerals containing the rare earths, and found that the bands may differ in relative intensities, but not in position. J. Becquerel showed that the bands become narrower and more intense as the temp. is lowered, and in the vicinity of the absorption bands, the crystals exhibit an anomalous magnetic rotatory dispersion. F. Weidert studied the absorption spectrum of glasses stained with didymium compounds.

The absorption spectrum of aq. soln. of praseodymium salts have been investigated by S. Forsling,[9] A. Langlet, W. Rech, A. Aufrecht, L. F. Yntema, P. Schottländer, G. P. Baxter and O. J. Stewart, J. E. Purvis, H. C. Jones and co-workers, B. Brauner, A. Bettendorff, C. R. Böhm, B. Stahl, W. C. Ball, etc. According to W. Rech, there are five well-defined bands in the visible spectrum of praseodymium chloride, or nitrate, with weak maxima in the yellow at 5964 and 5882; an intense maximum in the blue at 4813, and one at 4683, which is coincident with a neodymium band; and a broad intense band in the violet with a maximum at 4442—Fig. 8. The maxima given by different observers usually differ by a few units; thus, for the above bands B. Brauner gives 5963, 5895, 4812, 4693, and 4447 respectively. The absorption in the yellow can be seen only with conc. soln. F. G. Wick found that the effect of press. produces the same changes as those produced by lowering the temp., or decreasing the conc. Measurements of the absorption spectrum in organic solvents were made by H. Schäffer, and H. C. Jones and J. A. Anderson. The results show that the bands change their position owing to the formation of complexes between solute and solvent. F. Weidert studied the absorption spectra of glasses containing didymium oxides.

The absorption spectrum of aq. soln. of neodymium is complex, and very rich in bands; it has been measured by E. Demarçay, W. W. Strong, S. Forsling, C. A. von Welsbach, J. E. Purvis, L. F. Yntema, B. Brauner, O. Boudouard, W. Rech,

B. Holmberg, B. Stahl, F. Exner, G. Dimmer, G. P. Drossbach, W. Muthmann and L. Stützel, C. Garnier, G. P. Baxter and co-workers, etc. According to W. Rech, intense maxima occur at 7324, 5800, 5780, 5750, 5740, 5210, 5200, 5120, 5090, 4274, 3556, 3540, 3507, 3465, 3288, and 2983; while less intense bands have maxima at 6890, 6790, 6730, 6360, 6280, 6250, 6220, 5870, 5830, 5710, 5470, 5310, 5250, 4870, 4800, 4750, 4690, 4610, 4327, 4290, 4180, 3801, 3399, 3231, 3144, 3067, 3047, 3030, 3015, 2998, 2937, 2913, and 2902. The band at 4690 coincides with one due to praseodymium, so that in a mixed soln. the two bands overlap and so intensify one another. The two bands 4610 and 4750 partially overlap the 4632 and 4761 bands of samarium. They also clash with europium bands, and since these two elements constantly occur with samarium, the absorption spectrum is not of much use as a test. The two bands, 5800 and 5470, which appear in the absorption spectrum of the nitrate are not shown in the spectrum of the chloride. L. Isakoff found soln. of neodymium chloride show an anomalous dispersion. W. Rech's photograph is shown in Fig. 9. H. Schäffer, and H. C. Jones with J. A. Anderson, with W. W. Strong, and with J. S. Guy, have measured the absorption spectra in non-aq. soln. There is a marked resemblance between the absorption spectrum of neodymium chloride in glycerol and that of the same substance in water, but the former are rather closer to the red end; the absorption spectrum in ethyl chloride is very different from that in water. The absorption spectra of aq. soln. of neodymium acetate are less intense, wider, and nearer the red end than with aq. soln. of the chloride. A. G. Wick found a press. of 3500 atm. had the same influence on the absorption spectrum of neodymium nitrate as cooling to —60°.

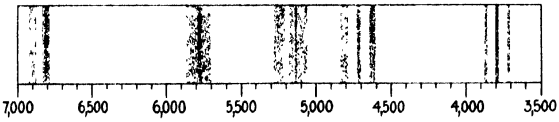

FIG. 9.—The Absorption Spectrum of Aqueous Solutions of Neodymium Chloride.

The absorption spectra of aq. soln. of samarium salts are not very intense, but are characteristic; the bands have been measured by C. Demarçay,[10] C. R. Böhm, J. L. Soret, L. J. Yntema, L. de Boisbaudran, A. Bettendorff, S. Forsling, G. Krüss and L. F. Nilson, W. Prandtl, R. Thalén, W. Muthmann and co-workers, etc. The strongest absorption is in the blue and violet regions. E. Demarçay reported that a 20 per cent. soln. of the nitrate in conc. nitric acid, with a soln. 13 mm. thick, has some complex bands: 5590, 5290, 4980, 4760, 4630, 4530, 4430, 4170, 4070, 4020, 3900, 3750, and 3620. The bands 5290, 4530, 4070, and 3900 are very feeble, being visible only with thick layers of soln., or in conc. soln. According to S. Forsling, maxima in the bands of the absorption spectrum of an aq. soln. of the chloride, are 5600, 5001, 4804–4783, 4761–4727, 4632, 4443–4383, 4177, 4157, 4083, 4077, 4035–4030, 4016–4007, 3942–3932, 3906, 3752–3742, 3738–3732, and 3630–3615—*vide* Fig. 10. The two samarium bands at 4632 and 4761 overlap the neodymium bands at 4610 and 4750. J. Becquerel measured the influence of the magnetic field and low temp. on the absorption spectra. H. C. Jones and W. W. Strong measured the absorption spectrum of samarium in non-aq. solvents.

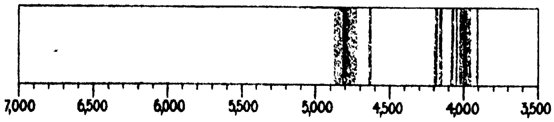

FIG. 10.—Absorption Spectrum of Samarium Chloride.

In 1881, W. Crookes[11] showed that many substances bombarded by cathode rays emit a phosphorescent light which generally gives a continuous spectrum ; but less frequently, the spectrum is discontinuous—**cathodic phosphorescent spectrum.** In studying the yttria earths he was attracted by a pair of orange bands of wave-length 5970 and 6030, which he attributed to an element X. He found that compounds of X are sensibly phosphorescent only when very intimately mixed with certain other substances—*e.g.* compounds of calcium. He finally identified the element X with samarium. He assumed that samarium is a complex of four meta-elements. L. de Boisbaudran showed that purified substances are not sensibly phosphorescent when exposed to the cathode rays. The addition of another substance may produce cathodic phosphorescence which increases in intensity as the proportion of the foreign matter increases until it reaches a maximum, and any further increase reduces the intensity of the effect by dilution. The optimum addition for the maximum effect is independent of the intensity of the cathodic rays, or of the temp., although the latter may modify the spectrum. A similar result obtains with each band in the phosphorescent spectrum, although the effect on any band varies independently of the effect on other bands. The foreign material which induces the phosphorescent effect is called the *phosphorogen.* These substances have been studied by G. Urbain, L. Brüninghaus, etc.—*vide* phosphorescent zinc sulphide. Purified lanthana gives no cathodic phosphorescent spectrum, and the reports by W. Muthmann and E. Baur, E. Baur and R. Marc, W. Crookes, and A. Bettendorff are based on materials tainted with impurities. Praseodymium gives a red cathodic phosphorescence, when diluted with lime, with maxima at 6780, 6700, 6340, 6265, 6200, 6065, 6045, 5790, 5570, 5527, 5405, 5355, 5255, 5170, and 5110. Praseodymium sulphate also gives a red phosphorescence when diluted with calcium sulphate ; the maxima in the spectrum are at 6100, 6000, and 5876. Neodymia, diluted with lime, gives a cathodic phosphorescent spectrum with maxima at 5045, 4690, 4660, 4610, 4575, 4515, 4400, 4295, 4270, 4230, 4220, 4190, 3980, and 3920 ; while neodymium sulphate diluted with calcium sulphate gives a broad band between 5770 and 5010. Samarium gives an orange-yellow, orange, or orange-red cathodic phosphorescence. The maxima in the system samaria-lime are at 6740, 6605, 6470, 6265, 6150, 6052, 5865, 5762, 5683, 5561, and 5486, the system samarium sulphate and calcium sulphate has maxima at 6425, 6180, 6040, 5950, 5855, 5630, 5560, and 5300 ; the system samarium fluoride and calcium fluoride has the maxima 6530, 6220, 6190, 6042, 5725, 5713, 5675, 5580, and 5540 ; the system samaria diluted with gadolinia has maxima 6670, 6550, 6450, 6295, 6165, 6075, 5985, 5840, 5765, 5695, and 5655 ; and the system samarium sulphate diluted with gadolinium sulphate has maxima at 6455, 6355, 6035, 5980, 5885, 5610, and 5545.

The **X-ray spectrum** of lanthanum has been measured by M. de Broglie,[12] and G. Kettmann; the X-ray spectra of lanthanum and cerium by I. Malmer, and D. Coster and co-workers; and those of lanthanum, cerium, praseodymium, neodymium, and samarium by H. G. J. Moseley, G. Hertz, E. Friman, J. R. Rydberg, A. Dauvillier, and E. Hjalmar. In general, the spectra are simple with 4 or 5 lines at the most—*vide* X-ray spectra. The K-series for lanthanum was measured by F. C. Blake and W. Duane, and M. Siegbahn and E. Jönsson, who found for $\alpha_2\alpha'=0{\cdot}376$; $\alpha_1\alpha=0{\cdot}372$; and $\beta_1\beta=0{\cdot}329$; while for the L-series, D. Coster, G. Hertz, E. Hjalmar, G. Kettmann, and M. Siegbahn gave $\alpha_2\alpha'=2{\cdot}66893$; $\alpha_1\alpha=2{\cdot}65968$; $\beta_1\beta=2{\cdot}45330$; $\beta_2\gamma=2{\cdot}298$; $\gamma_1\delta=1{\cdot}87382$; $\beta_4\upsilon=2{\cdot}44426$, and $\beta_3\phi=2{\cdot}40531$. For the K-series of cerium, F. C. Blake and W. Duane, and M. Siegbahn and E. Jönsson gave $\alpha_2\alpha'=0{\cdot}360$; $\alpha_1\alpha=0{\cdot}355$; and $\beta_1\beta=0{\cdot}314$; and for the L-series, D. Coster, G. Hertz, E. Hjalmar, and M. Siegbahn gave $\alpha_2\alpha'=2{\cdot}56511$; $\alpha_1\alpha=2{\cdot}55600$; $\beta_1\beta=2{\cdot}35100$; $\beta_2\gamma=2{\cdot}20380$; $\gamma_1\delta=2{\cdot}04433$; $\beta_5\zeta=2{\cdot}19600$; $\beta_4\upsilon=2{\cdot}34480$; and $\beta_3\phi=2{\cdot}40531$. For the K-series of praseodymium, M. Siegbahn and E. Jönsson, gave $\alpha_2\alpha'=0{\cdot}347$; $\alpha_1\alpha=0{\cdot}355$; $\beta_1\beta=0{\cdot}314$; and for the L-series, D. Coster, G. Hertz, E. Hjalmar, and M. Siegbahn gave $\alpha_2\alpha'=2{\cdot}46763$; $\alpha_1\alpha=2{\cdot}45770$; $\beta_1\beta=2{\cdot}25390$; $\beta_2\gamma=2{\cdot}11468$; $\gamma_1\delta=1{\cdot}95681$; $\beta_4\upsilon=2{\cdot}254$; and $\beta_3\phi=2{\cdot}21237$. For the K-series of neodymium, W. Duane and T. Shimizu, and M. Siegbahn and

E. Jönsson gave $\alpha_2\alpha' = 0{\cdot}335$; $\alpha_1\alpha = 0{\cdot}330$; and $\beta_1\beta = 0{\cdot}292$; and for the L-series, D. Coster, G. Hertz, E. Hjalmar, and M. Siegbahn gave $\alpha_2\alpha' = 2{\cdot}37563$; $\alpha_1\alpha = 2{\cdot}36531$; $\beta_1\beta = 2{\cdot}16221$; $\beta_2\gamma = 2{\cdot}031$; $\gamma_1\delta = 1{\cdot}87383$; $\gamma_2\theta = 1{\cdot}801$; $\beta_4\nu = 2{\cdot}162$; and $\beta_3\phi = 2{\cdot}12230$. For the L-series of samarium, D. Coster, E. Hjalmar, and M. Siegbahn gave $\alpha_2\alpha' = 2{\cdot}20568$; $\alpha_1\alpha = 2{\cdot}19501$; $\beta_1\beta = 1{\cdot}99357$; $\beta_2\gamma = 1{\cdot}877$; $\gamma_1\delta = 1{\cdot}72309$; $\gamma_2\theta = 1{\cdot}657$; and $\beta_3\phi = 1{\cdot}958$. W. M. Hicks found that the line spectra of scandium, lanthanum, yttrium, and ytterbium show a doublet series. W. Duane measured the absorption frequencies of the X-rays for cerium. J. Carrera gave for the absorption coeff. for X-rays: La, 53·48; Ce, 53·53; Pr, 55·56: Nd, 56·58; and Sm, 58·71. R. Pohl and P. Pringsheim studied the **photoelectric effect** with cerium.

Cerium is a poor conductor of electricity. According to C. Benedicks,[13] the **electrical conductivity** is $0{\cdot}0128 \times 10^6$ reciprocal ohms, at 18°, and for praseodymium, $0{\cdot}0114 \times 10^6$, and for neodymium, $0{\cdot}0130 \times 10^6$ reciprocal ohms. According to C. Benedicks, the sp. **electrical resistance** of cerium is 78×10^{-6} ohms per cm. cube at ordinary temp., while A. Hirsch gave $71{\cdot}6 \times 10^{-6}$ ohms. P. W. Bridgman found 0·001476 for the temp. coeff. of the resistance of an impure lanthanum between 0° and 100°, and for the press. coeff. in kgrms. per sq. cm.:

		Pressure coefficient.		
Temp.	Resistance.	0 kgrm.	12,000 kgrms.	Average.
0°	1·000	$-0{\cdot}0_5 39$	$-0{\cdot}0_5 25$	$-0{\cdot}0_5 331$
50°	1·0750	$-0{\cdot}0_5 39$	$-0{\cdot}0_5 36$	$-0{\cdot}0_5 377$
100°	1·1476	—	—	—

C. Benedicks gave 79–88 microhms per cm. cube for praseodymium. P. W. Bridgman gave 0·000799 for the temp. coeff. of the resistance of neodymium, between 0° and 95°, and for the press. coeff. in kgrms. per sq. cm.:

		Pressure coefficient.		
Temp.	Resistance.	0 kgrms.	12,000 kgrms.	Average.
0°	1·0000	$-0{\cdot}0_5 238$	$-0{\cdot}0_5 183$	$-0{\cdot}0_5 213$
50°	1·0400	$-0{\cdot}0_5 250$	$-0{\cdot}0_5 197$	$-0\ 0_5 226$

According to A. Hirsch, the **electrode potential** of cerium could not be successfully measured in alcoholic soln. of cerium chloride, because of the rapid formation of films on the metal; but from the decomposition potential of normal cerium chloride, and the heats of formation and soln. of that chloride, the single potential of cerium in a *N*-soln. of its chloride, measured against a normal calomel electrode, is −3·16 volts. C. Erk, E. F. Smith, G. Bricout, etc., have shown that the electrolysis of soln. of cerous salts with platinum electrodes is attended by the anodic oxidation of the cerium, so that in neutral or feebly acid soln., ceric hydroxide or basic ceric salts are deposited on the anode, and in strongly acid soln., ceric salts pass into soln. J. Sterba found most of the cerous salt is oxidized. G. von Knorre thus oxidized 91 per cent. of a soln. of ammonium cerous nitrate, and A. Job oxidized it all. G. Kolle found that a large anode surface, small cathode density, and an optimum temp. of 50° favour the oxidation. W. Krilitschewsky, and E. Mühlbach also studied the conditions of oxidation. E. Baur and A. Glässner, and E. Mühlbach have studied the **oxidation potential**; and C. A. von Welsbach, and W. Krilitschewsky, the possibility of using cerium accumulators with an electrolyte of zinc, cerous, and ceric sulphates, a cathode of zinc amalgam, and an anode of carbon. The results are not satisfactory. A. Heydweiller found the **ionic velocity** at infinite dilution to be $\frac{1}{3}$La = 50; and $\frac{1}{3}$Sa = 53·5 at 18°; and A. Noyes and K. G. Falk, $\frac{1}{3}$La = 72 at 25°.

A. Hirsch measured the **thermoelectric force** of cerium against copper with the cold junction at 30°, and the hot junction at 49·2°, and found 0·000075 volt; 100°, 0·000250 volt; 151°, 0·000387 volt; and at 200·5°, 0·000502 volt. Cerium is paramagnetic; the **magnetic susceptibility**, according to S. Meyer, is 12×10^{-6}

C.G.S. units per gram; M. Owen gives 15×10^{-6} at 18°. The latter also found that a sample of lanthanum of doubtful purity was paramagnetic; praseodymium and neodymium are paramagnetic; M. Owen found at 18°, 25×10^{-6} C.G.S. units for praseodymium; and 36×10^{-6} C.G.S. units for neodymium. B. Cabrera, and A. Dauvillier have discussed the magnetic properties of these elements.

§ 10. The Chemical Properties of the Cerium Family of Metals

C. A. Matignon[1] found that cerium, lanthanum, neodymium, praseodymium, and samarium readily adsorb **hydrogen.** C. Winkler heated ceric oxide with magnesium at a high temp. in an atm. of hydrogen and obtained **cerium hydride** mixed with magnesia; lanthanum behaved in a similar manner, furnishing **lanthanum hydride**, LaH_3. *According to W. Muthmann and K. Kraft, cerium hydride is best obtained by passing purified hydrogen over cerium turnings at 250°-270°; the metal burns with a brilliant flame, producing cerium hydride whose composition, represented by some not very concordant analyses, corresponds with a mixture of cerium trihydride, CeH_3, and of cerium dihydride, CeH_2. A. Hirsch, and A. Sieverts and G. M. Goldegg, studied the action of hydrogen on cerium and lanthanum resulting in the formation of the trihydrides. Lanthanum behaves* similarly; here the reaction begins at 240°, and the metal burns with a reddish-yellow light. F. Kellenberger and K. Kraft found the sp. ht. of cerium hydride to be 0·088915 and the mol. ht. 12·715, whence the at. ht. of hydrogen is 2·15, and that of cerium 6·27. The sp. ht. of lanthanum hydride is 0·087335, and the mol. ht. 12·34, which gives 2·06 for the at. ht. of hydrogen if the at. ht. of lanthanum be 6·189. The hydrides were found by C. A. Matignon to be readily dissociated by heat. According to G. I. Tschukoff, the dissociation press. of cerium hydride at 450° does not exceed one mm. W. Muthmann and E. Baur found the dissociation press. of cerium and lanthanum hydrides at various temp. In each case, the press. did not remain constant at any given temp., but slowly changed. This was attributed to the hydrides undergoing a slow molecular change which is accompanied by a change in the dissociation press. When cerous hydride is shaken in a closed glass tube, it emits light. W. Muthmann and H. Beck prepared **neodymium hydride**, NdH_3, by the action of hydrogen on strips of the metal at 220°; **praseodymium hydride**, PrH_3, was obtained in a similar way. C. Matignon prepared the two last-named hydrides, and also **samarium hydride**, SaH_3, by heating the oxides with magnesium in an atm. of hydrogen. W. Muthmann and co-workers state that the hydrides of cerium, lanthanum, neodymium, and praseodymium are brittle amorphous solids, the cerium and lanthanum compounds are bluish-black, the neodymium compound is indigo-blue, and the praseodymium compound is green. W. Muthmann and K. Kraft said that cerium hydride is stable in dry air, but rapidly decomposes in moist air, often igniting spontaneously. When heated in dry air, hydrogen is evolved and a mixture of cerium dioxide and nitride is formed. When purified cerium hydride is treated with a slow stream of moist air, F. W. Dafert and R. Miklauz say that no ammonia is formed, but when allowed to take fire spontaneously, the cerium formed by the dissociation of the hydride partly combines with nitrogen from the air, and then gives ammonia with moisture. Cerium often contains traces of nitrogen, with the result that the hydride then smells of ammonia on exposure to the air. J. Lipski found that when dry, purified nitrogen is passed over the freshly prepared hydride in the cold, ammonia is formed rapidly—about one-half the possible quantity in three and a half hours; the reaction, however, soon becomes slower, probably owing to superficial formation of nitride. The reaction is $CeH_3+N_2=CeN+NH_3$. Raising the temp. to 200° increases the rate of reaction very little. F. W. Dafert and R. Miklauz observed no signs of the formation of an imide or other compound containing hydrogen or nitrogen. According to W. Muthmann and K. Kraft, cerium hydride dissolves in acids, evolving hydrogen and forming cerous salts, and it is decomposed by moist air and alkali soln. with the liberation of hydrogen. Lanthanum, praseodymium, and neodymium hydrides behave in a similar manner.

According to W. Muthmann and L. Weiss, cerium, praseodymium, and neodymium, preserve their lustre in dry air, but are tarnished in moist air. Lanthanum tarnishes rapidly, even in dry air. When cerium is exposed to air it very slowly acquires a yellow film which slowly turns bluish-green, and probably contains some cerium dioxide; samarium tarnishes quickly in air and becomes coated with a yellow deposit. A. Hirsch found that cerium burns with luminescence when heated in air to 160°; and if a lump of cerium, sealed in a glass bottle, be kept warm for some time, a black powder is formed on the surface of the cerium, and when the bottle is opened the powder ignites at the temp. of the room. He added that the phenomenon is probably due to the formation of a highly pyrophoric *cerium suboxide*. When cerium is scratched with a steel needle, when filed, or when struck with a piece of flint, it emits showers of sparks. Cerium wire burns in Bunsen's flame with a more intense light than does magnesium wire. Lanthanum wire burns brilliantly under similar conditions. The products of the combustion of cerium and lanthanum in air contain oxide and nitride. W. Muthmann and K. Kraft give 150°-180° for the ignition temp. of cerium in **oxygen**, and 440°-460° for that of lanthanum—under similar conditions, magnesium ignites at 540°, and aluminium at 580°. G. Tammann investigated the velocity of attack by oxygen on cerium, and lanthanum. H. C. Kremers and R. G. Stevens gave 445° for the ignition temp. of lanthanum. They found the metal is not pyrophoric; but it is easily corroded even in dry air. N. N. Mittra and N. R. Dhar studied the induced oxidation of nickelous oxide during the primary oxidation of cerous hydroxide.

A. Hirsch said that 98 per cent. cerium is very slightly attacked by cold **water**, but in boiling water there is a slow evolution of hydrogen, and the metal is tarnished black. Lanthanum slowly forms the hydroxide with cold water, and rapidly with hot water; in both cases hydrogen is evolved. Praseodymium is also slowly attacked by cold, and rapidly by hot water. According to A. Hirsch, at room temp., a conc. soln. of **sodium hydroxide** has no action on the metal, but a boiling soln. has a slight action; at the room temp., a soln. of **ammonium chloride**, or of **potassium chloride**, has a moderate action on the metal. This is explained by assuming that by the action of the water on the metal a small amount of cerium hydroxide is formed which is soluble in soln. of the salts in question; a fresh surface of the metal is exposed to attack by the solvent, and the cycle of actions is repeated. The action is more pronounced with boiling soln. At room temp., a 3 per cent. and a 30 per cent. soln. of **hydrogen peroxide** have a slight action on the metal. Dil. nitric acid, ammonium chloride, potassium chloride, and 3 per cent. hydrogen peroxide at boiling temp. gave moderate action; dil. sulphuric acid, conc. and dil. hydrochloric acid, conc. nitric acid and 30 per cent. hydrogen peroxide, gave vigorous evolution of gas at boiling temp.

According to A. Hirsch, when cerium filings are heated in a stream of **chlorine**, they emit a bright light at 210°-215°, forming anhydrous *cerous chloride;* the action with **bromine** at 215°-220° is similar to that with chlorine, but it is not quite so vigorous. No light is emitted when **iodine** vapour acts on the metal at 300°, but some *cerous iodide* is formed. Lanthanum behaves similarly. Dil. and conc. **hydrochloric acid** in the cold act vigorously on cerium. When cerium filings are heated in the vapour of **sulphur**, some *cerium sulphide* is probably formed, since the product gives off hydrogen sulphide when treated with an acid. Both **selenium** and **tellurium** react vigorously when added to molten cerium. With selenium, the product forms a powder which is impure *cerium selenide*, and a pyrophoric alloy which is a soln. of the selenide in an excess of cerium; with tellurium, a brown pulverulent telluride is formed, and this gives off hydrogen telluride when treated with acids. At room temp., dil. **sulphuric acid** acts vigorously on cerium, but the conc. acid has no perceptible action on cerium either in the cold or at the b.p. Cold conc. sulphuric acid has but little action on lanthanum, although the dil. acid attacks it rapidly.

A. Sieverts and G. M. Goldegg found the absorption of nitrogen to be very slow. According to A. Hirsch, when cerium is heated to about 1000° in a stream of **nitrogen**, no luminescence occurs, but some nitride is formed; and, according to C. A. Matignon, when a mixture of the oxides of one of the five cerium metals is heated with magnesium in a stream of nitrogen, the corresponding nitride is formed. Conc. aq. **ammonia** has no visible action on cerium, neither at room temp. nor at the b.p. The action of dil. or conc. **nitric acid** is moderately vigorous in the cold, and a brown crust of the dioxide is formed. Nitric acid oxidizes lanthanum violently. H. Beck found that heated cerium readily reacts with **phosphorus**, forming a series of phosphides. A. K. Goard and E. K. Rideal investigated the catalytic oxidation *of* **arsenites** *from the point of view of the oxidation potentials. A. Hirsch found that when cerium is heated with* **arsenic,** *an endothermal reaction ensues and a soft somewhat pyrophoric alloy is formed, which does not decompose* when kept; with **antimony,** much heat is evolved, and when freshly made, the alloy is pyrophoric; it disintegrates to a powder when kept for a few months in air. J. Kellermann studied the alloys of cerium with arsenic and antimony. H. Kunheim patented the use of arsenic or antimony with the cerite metals for the preparation of pyrophoric alloys; and J. Kellermann, alloys with **bismuth.** According to R. Vogel, cerium and bismuth combine with great development of heat. Porcelain tubes are rapidly corroded, but carbon tubes may be used, and the alloys are not seriously contaminated with carbide. The thermal effects are often small, and the micro-structure has been largely employed in determining the form of the diagram. The sections must be polished with wet alumina, but they oxidize very rapidly, and the polished surfaces cannot be preserved. Four compounds are formed: **cerium tritabismuthide,** $BiCe_3$, **cerium tritetritabismuthide,** Bi_3Ce_4, **cerium bismuthide,** BiCe, and **cerium dibismuthide,** Bi_2Ce. Cerium tritetritabismuthide, Bi_3Ce_4, melts at 1630°, and appears as a maximum on the f.p. curve. It crystallizes in polygonal grains. Cerium tritabismuthide, $BiCe_3$, is formed at 1400°, and is softer than cerium tritetritabismuthide, Bi_3Ce_4. It forms a eutectic with cerium at 757°. Cerium bismuthide, BiCe, is formed at 1525°, and cerium dibismuthide, Bi_2Ce, at 882°, whilst the second eutectic point practically coincides with the m.p. of bismuth. All the alloys are more readily attacked by water than is cerium alone; the action of water on alloys with between 25 and 75 per cent. of bismuth may even raise them to incandescence.

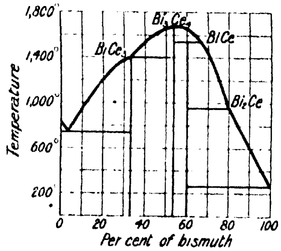

FIG. 11.—Freezing-point Curve of Alloys of Bismuth and Cerium.

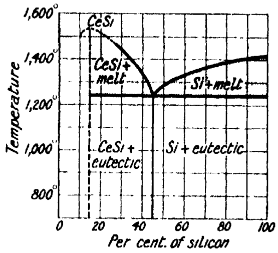

FIG. 12.—Freezing-point Curve of Alloys of Silicon and Cerium.

A. Hirsch found that when cerium is heated with **carbon,** the two elements readily react, forming a carbide; and when the metal is heated to 500° in an atm. of **carbon monoxide,** there is no visible reaction, although part of the cerium is oxidized. W. Muthmann and K. Kraft found that both lanthanum and cerium reduce **carbon dioxide** and carbon monoxide, forming ceric oxide, and both **ethylene** and **acetylene** react with lanthanum, furnishing the hydride and carbon. S. Medsforth investigated the effect of cerium oxide in promoting the activity of nickel in reducing the carbon oxides by hydrogen. A. Hirsch found that at room temp., **ethyl alcohol, amyl alcohol, chloroform,** and **carbon tetrachloride** have no visible action on cerium; and ethyl **ether** has but a slight action; at the b.p., chloroform and carbon tetrachloride have no action on cerium, while the action with ethyl or amyl alcohol or ethyl ether is but slight. W. Muthmann and K. Kraft found that **methyl chloride** reacts with cerium between 500°-600° giving a mixture of carbon and cerium chloride and hydride: $3CH_3Cl+4Ce=CeCl_3+3CeH_3+3C$. A. K. Goard and E. K. Rideal studied the catalytic oxidation of **sugars** by cerous salts from the standpoint of the oxidation potentials. A. Hirsch found that cerium reacts with **silicon,** forming **cerium silicide,** CeSi; the same comound is obtained by heating cerium oxide with silicon. According to R. Vogel, he fact that cerium combines with lead and tin with development of heat, formng several compounds, indicates that it does not belong to the same chemical family of the fourth group. It is now found that it combines with silicon at high temp. with great violence. It has not been found possible to prepare alloys containing more than 70 per cent. of cerium, as combination does not take place until 1400°, and the heat developed brings about the destruction of the containing vessel, or, if carbon crucibles be used, there is a considerable production of cerium carbide, in which case the alloys rapidly disintegrate in air. Solid silicon floats on molten cerium, and at a sufficiently high temp. combines explosively. Between 0 and 70 per cent. Ce the f.p. curve has two branches, intersecting at 1240° and 53 per cent. Ce. The eutectic times indicate that the maximum on the curve must be at 83 per cent. Ce, corresponding with a compound, cerium silicide, $CeSi$, melting above 1500°. This compound forms yellow, rounded crystallites, and the eutectic has a distinct lamellar structure. Free silicon crystallizes in needles, which are harder than the compound. The alloys are brittle, very stable in air, and are not pyrophoric. Molten cerium attacks **silicates**; **porcelain** crucibles are attacked, and a layer of cerium silicide is formed which protects the material from further attack; and the silicide does not appear to dissolve in the metal. Magnesia crucibles are best used for melting the metal. The reducing action of cerium, or of a mixture of the cerium group of metals—with or without aluminium or magnesium—on the **metal oxides,** was proposed by R. Escales, in place of that of magnesium or of aluminium in the thermite process.

The alloys of the cerium metals.—The cerium metals, so far as they have been examined, readily form alloys with other metals. The alloys are usually brittle, and can be readily pulverized. Various alloys were described by L. Guillet. The following deals with the alloys of those metals which have already been discussed in this treatise. According to A. Hirsch,[2] **sodium** dissolves quietly in cerium, forming a hard, slightly pyrophoric alloy, which is somewhat oxidized on exposure to air. He also found that when cerium and **copper** are melted together under a layer of sodium chloride in a magnesia crucible, there is formed a hard and brittle alloy, although the two components are soft and malleable. The alloy disintegrated to a powder on exposure to air. The copper-cerium alloys were mentioned by W. Borchers, H. Kellermann, and F. Fattinger as illustrations of the great faculty possessed by cerium of alloying with the metals. L. Stockem prepared some copper-cerium alloys by melting in an electric arc furnace a mixture of carbon with cerium and copper oxides, and also by applying the thermite aluminium process to a mixture of cerium and copper oxides. A. Hirsch, and F. Hanaman melted the two metals under a layer of fused alkali chloride by adding the cerium to molten copper, or *vice versa* for alloys with over 80 per cent. of cerium. The f.p. curve, Fig. 13, has two well-marked maxima, corresponding with **cerium hexacupride,** Cu_6Ce, which melts at 935°, and **cerium dicupride,** Cu_2Ce, melting at 820°. There are also two compounds which are formed by reactions between solid and liquid, thus giving rise to breaks in the f.p. curve; **cerium tetracupride,** Cu_4Ce, at 780°, and **cerium cupride,** $CuCe$, at 514°. There are three eutectic points, at 875°, 757°, and 415°, occurring at 17 per cent., 44 per cent., and 84 per cent. of cerium respectively. Solid soln. are not formed. The hardness curve of the alloys has two pronounced maxima, corresponding with the compounds Cu_6Ce and Cu_2Ce, the former being nearly four times as hard as copper. The colour of the alloys

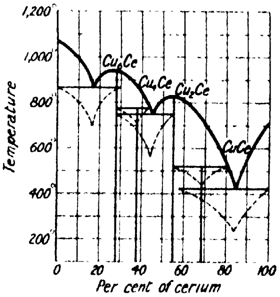

FIG. 13.—Freezing-point Curve of Copper-Cerium Alloys.

resembles that of copper as far as the first eutectic; from that point to the third eutectic it resembles that of bronze, and then becomes steel-grey. Only those alloys which lie between 55 per cent. and 85 per cent. Ce are pyrophoric. Those containing less than 30 per cent. Ce are stable and retain their colour in air; richer alloys soon disintegrate. G. Tammann studied the electrode potential and chemical behaviour of the Ce—Cu alloys. A. Hirsch observed that **silver** forms alloys with cerium with but a small thermal change. The alloy has a silvery white lustre, and is hard and brittle. A compound is probably formed. When **gold** is added to molten cerium, there is a slight flash from the crucible, but the reaction is not violent. The alloy is fairly soft, and has a reddish colour. It disintegrates to a very dark purple powder when allowed to stand in air.

M. Moldenhauer obtained alloys of cerium and **calcium** by reducing cerous fluoride with calcium; and A. Hirsch, by melting the two metals under a layer of alkali chloride. The combination occurs quietly without the evolution of much heat; the alloys are white and harder than either constituent. When scratched with a file, the alloy emits a shower of bright sparks. It is stable in air, oxidizes very slowly, and does not disintegrate. W. Muthmann and H. Beck, A. Hirsch, and R. Vogel also prepared alloys of **magnesium** and cerium—A. Hirsch by a process like that used for calcium-cerium alloys, and R. Vogel by melting an intimate mixture of the two elements in a carbon crucible at a temp. not exceeding 900°. The f.p. curve has maxima at 738° and 780°, corresponding with the compounds **cerium magneside,** $CeMg$, and **cerium trimagneside,** $CeMg_3$, and a break at 620°, corresponding with **cerium enneamagneside,** $CeMg_9$. A minute maximum at 632° is also inferred, due to **cerium tetritamagneside** or **quadrantomagneside,** Ce_4Mg. Solid soln. are only formed between cerium magneside and cerium trimagneside, whilst cerium quadrantomagneside breaks up into cerium and cerium magneside at 497°. This is inferred from the microscopic structure, which is developed by heat-tinting.

Alloys corresponding with the compounds cerium quadrantomagneside and cerium magneside are pyrophoric. Cerium magneside is hard (5 on Mohs' scale), and oxidizes rapidly on heating. When containing magnesium in solid soln. the compound explodes violently in Bunsen's flame, the magnesium vapour being enclosed in a crust of oxide. Moist air at the ordinary temp. has very little action. Cerium trimagneside is still more stable towards air and acids, and is not pyrophoric. Cerium enneamagneside is softer, and brittle. It falls spontaneously into fragments, which retain their silvery lustre, indicating some polymorphic change. According to A. Hirsch, most of the alloys are brittle and can be pulverized, but those with 75 to 85 per cent. of cerium are so highly pyrophoric that it is difficult to pulverize them without ignition. The alloys with the higher proportions of cerium furnish excellent flash-light powders; and they are also splendid reducing agents, as the combination of cerium and magnesium is an endothermic reaction, and when the alloy is oxidized, more heat is emitted than from an eq. mechanical mixture of the two constituents. The fact that the alloys of from 60 to 75 per cent. cerium content may be easily pulverized in a mortar to a fineness of 200 mesh should render these alloys valuable for thermal reductions. The optical constants of cerium metal could not be obtained because of the formation of a film of oxide on the surface, but the indices of refraction and the coeff. of absorption for magnesium-cerium alloys were:

Per cent. cerium	0	26	61	83
Refractive index	0·32	0·73	1·43	1·60
Absorption coeff.	1·74	2·30	4·79	12·0

W. Muthmann and H. Beck state that 84·9 cals. are absorbed in the formation of a gram of the alloy with 46·94 per cent. of cerium; and the heat of combustion is 3952·4 cals. per gram. The sp. gr. of the alloy is 2·744; it is silver-white, and very brittle; it does not change in air, but burns with an intensely bright flame; it is readily attacked by dil. acids, with the evolution of hydrogen; at 200°–400° in hydrogen, cerium hydride is formed; and at 900° in air, nitrides of the two metals are formed.

A. Hirsch, and W. Muthmann and H. Beck found that **zinc** unites with molten cerium with explosive violence, and a large amount of heat is evolved. A. Hirsch said the alloy he prepared was hard, brittle, pyrophoric, and remained unoxidized on exposure to air, but W. Muthmann and H. Beck found the alloy with 32·75 per cent. of cerium is bluish-white, and very brittle; its m.p. is high; its heat of formation is 94·48 cals. per gram; its heat of combustion is 1305·5 cals. per gram; it oxidizes readily on exposure to air; dissolves in dil. acids; and forms cerium hydride when heated to 200°–400° in hydrogen. F. Clotofsky found that the electromotive behaviour of cerium-zinc alloys show the existence of two compounds, **cerium quadrantozincide, or tetritazincide,** Ce_4Zn, and **cerium hemizincide,** Ce_2Zn. The velocity constants of the formation of the former was computed to be 4×10^{77}, and of the latter 10^{57}. A. Hirsch found that **cadmium** unites vigorously with cerium, and much heat is evolved. The alloy is hard, brittle, and pyrophoric. On exposure to air, a film of oxide is formed, but the alloy does not disintegrate. C. Winkler noted that cerium dissolves in **mercury,** and by this solvent he extracted the metal from the products of the reduction of ceric oxide with magnesium. W. Kettembeil found that it is not possible to prepare amalgams of cerium and of praseodymium or neodymium by the electrolysis of salts of these elements using a mercury cathode. A. Hirsch also found that cerium readily forms amalgams; those with up to 2 per cent. of cerium are liquid; the others are solid. The amalgams readily oxidize in air; and those with 8–10 per cent. of cerium fire spontaneously on exposure to air. According to H. Beck, amalgams containing between 10 and 16 per cent. of cerium, possess the property of igniting spontaneously in the air; with a content greater than 40 per cent. Ce, they ignite rapidly in these conditions and throw out intense sparks which give an exceedingly bright light. The intensity of production of the sparks increases with the proportion of cerium up to a content of 80 per cent., after which the pyrophoric power considerably decreases. The alloys can be obtained by heating the finely divided rare metal in a closed vessel in contact with mercury vapour at a temp. of 500°–600° C., the intensity and duration of the heating being adjusted according to the amount of mercury it is desired to absorb. W. Muthmann and H. Beck found that a liquid amalgam of cerium, containing 2·74 per cent. of the metal, and a solid amalgam, containing 10·41 per cent., can be prepared by adding cerium to boiling mercury in an atm. of carbon dioxide. The amalgams react with water with the evolution of hydrogen, and become covered with a very voluminous coat of ceric hydroxide in moist air; spontaneous combustion frequently takes place.

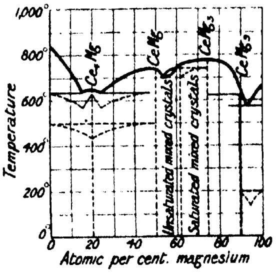

FIG. 14.—Freezing-point Curve of Magnesium-Cerium Alloys.

A. Hirsch found **aluminium** unites with molten cerium quietly, forming a hard, brittle alloy which disintegrates without oxidation. O. Barth, and W. Borchers made cerium-aluminium alloys by adding cerium fluoride to the electrolyte employed in the manufacture of aluminium, and it is claimed that it improved the tensile strength and elongation of aluminium without interfering with its working qualities. The alloys have been studied by J. Schulte, and by H. W. Gillett and V. H. Schnee; the latter reported that the use of cerium in aluminium alloys is "an ex*p*ense not attended by any benefit." According to R. Vogel, cerium and aluminium may be melted together at 1100°, when combination occurs and the temp. rises to 1600°–1700°. Repeated remelting is necessary in order to obtain a homogeneous mixture. The development of heat is a maximum at the composition of **cerium tetraluminide,**

$CeAl_4$. Alloys rich in aluminium are fused in carbon tubes, and the remainder in porcelain tubes, which are very little attacked at 1100°. Many of the thermal changes in the system are indistinct, and the diagram has been completed from microscopical observations. The f.p. curve, Fig. 15, has two maxima, at 614°, corresponding with the compound **cerium tritaluminide,** Ce_3Al, and at 1460°, corresponding with **cerium dialuminide,** $CeAl_2$. There are also breaks at 595°, 780°, and 1250°, corresponding with the formation of the compounds **cerium hemialuminide,** Ce_2Al, **cerium aluminide,** CeAl, and cerium tetraluminide, $CeAl_4$, respectively. The last compound undergoes a transformation at 1005°. There are three eutectic points, and solid soln. are not formed. L. Guillet also obtained these five aluminides. The alloys, with the exception of those containing more than 75 per cent. Ce, are stable towards air and water. Cerium dialuminide is hardly attacked by conc. hydrochloric, nitric, or sulphuric acid, but burns vigorously when heated in Bunsen's flame. Only the alloys richest in cerium give sparks when filed. The maximum hardness, 6 on Mohs' scale, is given by cerium dialuminide, $CeAl_2$. W. Muthmann and H. Beck found needles or prisms of cerium tetraluminide remain when an alloy of the two metals is treated with a soln. of alkali hydroxide. The alloy is brittle. The crystals are rhombic or monoclinic with the axial ratio $a:b=0{\cdot}7706:1$. The sp. gr. is 4·183; the heat of combustion is 3441·19 cals. per gram when the calculated value is 3940·5 cals. per gram; and the heat of formation is 499·3 cals. Lanthanum was found by W. Muthmann and H. Beck to furnish **lanthanum tetraluminide,** $LaAl_4$, in crystals isomorphous with those of the cerium compound. The monoclinic or rhombic crystals have the axial ratios $a:b:c=0{\cdot}7517:1:—$; the sp. gr. is 3·923; the heat of combustion, 3481·6 cals. per gram; and the heat of formation 395·4 cals. The aluminium alloys of cerium and lanthanum are very stable; are not affected by exposure to air; are not attacked by nitric acid, and are dissolved by hydrochloric acid and aq. potassium hydroxide, but less readily than their components. The alloy known as *Mischmetall*, *Cermischmetall*, or *Ceritemetall*, is obtained by the electrolysis of a mixture of the chlorides of the cerium earths from monazite sand—containing roughly 45 per cent. Ce_2O_3; 25 per cent. La_2O_3; 15 per cent. Nd_2O_3; and the remainder contains the sesquioxides of praseodymium, samarium, and yttrium metals. Consequently, the **mischmetall** is a mixture of the rare earth metals—cerium, lanthanum, neodymium, praseodymium, and samarium—with more or less of the yttria earth metals. A. Sieverts and G. M. Goldegg studied the action of hydrogen and nitrogen on the mischmetals.

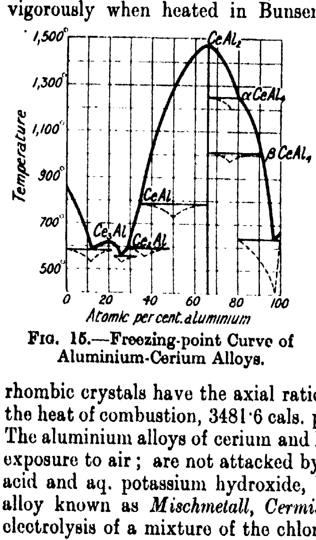

FIG. 15.—Freezing-point Curve of Aluminium-Cerium Alloys.

Reactions of analytical interest.—As previously indicated, the rare earths are isolated by removing silica by evaporation with hydrochloric acid, and precipitating the hydrogen sulphide group. The gas is expelled from the filtrate by boiling, and treated with a boiling soln. of oxalic acid added slowly with constant stirring. The washed and ignited precipitate is dissolved in the minimum quantity of acid, a little alcohol is added to reduce the ceric to cerous salts, and an excess of potassium sulphate is added. After standing a few hours, the precipitate is washed with a soln. of potassium sulphate. The filtrate contains the yttrium and terbium earths; the precipitate, the cerium earths as sparingly soluble double sulphates. The precipitate is dissolved in dil. hydrochloric acid, precipitated with oxalic acid, washed, dried, and ignited. The oxides can be dissolved in hydrochloric acid and the components separated as previously described.

The general reactions of soln. of cerous, lanthanum, praseodymium, neodymium, and samarium salts are as follows: A precipitate of the hydroxide, $R(OH)_3$, is produced by **ammonium hydroxide** or **ammonium sulphide**; the precipitate is not soluble in an excess of the reagent, but is readily soluble in acids. The precipitation does not occur if much citric or tartaric acid be present. The colour of the precipitate with cerous and lanthanum hydroxides is white; with samarium hydroxide, faintly yellow; with praseodymium hydroxide, green; and with neodymium hydroxide, blue. Cerous hydroxide gradually oxidizes and becomes yellow on exposure to air. W. Biltz[3] showed that lanthanum hydroxide is peculiar in adsorbing **iodine** and acquiring a blue colour like starch. The blue colour is destroyed by acids and alkalies. The hydroxides are also precipitated by soln. of **potassium or sodium hydroxide.** According to R. J. Meyer and co-workers, with sufficient tartaric acid, the precipitation by sodium hydroxide is completely prevented; potassium hydroxide precipitates double potassium tartrates with the members of the yttrium group provided the soln. is boiling; and ammonium hydroxide precipitates double ammonium tartrates of the members of the yttrium group from cold soln. and the precipitates become crystalline when warmed. Precipitates of the carbonates or basic carbonates are produced by soln. of **potassium, sodium, or ammonium carbonate**; the precipitate is very sparingly soluble in an excess of the reagent. Precipitated lead carbonate gives no precipitation, but barium carbonate slowly precipitates all the ceria earth from cold soln. With **oxalic acid,** or **ammonium oxalate,** a precipitate of the oxalate is obtained which is almost insoluble in oxalic acid, but slightly soluble in a soln. of ammonium oxalate. A crystalline double salt is precipitated by **potassium, sodium, or ammonium sulphate,** the double salt is sparingly soluble in cold water, fairly soluble in hot water, and almost insoluble in a sat. soln. of the alkali sulphate. A boiling soln. of **sodium acetate** or of **sodium thiosulphate** gives no precipitation. Neutral or slightly acid soln. give no precipitate with **hydrogen dioxide.** With **tartaric acid,** no precipitation occurs. With **hydrofluoric acid,** the sparingly soluble fluoride is precipitated and the salt is insoluble in soln. of alkali fluorides, but appreciably soluble in hot mineral acids. With **iodic acid,** the iodates are precipitated, and they are readily soluble in nitric acid.

Cerous salts are readily oxidized in acid soln. by the action of lead dioxide and nitric acid; by persulphates; by anodic oxidation; etc., as previously described. Ceric salts are readily reduced to cerous salts by the usual reducing agents—alcohol, hydriodic acid, hydrogen sulphide, sulphurous acid, hydrogen dioxide, nitrous acid, ferrous sulphate, etc. Ceric salts give a precipitate of ceric hydroxide when treated with ammonium hydroxide or sulphide, or an alkali hydroxide. Sodium or potassium carbonate gives a precipitate, almost insoluble in an excess of the reagent; with ammonium carbonate the precipitate dissolves in a large excess of the reagent, but is reprecipitated on boiling the soln. Lead carbonate precipitates ceric hydroxide; barium carbonate precipitates all the cerium from cold soln. Oxalic acid, ammonium oxalate, and tartaric acid reduce ceric to cerous salts—*q.v.* Ceric salts give a precipitate with potassium sulphate, but not with sodium or ammonium sulphate. Sodium acetate precipitates a basic acetate from a boiling soln. Sodium thiosulphate gives a precipitate of ceric hydroxide. Iodic acid precipitates ceric iodate sparingly soluble in nitric acid.

W. Gibbs[4] proposed the lead dioxide test for ceria in 1864. It is based on the more intense coloration exerted by ceric salts, when cerous salts are oxidized. A soln. of cerium sulphate with the eq. of 0·000025 grm. of ceria, when boiled with lead dioxide and nitric acid (1 : 2), gives a faint yellow colour under conditions where the untreated soln. gives no coloration. W. Gibbs later replaced lead dioxide by bismuth tetroxide, and detected 0·000017 grm. of ceria under similar conditions. W. N. Hartley claimed that 0·00001 grm. of ceria can be detected by the action of ammonium acetate and hydrogen dioxide, although L. de Boisbaudran, and P. T. Cleve found ammonium hydroxide and hydrogen dioxide is far more sensitive. P. C. Plugge added a drop of a soln. of one part of strychnine in 1000 of sulphuric acid to the dry mass obtained by evaporating an alkaline soln. He found that 0·0001 part of ceria gave a blue or violet tint which changed to a reddish colour; 0·00001 grm. of ceria gave a faint blue which rapidly faded. The strychnine test does not work if oxalic acid be present.

The uses of the cerium earths.—According to E. Stern,[5] in 1913, about 3300 tons of monazite were consumed annually in producing the 300 tons of thorium nitrate used in making incandescent mantles; about 315 million mantles were made in that year. About 100 tons of ceria were obtained as a by-product. Of this, about 3 tons were used in making gas mantles; 200 tons in making pyrophoric alloys; and 300 tons of cerium fluoride in impregnating arc-light carbons. C. R. Böhm has discussed the applications of the rare earths in his *Die Verwendung der seltenen Erden* (Leipzig, 1913). For *gas mantles—vide* the uses of thorium. A mixture of 100 grms. of thorium nitrate; 0·8 to 0·1 grm. cerium nitrate; 0·2–0·5 grm. beryllium nitrate; and 0·10 to 0·25 grm. of magnesium nitrate is employed for impregnating the mantles. Mantles for high-press. gas may have 2·8 per cent. of ceria. For stamping the mantles before burning off, a soln. containing didymium nitrate is used. A little yttria earth, along with thoria and zirconia, is employed in making the filaments for Nernst's lamps. The pyrophoric alloys are used in the manufacture of modern automatic gas lighters, petrol lighters, cigarette lighters, for indicating the path of projectiles in the so-called tracer shells and tracer bullets, etc. Here, the "flint and steel" of our forefathers is revived; the steel is replaced by the so-called pyrophoric alloys. It has been known for a long time that metals other than steel give pyrophoric sparks when struck. Thus, G. Chesneau observed that sparks can be detached from uranium by friction with hard steel, and these sparks instantly ignite mixtures of methane and air, and alcohol, benzene, or light petroleum poured on cotton. The estimated temp. is over 1000°. The sparks detached from steel have not so high a temp. since they ignite none of these gases and vapours. The term **pyrophoric alloy** is applied to those brittle metals or alloys which, when struck with hard steel, furnish a shower of small particles which are heated sufficiently to allow them to ignite. The cerium family of metals also gives sparks, but the metals are too soft to be useful. C. A. von Welsbach found that cerium, or mischmetall, when alloyed with iron, cobalt, or nickel, becomes brittle enough to enable the alloys to be employed for the purpose. The alloy with 35 per cent. of iron and 65 per cent. of mischmetall is called *auer-metal*. Numerous other alloys with cerium or mischmetall have been patented. The so-called *kunheim-metal* was patented by H. Kunheim. It contains hydrides of some of these metals. Its composition approximates: mischmetall, 85 per cent.; magnesium, 10; aluminium, 1·0; iron, 0·5; hydrogen, 1·3; and silicon, 0·5. H. Kunheim patented alloys with particles of carborundum, boron, silicon, metals, oxides, peroxides, salts, phosphorus, sulphur, arsenic, and antimony. H. Kellermann, R. Grimshaw, R. Kremann and co-workers, J. F. G. Hicks, B. Simmersbach, J. Camillo, and G. Olsen have described many others. H. Beck found that alloys of mercury with mischmetall or cerium can be made to ignite spontaneously in air and then give off bright sparks, provided the amalgam is mixed with an oxidizing agent such as a chlorate. B. Simmersbach has reviewed the history of the cerium-alloy industry. A. Hirsch suggested the use of magnesium-cerium alloys as flash-light powders. G. Senftner proposed utilizing the pyrophoric alloys as arc-lamp electrodes either mixed with the carbon, or alone. The incorporation of salts of cerium, particularly the fluoride, in carbons used for arc-lamp electrodes, has been patented. C. W. von Siemens used cerium, lanthanum, and didymium tungstates or molybdates. It is claimed that the arc then gives a more intense light, and burns easily and quietly. The use of cerium fluotitanate was patented by the General Electric Co. Cerium nitride and carbide have been tried as a filament for incandescent electric lamps by the General Electric Co.—but with no commercial success.

Glasses for railway carriages in hot countries have been mixed with a little nickel and manganese oxides with the idea of cutting off the heat rays of the sun without interfering appreciably with the transparency to luminous rays. W. Crookes suggested introducing ceria with the same object, and for making glare-reducing spectacles, etc. O. Schott discusses the use of ceria for tinting glass yellow; and of didymia for making blue optical glass. W. Muthmann and co-workers discuss the use of neodymium phosphate for producing an amethyst-red porcelain colour; and of praseodymium phosphate for producing a bright green—mixtures produce intermediate tints. Cerium titanate produces a bright yellow colour; cerium molybdate, a bright blue; cerium tungstate, a bluish-green; cerium manganititanate, an orange-yellow; and neodymium tungstate, a bluish-red. R. Rickmann and E. Rappe discussed the use of cerium dioxide as a yellow opacifying agent for glass and enamel. O. N. Witt, G. Matschak, C. Baskerville and T. B. Foust, and R. Gnehm discuss the use of cerium salts as a mordant in dyeing cotton, etc.; E. Stern, the weighting of silk; and F. Garelli, W. Eitner, and M. Parenzo, the dyeing and tanning of leather; and A. and L. Lumière, and A. Seyewetz and J. T. Gateau, in photography. There is a patent by C. A. von Welsbach for the use of cerium sulphate for accumulators, and W. Krilitschewsky found that such accumulators had some advantages over those made of lead. W. Plüddemann, and V. Hölbling and H. Ditz discuss the use of cerium earths as catalysts in the oxidation of sulphur dioxide to sulphur trioxide—but the suggestion does not appear to be of any industrial use; and H. Ditz and B. M. Margosches, the production of chlorine by passing a mixture of hydrogen chloride and air over cerium chlorides heated to 350°–480°. H. Kunheim and N. Whitehouse found that cerium hydride and nitride serve as catalysts in the union of hydrogen and nitrogen to form ammonia, but the catalyst does not retain its activity very long. J. Bekk, and M. Reimer tried cerium dioxide in place of platinum as catalyst for rapid organic combustions. K. Kruis, H. Bührig, and O. N. Witt discuss the use of alkali cerium sulphates as catalysts in the production of aniline black by the action of alkali chlorate or chromate on aniline. While alloys of the cerium earth metals are very strong reducing agents and reduce columbium, tantalum, zirconium, cobalt, nickel, chromium, manganese, vanadium, tungsten, uranium, boron, silicon, etc., from their oxides on a small scale. Acid soln. of ceric salts are strong oxidizing agents, and A. Meister and co-workers claim that they are more efficient than chromates for the production of aldehydes and quinones from aromatic hydrocarbons.

Cerium salts are used to a very limited extent in therapeutics. Like bismuth, they act as a sedative. Mixed cerium earth oxalates in small doses have been recommended to prevent nausea in cases of stomach catarrh, pregnancy-sickness, mal de mer, etc.; didymium salicylate is sold under the trade-name *dymal* as a non-irritant antiseptic dressing for wounds; double ceric sulphates have been sold under the trade-name *ceriform* for the same purpose. E. Schering recommended cerium phenolate as a less toxic disinfectant than phenol, but with the same efficiency. The chlorides of the rare earths are said to act like ferric chloride in stopping bleeding; and proposals have been made to use cerous bromide in place of alkali bromides.

§ 11. The Valency of the Rare Earth Metals, and their Position in the Periodic System

At the beginning of the nineteenth century, J. J. Berzelius[1] regarded ceria and yttria as dioxides, assigning to them the formulæ respectively CeO_2 and YO_2 ; and he gave ceric oxide the formula CeO_3. Influenced by the applications of P. L. Dulong and A. P. Petit's rule, and the law of isomorphism, J. J. Berzelius admitted the existence of sesquioxides, and in 1826, he altered the formulæ of ceria and yttria to CeO and YO respectively, and that of ceric oxide to Ce_2O_3. Up to 1870, the formulæ of the rare earths, lanthana, didymia, yttria, erbia, and terbia were written RO because their strong basic characters were considered to be analogous with those of the alkaline earths. Ceria was given the formula Ce_3O_4, and H. Zschiesche supposed it to be a mixture of the oxides CeO and CeO_2 analogous with red-lead. This explanation could neither be proved nor disproved with the then state of knowledge of the ceric salts. In 1870, D. I. Mendeléeff proposed to change the fashionable formulæ of the rare earth oxides into the sesquioxide form R_2O_3; with the R-element tervalent, cerous oxide was also taken to be a sesquioxide, Ce_2O_3, of tervalent cerium, and ceric oxide, a dioxide, CeO_2, of quadrivalent cerium. P. T. Cleve, and S. Jolin supported D. I. Mendeléeff's suggestion for yttria, erbia, didymia, and ceria(ous), but they thought lanthana to be different, forming not La_2O_3 but LaO_2. L. F. Nilson's work on the selenites and chloroplatinates further strengthened the idea that the rare earths, lanthana included, are sesquioxides. In 1873, C. F. Rammelsberg raised some objections to D. I. Mendeléeff's hypothesis, but he accepted it three years later.

The rare earths have been likened to alumina, but the feeble basicity of aluminium hydroxide, coupled with its tendency to form basic salts, and the tendency of aluminium to form complex compounds with organic acids, are the reverse of those properties which characterize the rare earths. The highly basic properties of these earths appear to hinder the formation of complex derivatives; a like contrast occurs with cupric and barium salts. C. Winkler argued in favour of the assumption that these elements are quadrivalent, but B. Brauner showed that the hypothesis is inadequate. From his measurements of the sp. ht. of cerous and didymium tungstates, A. Cossa concluded that the rare earth elements are bivalent, G. Wyrouboff and A. Verneuil decline to accept the arguments based upon sp. ht., isomorphism, and the periodic law, and state that there is a close relationship between the chemical properties of the rare earth elements and the bivalent metals; but G. Urbain has shown that if this plan be rigidly followed, the rare earths can just as well be classed with tervalent bismuth. P. T. Cleve and M. Höglund showed that D. I. Mendeléeff's assumption furnishes simpler formulæ for the complex salts of yttrium and erbium than when the rare earth metals are assumed to be bivalent. For example, $3YSO_4.8H_2O$ becomes $Y_2(SO_4)_3.8H_2O$; $Y_3H_2(C_4H_4O_6)_4.6H_2O$ becomes $YH(C_4H_4O_6)_4.6H_2O$; etc. The ammino-chlorides also give simpler formulæ with a triadic than with a dyadic base. The chloroplatinates of the uni- and bivalent metals are built on the type $2KCl.PtCl_4$, and $MgCl_2.PtCl_4$, while the salts of the rare earths are built on the type $RCl_3.PtCl_4.nH_2O$. The corresponding salts of yttrium and indium are anomalous in that the former has the composition $4YCl_3.5PtCl_4.52H_2O$, and the latter, $2InCl_3.5PtCl_4.36H_2O$. P. T. Cleve found that the chloroplatinites and the selenites also agree better with the rare earths tervalent.

No volatile compounds of the rare earths have been prepared which allow the vapour density to be determined. Tervalent scandium does furnish compounds which can be volatilized without decomposition, and, in view of the very close relationship between scandium and the rare earths, it is inferred that the rare earth metals are tervalent. This is confirmed by mol. wt. determinations of the rare earths in soln. W. Muthmann, and B. Brauner showed that the raising of the b.p. of alcohol by anhydrous cerium, lanthanum, praseodymium, neodymium, and yttrium is in accord with the tervalency of these elements RCl_3, although, as C. A. Matignon has shown, these chlorides form complexes with the solvent. C. A. Matignon found the f.p. of aq. soln. neodymium, samarium, and ytterbium chlorides. The results are in accord with the tervalency of these elements when compared with F. M. Raoult's values for aluminium and chromium chlorides which are admittedly tervalent. Thus, the mol. depression of the f.p.:

$NdCl_3$	$SaCl_3$	$YbCl$	$AlCl_3$	$CrCl_3$
68·0	65·6	66·0	64·5	64·0

W. Biltz found that the f.p. of soln. of acetylacetonates of cerium and didymium in carbon tetrachloride; of praseodymium and samarium in carbon disulphide; and of neodymium in ethyl sulphide, are in accord with the view that in conc. soln., these compounds are present in doubled molecules $[R\{(CH_3.CO)_2CH_3\}_3]_2$, which break down on dilution. The electrical conductivities of lanthanum and yttrium chlorides by H. Ley; of cerium, praseodymium, neodymium, and samarium chlorides, and of lanthanum, cerium, and samarium sulphates by A. Aufrecht; of lanthanum nitrate by W. Muthmann; and of lanthanum, cerium, praseodymium, neodymium, samarium, gadolinium, yttrium, erbium, and ytterbium sulphates by B. Brauner, are in accord with the tervalency of the rare earth elements when tested by W. Ostwald's rule—**1**. 15, 13.

The sp. ht. of cerium, lanthanum, and didymium, measured by W. F. Hillebrand, *favour the view that these elements are tervalent; similarly also does L. F. Nilson* and O. Pettersson's work on the mol. ht. of the oxides and sulphates of aluminium, scandium, gallium, indium, and the metals of the rare earths; but, as indicated above, A. Cossa's work on the sp. ht. of the silicotungstates does rather favour the bivalency of these elements. The evidence from the isomorphism of the compounds of the rare earths is conflicting in that some favour the assumption that the earths are bivalent, and some that they are tervalent. It must also be added that G. Wyrouboff found that silicotungstates of cerium, lanthanum, and didymium are isomorphous with the corresponding salts of thorium, a quadrivalent element. The same evidence would favour the assumption that univalent lithium is bivalent. This shows that the nature of the basic element in the silicotungstates has but a minor influence on the crystalline form. Many of the salts of the rare earths are isomorphous with one another so that arguments which apply to the one apply to all. The value of the evidence from isomorphism is usually feeble since, as T. V. Barker has emphasized, there are cases of apparent isomorphism among unrelated salts.

(i) *Isomorphism with salts of bivalent elements.*—M. Delafontaine found that cadmium, didymium, and yttrium sulphates are isomorphous and crystallize like salts of the magnesium series of metal sulphates. T. Vogt showed that isomorphous mixtures of the fluorides of the alkaline earths and the rare earths occur in many minerals—yttrocerite, yttrofluorite, parisite, cordylite, etc.; A. Cossa and M. Zecchini, P. Didier, and A. Högbom showed that cerous and didymium tungstates and molybdates form mixed crystals with calcium tungstate and lead molybdate; and G. Wyrouboff showed that the silicotungstates of the alkaline earths form mixed crystals with the corresponding salts of cerium, lanthanum, and didymium.

(ii) *Isomorphism with salts of tervalent elements.*—G. Bodman has shown that the stable pentahydrated bismuth nitrate, $Bi(NO_3)_3.5H_2O$, is isomorphous with the labile pentahydrates of lanthanum and didymium; and labile hexahydrated bismuth nitrate, $Bi(NO_3)_3.6H_2O$, is isomorphous with the stable hexahydrates of the same two elements. G. Urbain, J. Blumenfeld, and H. Lacombe also showed that the yttria and terbia earths form mixed crystals with pentahydrated bismuth nitrate; that ammonium bismuth nitrate, $Bi(NO_3)_3.2NH_4NO_3.4H_2O$, is isomorphous with the lanthanum salt, $La(NO_3)_3.2NH_4NO_3.4H_2O$, and that the double salts of the type $2Bi(NO_3)_3.3M(NO_3)_2.24H_2O$, are isomorphous with the corresponding salts of cerium, lanthanum, praseodymium, neodymium, samarium, europium, and gadolinium, when M represents an atom of bivalent magnesium, manganese, zinc, nickel, or cobalt. G. Bodman also found that pentahydrated, octohydrated, and enneahydrated bismuth sulphates are isomorphous with the corresponding hydrated sulphates of the rare earths. P. T. Cleve, and L. F. Nilson found that yttrium selenite and chloroplatinate are isomorphous with the corresponding salts of tervalent chromium, aluminium, indium, and iron.

L. Benoist and H. Copaux found that cerium fits well into the curve where the at. wt. is plotted against the transparency to the X-rays on the assumption that in cerous salts cerium is tervalent. Similarly also the order of increasing at. number is nearly the same as that of increasing at. wt., and H. G. J. Moseley has shown that when the at. number is plotted with the sq. root of the frequency, the rare earth metals, with the exception of yttrium, come between barium and tantalum in accord with the tervalency of these elements. H. Freundlich and H. Schucht found that the action of salts of the rare earths on colloidal arsenic sulphide resembled that of salts of other tervalent metals.

At the time D. I. Mendeléeff published the periodic law,[2] the problem was to find places in the periodic table for the elements; at the present day fifteen vacant places in the table want filling. D. I. Mendeléeff was quite definite about the position of cerium; he placed it after tin in the fourth group and eighth series, and showed

that this element was then in conformity with the sp. ht. rule. He was also satisfied with the position of yttrium between gallium and indium in the third group, and sixth series, but rather doubtful about erbium, didymium, and lanthanum, which he placed :

Series	Groups II.		III.		IV.		V.	
4	Ca		(Sc)		Ti		V	
5		Zn		Ga		Ge		As
6	Sr		Y		Zr		Cb	
7		Cd		In		Sn		Sb
8	Ba		Di		Ce		—	
9		—		—		—		—
10	—		Er		La		Ta	

D. I. Mendeléeff was of the general opinion that we are too ignorant of the rare earths to justify the attempt to instal them in the table. D. I. Mendeléeff's erbium and didymium were afterwards shown to be complex, and with increasing knowledge lanthanum was assigned to the place occupied by didymium. The allocation of places in the table for the fifteen or sixteen rare earth elements has not been successfully accomplished, whether these elements be regarded as dyads or triads. The assumption that these elements are dyads leaves the table in a hopeless position; there is no suitable place for many members of the series—*e.g.* yttrium—and there are three candidates for one vacancy between molybdenum and ruthenium. If these elements be triads, yttrium falls in the place indicated above, the space between molybdenum remains vacant, and there are fourteen candidates for the vacant places between barium and tantalum. On the other hand, if these vacant places be filled by the elements ranged in the order of their at. wt. the majority occupy positions not in accord with their properties. Cerium remains in the position assigned to it by D. I. Mendeléeff; and this harmonizes with the properties of ceric compounds, and with their relations with titanium, zirconium, and thorium—*q.v.* Scandium, yttrium, and lanthanum then form a sub-group of the third group. At one time, B. Brauner considered that the rare earths from cerium to ytterbium form a zone of elements in the fourth group, so that Ce in the above scheme is replaced by ΣCe, where

$$\Sigma\mathrm{Ce} = \left\{\begin{array}{llll} \mathrm{Ce}, & \mathrm{Pr}, & \mathrm{Nd}, & - \\ -, & \mathrm{Sa}, & \mathrm{Eu}, & - \\ -, & \mathrm{Gd}, & -, & - \\ \mathrm{Tb}, & \mathrm{Ho}, & \mathrm{Er}, & - \\ \mathrm{Tm}, & \mathrm{Yb}, & -, & - \end{array}\right.$$

and the nine empty spaces of the ninth series of the table disappear. This forms the so-called **asteroid theory of the rare earths.** The scheme also assumes that there are nine undiscovered elements—*vide* **1.** 6, 6. C. Benedicks emphasized the slow change in the at. vol. of the rare earth elements in passing from lanthanum to ytterbium, and he assembled them all in the third and fourth groups of the periodic table, and, like B. Brauner, he omitted the ninth series. J. W. Retgers places lanthanum, cerium, didymium, samarium, erbium, and ytterbium in the eight series of the third group. G. Rudorf placed the rare earths in a special group.

R. J. Meyer believes that cerium should remain in the place assigned to it by D. I. Mendeléeff, and he instals the other elements as an assemblage in the place assigned to lanthanum. Cerium thus falls out of the atomic order. R. J. Meyer then arranges the rare earth elements in the form of three sub-groups, with five elements each, two of which have not yet been found.

Group III.		
(i)	(ii)	(iii)
La	Gd	Tm
Pr	Tb	—
Nd	Dy	—
Sa	Ho	Yb
Eu	Er	Lu

These sub-groups form a kind of minor periodic system—***ein periodisches System in kleinen.*** Several others support the view that the rare earths have no suitable place in any of the groups of the periodic table. L. Meyer's at. vol. curve—Fig. 4, Cap. VI—has five crests and four troughs, and then breaks off at barium, and continues on again from tantalum, forming one more crest. E. Baur is of the opinion that the hiatus does not correspond with another crest, but rather forms a zig-zag line, Fig. 16, commencing at lanthanum, and after reaching lutecium, drops down to tantalum. Hence, added E. Baur, lanthanum belongs to the 8th series of the third group, cerium to the 8th series of the fourth group, and the remainder belong to no group, and are best introduced in the table in the 8th series as an intermediate assemblage between the third and fourth groups.

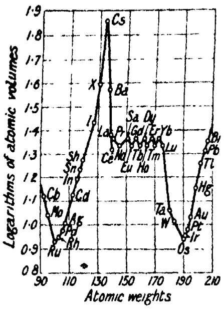

FIG. 16.—Portion of Atomic Volume Curve.

IV.		Rare Earth Group.	V.	
Zr				Cb
	Sn		Sb	
Ce		Pr Sa Gd Dy Er Yb Nd Eu Tb Ho Tm Lu		Ta
	Pb		Bi	

S. Meyer adopted a somewhat similar arrangement, including lanthanum and cerium in the same group. These proposals interrupt the continuity of the periodic table, and many geometrical arrangements have been suggested in which the discontinuity is more or less camouflaged.

Following B. de Chancourtois' *vis tellurique*—telluric screw—D. I. Mendeléeff said that the at. wt. of the elements could be ordered on one single spiral; and modifications have been suggested by J. E. Reynolds, W. Crookes, H. Baumhauer, E. Huth, C. Renz, F. Soddy, W. D. Harkins, C. R. Nodder, J. R. Partington, L. B. Tansley, I. W. D. Hackh, etc. In R. Vogel's modification, the elements are arranged as an ascending spiral in the order of their atomic numbers. Each turn of the spiral accommodates one short period of eight elements; and elements of the same group lie vertically above one another. He arranges subsidiary loops for the elements of the eighth group, and also for the rare earths. With the latter, the spiral, after passing barium, makes a complete turn, resuming the original path at tantalum. The sixteen rare earth elements are crowded on the subsidiary loop in such a way that lanthanum and cerium lie close to the vertical lines corresponding with the third and fourth groups, as illustrated by Fig. 17.

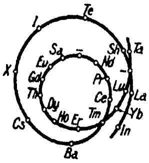

FIG. 17.—R. Vogel's Subsidiary Loop for the Rare Earth Elements.

Analogies between the rare earth elements and those of the eighth group of the periodic table, have been emphasized. J. E. Reynolds, for example, placed didymium and samarium in the eighth group. According to B. D. Steele, (i) the members of the different families iron, cobalt, and nickel; ruthenium, rhodium, and palladium; osmium, iridium, and platinum; and the rare earth family, are unusually difficult to separate from one another. (ii) The at. vols. of all these families are unusually small; and (iii), these elements are more strongly paramagnetic than is the case with other elements. Following the ideas of T. Bayley—1. 6, 3—and J. Thomsen, and ignoring the inert gases, the elements are arranged with two series each with seven members; and two series each with seventeen members. The three central members of each of the long series form a kind of interperiodic group. I. W. D. Hackh, I. D. Margary, and A. Werner have modified the idea, and arranged the elements with the rare earth metals as an intermediate group between barium and tantalum. B. Brauner in 1908 revived and modified a suggestion he made twenty-seven years earlier, by allocating the rare earths to various positions in the eighth, ninth, and tenth series of the third to the eighth groups:

Groups	.	II.	III.	IV.	V.	VI.	VII.	VIII.
Series	6	Sr	Y	Zr	Cb	Mo	—	Ra, Rh, Pd
	7	Cd	In	Sn	Sb	Te	I	
	8	Ba	La	Ce	Pr	Nd	Sa	Eu, —, —
	9	—	Gd	Tb	Dy	Ho	Er	Tm, Yb, —
	10	—	Lu	Hf	Ta	W	—	Os, Ir, Pt

As the at. wt. of the elements of the eighth series increase, there is a decrease in basicity and in the tendency to form complexes; while those in the ninth series increase in the tendency to form complexes, but decrease in basicity as the at. wt. increases. B. Brauner assigned the positions from the valencies of the elements deduced from the hydrides:

I.	II.	III.	IV.	V.	VI.	VII.	VIII.
CsH	BaH_2	LaH_3	CeH_4	PrH_3	NdH_2	(SaH)	(EuH_0)

He also said that some of the rare earth elements can form higher oxides than the sesquioxide in the presence of oxygen carriers.

The general result of this discussion is to show that scandium, yttrium, lanthanum, and cerium fit very well into the periodic table, but when the remaining rare earths are installed, the simplicity and regularity of the scheme are destroyed. The discontinuity may be masked, but it cannot be removed by the use of geometrical devices—spirals, helices, lemniscates, etc. If the rare earth elements be allocated in the order of their at. wt. in the twenty spaces in the periodic table between barium and tantalum, then it can no longer be said that the properties of the elements are periodic functions of their at. wt., Table XII, and the periodic law breaks down.

TABLE XII.—ALLOCATION OF THE RARE EARTHS IN D. I. MENDELÉEFF'S TABLE.

Groups	.	I.	II.	III.	IV.	V.	VI.	VII.	VIII.
Series	6	Rb	Sr	Y	Zr	Cb	Mo	—	Ru, Rh, Pd
	7	Ag	Cd	In	Sn	Sb	Te	I	
	8	Cs	Ba	**La**	**Ce**	**Pr**	**Nd**		
	9	**Sa**	**Eu**	**Gd**	**Tb**	**Dy**	**Ho**	**Er**	
	10	**Tm**	**Yb**	**Lu**	Hf	Ta	W		Os, Ir, Pt

In 1885, J. R. Rydberg introduced the use of integers in place of at. wt. since he thought the latter is not a simple quality, but has a complex nature, whereas the integers may be considered to represent a true independent variable. As with H. G. J. Moseley's at. numbers, the order chosen for J. R. Rydberg's at. numbers is that of increasing at. wt. except with four pairs of elements—argon and potassium, nickel and cobalt, iodine and tellurium, and praseodymium and neodymium. He rejected D. I. Mendeléeff's classification claiming that the system of elements does not consist of periods in the ordinary sense, but rather embodies quadratic groups, each group containing 4, 16, 36, or 64, *i.e.* $4p^2$ elements, where p is the number of the group, so that $p=1, 2, 3,$ or 4. Each element in J. R. Rydberg's Table is identified by an integral number which is two units above that chosen by H. G. J. Moseley as the atomic number, N—4. 25, 6. This is because the latter started his series with H, 1; He, 2,..., whereas J. R. Rydberg's first group with $p=1$, commencing with the hypothetical electron gas E, 0, runs on H, 1; then follow two hypothetical elements numbered 2 and 3, and the group ends with He, 4. It is suggested that the gases named *coronium* and *nebulium*, which have been revealed by the solar spectrum represent the unknowns in J. R. Rydberg's first group. This makes nebulium, 2, and coronium 3. The second group, $p=2$, contains the 16 elements from helium

TABLE XIII.—J. R. RYDBERG'S CLASSIFICATION OF THE ELEMENTS.

Valency.	0	1	2	3	4	5	6	7	8	
	E (0)									
		H (1)								
Group 1	— (2)									
		— (3)								
	He (4)

to argon; the third group, $p=3$, contains the 36 elements ranging from argon to xenon; and the fourth group, $p=4$, with 64 elements, ranges from xenon to uranium. Both Tables XII and XIII are in harmony with H. G. J. Moseley's work on the high frequency spectra of the elements—**3.** 25, 6—according to which, the sequence of the atomic numbers of the rare earths is as indicated in both tables—remembering that *J. R. Rydberg's atomic numbers* are two units higher than those of H. G. J. Moseley. When the at. numbers, N, are plotted against the sq. roots of the frequencies, the points lie on a series of smoothed curves approximating to straight lines. This fact is not likely to be chance, and it is accordingly assumed that the order of the atomic numbers is the outward symbol of a hidden mechanism of fundamental importance. With respect to the rare earths, H. G. J. Moseley's law indicates that an element with an at. wt. between that of neodymium and samarium awaits discovery, and four elements—presumably thulium, ytterbium, lutecium, and celtium—come between erbium and tantalum; terbium and holmium are not complexes, but are chemical individuals; nor is thulium likely to be a mixture of three elements as C. A. von Welsbach argued. Hence, in the ordinary sense of the term, only one rare earth element is missing from H. G. J. Moseley's and J. R. Rydberg's series. The arrangement cannot be reconciled with the general chemical and physical characters of the rare earth elements; but it agrees with the observations of W. M. Hicks: *viz.* (i) The line spectra of cadmium, europium, and mercury exhibit triplet series of the sharp and diffuse type; where the triplet intervals are approximately proportional to the squares of the at. wts.; (ii) gadolinium exhibits doublet series similar to those of aluminium, gallium, and titanium; and (iii), scandium, yttrium, lanthanum, and ytterbium also show doublet series.

In passing from hydrogen to uranium, the majority of the elements show conspicuous differences in their chemical properties, but there is an interruption in the normal sequence, for one group of elements suddenly appears whose members are so closely related chemically that their separation offers special difficulties. N. Bohr[3] showed that the nucleus theory of the atom, and the quantum theory of radiation offer a rational interpretation of the interruptions in the normal sequence of the elements by the rare earth groups. What can be called the atom's chemical properties are determined by the number and the arrangement of the electrons of the atom, but chiefly by the number and arrangement in the outermost group of electrons. When proceeding from hydrogen to uranium there are, in general, appreciable differences in the outermost group of electrons of two neighbour elements, hence the marked difference in the chemical behaviour of these elements. Furthermore, N. Bohr assumed that at a certain place in the periodic table a group of elements is encountered whose members show differences only in the constitution of the deeper lying electron groups of their atoms. Differences in the inner groups correspond with only small differences in the chemical behaviour, hence the great similarity in chemical behaviour of the group of the rare earth elements. According to N. Bohr's theory, the successive change in the inner groups of electrons occurs in the interval between lanthanum, at. wt. 57, and lutecium, at. wt. 71. He said: In the rare-earth elements there is a gradual development of the group 4-quantum electrons from a group containing 18 electrons into a group of 32 electrons, the numbers in the groups 5- and 6-quantum electrons remaining unchanged. In lutecium, the group of 4-quantum electrons is complete, and in the neutral atom of the next element hafnium, the number of electrons moving in 5- and 6-quantum orbits must exceed that of the rare earths by one. Lutecium must therefore be the last in the sequence. C. R. Bury expressed the same idea another way. He said that in general, succeeding elements differ by one electron in the outer shell, but in the rare earths, succeeding elements differ by one electron in an inner shell—probably the fourth of their kernels. Further, these elements do not show the variety of structure characteristic of other series, although some of these elements show signs of having more than one structure. Among a number of possibilities, he suggested the following electronic structures for the rare earth elements :

At. No.			At. No.		
58	Ce	(2, 8, 18, **18**, 8, 4)	65	Tb	(2, 8, 18, **26**, 8, 3)
59	Pr	(2, 8, 18, **19**, 8, 4)	66	Ds	(2, 8, 18, **27**, 8, 3)
60	Nd	(2, 8, 18, **21**, 8, 3)	67	Ho	(2, 8, 18, **28**, 8, 3)
61	...	(2, 8, 18, **22**, 8, 3)	68	Er	(2, 8, 18, **29**, 8, 3)
62	Sa	(2, 8, 18, **23**, 8, 3)	69	Tm	(2, 8, 18, **30**, 8, 3)
63	Eu	(2, 8, 18, **24**, 8, 3)	70	Yb	(2, 8, 18, **31**, 8, 3)
64	Gd	(2, 8, 18, **25**, 8, 3)	71	Lu	(2, 8, 18, **32**, 8, 3)

H. G. J. Moseley's[4] arrangement of the at. numbers of the elements shows that a rare earth is missing for No. 61. J. M. Eder postulated the existence of *euro-samarium* from spectroscopic data. C. C. Kiess found lines common to neodymium and samarium, and suggested they may belong to the missing element. L. F. Yntema examined the monazite and gadolinite earths by X-ray analysis and spectroscopically, and considered it probable that an element of this number may be present in the fraction containing neodymium and samarium.

§ 12. The Atomic Weights of the Cerium Family of Metals

The earlier determinations of the at. wt. of cerium must have been made on ceria contaminated with other earths, since later observations have shown that unknown and unsuspected rare earths accompany the raw materials, and these could not have been all removed by the methods of purification employed. In 1868, C. Wolf[1] showed reasons for suspecting the homogeneity or the chemical individuality of ordinary cerium, but he died before completing his work. B. Brauner, in 1885, suspected that cerium may be a mixture, and he claimed that (i) by the fractional soln. of ceria in sulphuric acid; (ii) by the extraction of partially reduced ceric oxide; (iii) by fractional precipitation with oxalic acid; (iv) by fractional crystallization of the sulphate; (v) by fractional crystallization of ceric ammonium nitrate or of cerous ammonium nitrate; and by the fractionation of basic nitrate or sulphate, ceria can be separated into two forms, one of which is insoluble in cold hydrochloric acid, and the other dissolves in hydrochloric acid. The one form gives a white oxide, and the other a dark salmon-coloured oxide of an element which he designated *metacerium*. The spark spectra of both forms had some lines in common, whereas other lines are characteristic of each. P. Schützenberger also claimed to have separated cerium by the basic nitrate process into (i) *cerium*-1, which gave a white oxide with an at. wt. 139·5; and (ii) *cerium*-2, with an oxide-coloured rouge, *rosé ou brun rose clair;* and, in conjunction with O. Boudouard, they declared that cerium from cerite is different from that from monazite. G. Wyrouboff and A. Verneuil showed that the methods employed by P. Schützenberger and O. Boudouard were not sufficient to separate ceria from thoria and the yttria earths; and that cerium from cerite and monazite is the same element. G. P. Drossbach failed to confirm B. Brauner's results, and in 1906, the last-named said that his metacerium was mainly terbium. It is, therefore, inferred that when adequately purified by known methods cerium is a homogeneous individual.

In 1882, B. Brauner[2] claimed to have obtained from lanthana an earth with an at. wt. and basicity intermediate between lanthana and didymia; and P. T. Cleve obtained an analogous earth which he named provisionally β-Di; but later found that the spark spectrum agreed with that of lanthana when an incorrect measurement of one of the lanthanum spectral lines by R. Thalén was rectified. He then expressed the opinion that there is no intermediate between lanthanum and didymium. P. Schützenberger likewise claimed to have resolved lanthana, but B. Brauner and F. Pavlicek claimed that he had not eliminated yttria from his lanthana; the last-named also confirmed the previous work of B. Brauner on the existence of an intermediate element which imparts to lanthana a pale buff tint. This inference has not been confirmed, and it meets with no support from H. G. J. Moseley's[3] observations on the high-frequency spectra.

The homogeneity of praseodymium, neodymium, and samarium has been denied by G. Krüss and L. F. Nilson, W. Crookes, H. Becquerel, A. Bettendorff, C. M. Thompson, L. M. Dennis and E. M. Chamot, C. R. Böhm, C. Baskerville and co-workers, and B. Brauner. In most cases the opinions have been founded on the absorption spectra. The high-frequency or X-ray spectra are in accord with the assumption that an earth remains to be discovered, and its at. wt. lies between those of neodymium (144·3) and samarium (150·4), but no clear evidence of the nature of the alleged companion elements has been adduced. E. Demarçay failed to find any difference in neodymia derived from cerite, samarskite, and mosandrite by different methods of fractionation; and no difference could be detected in neodymia after repeated fractionation; nor could he find any evidence of complexity after the repeated fractionation of samaria. It was therefore inferred that samarium and neodymium are homogeneous. This conclusion was confirmed by W. Muthmann and L. Weiss, W. Feit and C. Przibylla, C. A. von Welsbach, G. Eberhard, O. Holmberg, G. P. Baxter and H. C. Chapin, W. Rech, C. Baskerville and R. Stevenson, G. Urbain, and H. Lacombe. The homogeneity of praseodymium has been tested by C. von Scheele, C. A. von Welsbach, W. Muthmann and L. Weiss, W. Feit and C. Przibylla, W. Rech, G. P. Baxter and O. J. Stewart, and H. Lacombe, but there is no clear evidence of complexity, nor, indeed, of the existence of an element with an at. wt. intermediate between those of praseodymium and neodymium. The X-ray spectra fit with the assumption that the **atomic numbers** are La, 57; Ce, 58; Pr, 59; Nd, 60; Sa, 62, with an unknown element between neodymium and samarium.

Considering the designation rare element, a remarkable number of determinations of the at. wt. of some of these elements has been made. The unusual chemical and physical properties of these substances, and their relations to the periodic system, have been the magnet. The at. wt. of cerium has attracted more attention than that of a common element like iron; similarly also with the at wt. of lanthanum. Nevertheless, owing to the extraordinary difficulties attending the purification of the materials, and the difficulties attending the analytical operations, the degree of accuracy of the results is of a lower order than that of the common elements. J. J. Berzelius[4] in his at. wt. tables of 1814–18 gave 137·9 as the value of this constant for **cerium** on the assumption that the element is tervalent; W. Hisinger apparently made the determination. In 1840, F. J. Otto gave the value 138·91.

A. Beringer obtained 142·06 by converting the carbonate into chloride and 142·29 by analyzing the sulphate: $2CeO_2 : 3BaSO_4$. C. F. Rammelsberg obtained 135·59, and R. Bunsen and J. Jegel, 138·29, from the same ratio. R. Hermann obtained 138·52, and J. C. G. de Marignac, 142·05, from the ratio $Ce_2(SO_4)_3 : 3BaSO_4$; the last-named also obtained 142·43 from the ratio $Ce_2(SO_4)_3 : 3BaCl_2$; T. Kjerulf obtained 174·6 a worthless value—and C. F. Rammelsberg, 138·19 from the ratio $Ce_2(C_2O_4)_3 : 6CO_2$; and R. Bunsen and J. Jegel, 140·25, from the ratio $Ce_2(C_2O_4)_3 : 2CeO_2$.

It is not likely that results obtained prior to the discovery of lanthanum (1839) and didymium (1843) can have much value, since the ceria was virtually certain to have been contaminated with these elements. Not until about 1860 were the materials tested for the presence of foreign earths by spectrum analysis. Prior to that year, the ceria employed was of an uncertain degree of purity. From the ratio $Ce_2(SO_4)_3 : 2CeO_2$, C. Wolf computed the at. wt. 138·75; C. H. Wing (1870), 137·88; B. Brauner (1885), 140·22; G. Wyrouboff and A. Verneuil (1897), 139·52; G. Kölle (1898), 138·81; and B. Brauner and A. Batek, 140·21; B. Brauner (1885) obtained 140·24 from the ratio $Ce_2(SO_4)_3 : Ce_2O_3$. From the ratio $Ce_2(SO_4)_3.8H_2O : 8H_2O$, G. Wyrouboff and A. Verneuil (1897) obtained 139·21; and from the ratio $Ce_2(SO_4)_3.8H_2O : 2CeO_2$, 139·43; and from the same ratio, B. Brauner obtained 140·25. From the ratio $Ce_2(SO_4)_3 : 3BaSO_4$, P. Schützenberger obtained 139·45. From the ratio $Ce_2(C_2O_4)_3 : 2CeO_2$, H. Bührig obtained 141·43; and from the ratio $Ce_2(C_2O_4)_3 : 6CO_2$, 141·59. From the ratio $2CeO_2 : 3C_2O_3$ (*i.e.* loss on ignition of oxalate), B. Brauner obtained 140·01 in 1895, and 140·25 in 1903; while B. Brauner and A. Batek obtained 140·27. From the ratio $CeCl_3 : 3Ag$, H. Robinson (1884) obtained 140·19. B. Brauner computed 140·25 for the best representative value; and F. W. Clarke, 140·197 ± 0·0038. The International Table, 1920, gives 140·25.

The at. wt. of **lanthanum** was stated by its discoverer, C. G. Mosander,[5] to be 680 when oxygen is 100; *i.e.* 139·2 when oxygen is 16. This value is much nearer the mark than many later determinations. Determinations by M. Choubine (1842), C. F. Rammelsberg (1842), and R. Hermann (1843) gave values which were inaccurate because the lanthana must have been contaminated with didymia. From the ratio $La_2(SO_4)_3 : 3BaSO_4$,. J. C. G. de Marignac obtained 139·5 and 148·3; C. Czudnowicz, 133·0; C. Erk, 135·82. From the ratio $La_2(SO_4)_3 : 3BaCl_2$, J. C. G. de Marignac obtained 141·3. From the ratio $La_2O_3 : La_2(SO_4)_3$, M. Holzmann obtained 139·2; C. Czudnowicz, 146·5; R. Hermann, 139·50; H. Zschiesche, 135·33; C. Erk, 135·63; J. C. G. de Marignac, 138·80; P. T. Cleve, 139·27 and 138·34; B. Brauner, 138·86, 138·34, and 138·21; G. Bodmann, 138·94; O. Brill, 139·79; F. A. Bauer, 138·75; A. Bettendorff, 138·69; W. Gibbs, 139·70; P. Schützenberger, 138·0 and 135·0; B. Brauner and F. Pavlicek, 139·03; and H. C. Jones, 138·77 and 138·80. From the ratio $La_2O_3 : 3BaSO_4$, M. Holzmann obtained 139·46; from the ratio $La_2(IO_3)_6.3H_2O : La_2O_3$, 137·59; and from the ratio $La_2Mg_3(NO_3)_{12}.24H_2O : La_2O_3$, 138·68. From the ratio $LaCl_3 : 3AgCl$, R. Hermann obtained 139·25; G. P. Baxter and co-workers, 138·89; and B. S. Hopkins and F. S. Driggs, 138·91. R. Hermann obtained from the ratio $La_2O_3 : 3CO_2$, 139·36. From the ratio $La_2O_3 : 3C_2O_3$, W. Gibbs obtained 139·70, and H. C. Jones, 139·07. From the ratio $La_2O_3 : 3H_2SO_4$, W. Feit and C. Przibylla obtained 139·09. B. Brauner gives 139·0 for the best representative value; F. W. Clarke, 138·8. The International Atomic Weight Commission for 1921 gave 139·0.

The at. wt. of **didymium** determined by J. C. G. de Marignac[6] and others, lost interest when C. A. von Welsbach[7] demonstrated that it is compounded of praseodymium and neodymium of at. wt. approximately 143·6 and 140·8 respectively; more accurate determinations give more nearly 141 for the former, and 144 for the latter. It therefore appears as if C. A. von Welsbach had somehow got the labels of his materials crossed. B. Brauner calculated 141·09 for the at. wt. of **praseodymium** from the ratio $Pr_2(SO_4)_3.8H_2O : Pr_2O_3$; and from the ratio $Pr_2(SO_4)_3 : Pr_2O_3$, 140·95 and 140·96; H. C. Jones from the same ratio obtained 140·46, and C. von Scheele, 140·53. From the ratio $Pr_2O_3 : 3C_2O_3$, B. Brauner obtained 140·98, and C. von Scheele, from the ratios $Pr_2O_3 : 3C_2O_3 : Pr_2(SO_4)_3$, 139·72 to 140·15. W. Feit and C. Przibylla obtained 140·62 from the ratio $Pr_2O_3 : 3H_2SO_4$; and G. P. Baxter and O. J. Stewart, 140·93 from the ratio $PrCl_3 : 3AgCl$, and for the ratio $PrCl_3 : 3Ag$, 140·92. B. Brauner estimates the best representative value to be 140·97; and F. W. Clarke, 140·619 ± 0·0033. The International Atomic Weight Commission for 1920 gives 140·9.

For the at. wt. of **neodymium** B. Brauner obtained 143·63 and 143·89 from the ratio $Nd_2O_3 : Nd_2(SO_4)_3$; O. Boudouard, 143·05; H. C. Jones, 143·6; O. Holmberg, 144·10; O. Brill, 142·46; and C. A. von Welsbach, 144·54. W. Feit and C. Przibylla obtained 144·5 from the ratio $Nd_2O_3 : 3H_2SO_4$. G. P. Baxter and H. C. Chapin obtained 144·272 from the ratio $NdCl_3 : 3AgCl$, and 144·268 from the ratio $NdCl_3 : 3Ag$. G. P. Baxter and co-workers (1916) from the last-named ratio obtained 144·261. B. Brauner gave 143·9 for the best representative value; and F. W. Clarke, 143·910 ± 0·0051. The International Atomic Weight Commission for 1920 gives 144·3.

M. Delafontaine's[8] decipium, L. de Boisbaudran's **samarium,** and J. C. G. de Marignac's Y_β gave an at. wt. approximating to 159·171. The determinations by J. C. G. de Marignac, B. Brauner, P. T. Cleve, A. Bettendorff, and W. Muthmann and L. Weiss must have been made with impure material. It was not until 1900–1904 that E. Demarçay, and G. Urbain and H. Lacombe prepared material of a high degree of purity and free from europium; samaria prepared before that probably contained europium. Nevertheless, the earlier determinations do not differ very much from more recent values. From the ratio $Sa_2(SO_4)_3 : Sa_2O_3$, J. C. G. de Marignac obtained 149·4 and 149·87; B. Brauner, 150·7 and 150·66; P. T. Cleve, 150·15; A. Bettendorff, 150·44; W. Muthmann and L. Weiss, 151·39; E. Demarçay, 147·2–148·0; and G. Urbain and H. Lacombe, 150·53. From the ratio $Sa_2O_3 : Sa_2(SO_4)_3.8H_2O$, J. C. G. de Marignac obtained 150·01; B. Brauner, 150·76; and G. Urbain and H. Lacombe, 150·48. From the ratio $Sa_2(SO_4)_3.8H_2O : Sa_2(SO_4)_3$, the last-named obtained 150·31. From the ratio $Sa_2O_2(SO_4) : SaO(SO_4)_2$, C. Matignon obtained 150·6, and W. Feit and C. Przibylla, 150·56 from the ratio $Sa_2O_3 : 3H_2SO_4$. O. J. Stewart and C. James obtained 150·43 from the ratio $SaCl_3 : 3Ag$. A. W. Owens and co-workers found from the ratio $SaCl_3 : 3Ag$, an at. wt. 150·43, the range being 150·40 to 150·49. For the best representative value, B. Brauner gave 150·44; F. W. Clarke, 150·390 ±0·0071. The International Atomic Weight Commission for 1920 gave 150·4.

§ 13. The Oxides of the Cerium Family of Earths

Each of the rare earths forms a basic sesquioxide in which the metal is tervalent. The sesquioxides are all stable. and constitute the rare earths properly so called. The sesquioxides of the rare earth metals other than those of terbium, praseodymium, and cerium are stable in air, even at a bright red heat. The three rare earths just named pass into higher oxides when heated in air, and in the case of ceria, oxidation occurs at a comparatively low temp. In some cases higher oxides or hydroperoxides are formed by the action of hydrogen dioxide. According to C. Winkler,[1] there is no sign of the formation of *cerium monoxide*, CeO, when ceric oxide is reduced by magnesium. The ignition of the hydroxides, carbonates, nitrates, sulphates, oxalates, and of the salts of many other oxy-acids furnishes *lanthana*, or **lanthanum sesquioxide,** La_2O_3; *neodymia*, or **neodymium sesquioxide,** Nd_2O_3; and *samaria*, or **samarium sesquioxide,** Sa_2O_3. It is generally difficult—particularly with the lanthanum salt—to get rid of the last trace of sulphate by ignition. The sesquioxides of these elements were also formed by W. Muthmann and L. Weiss, etc., by the combustion of the metals. In the case of *praseodymia*, or **praseodymium sesquioxide,** Pr_2O_3, the higher oxide obtained by ignition is to be reduced to the sesquioxide by heating it in a stream of hydrogen at a red heat, say 900°. The preparation of cerium sesquioxide offers some difficulty because of the great stability of ceric oxide which is the product obtained by calcining the oxy-salts, etc., of cerium. The higher oxide of cerium is not reduced to the sesquioxide so readily as is the case with praseodymium dioxide; the reduction of the red-hot oxide by

---

hydrogen, as J. Sterba has shown, is incomplete at atm. press.; but, according to E. Newbery and J. N. Pring, *ceria*, or **cerium sesquioxide,** or **cerous oxide,** Ce_2O_3, can be obtained by reducing ceric oxide by heating it to 2000° in hydrogen at 150 atm. press. W. Guertler found ceric oxide is reduced to the sesquioxide by heating it white hot in the reducing atm. of a petroleum injector furnace. C. F. Rammelsberg said that it is obtained by calcining cerous carbonate in hydrogen free from ozone. If cerous oxalate be calcined in vacuo, or in a stream of hydrogen, a mixture of ceric and cerous oxides and carbon is obtained. C. G. Mosander, and A. Beringer said that cerous oxide is formed by calcining ceric oxide to a high temp. in a carbon crucible, or in a stream of hydrogen. This is doubtful, for, according to R. J. Meyer, P. Didier, and J. Sterba, when the hydroxide, carbonate, nitrate, or oxalate is heated in hydrogen or in the absence of air, the dark blue product has a composition approximating Ce_4O_7. L. M. Dennis and W. H. Magee say that a white cerous oxide can be obtained by calcining the hydroxide in an inert atm.; but later observations have shown that in the dehydration of the dried hydroxide, water is decomposed and the cerous oxide is oxidized. C. Winkler found that some cerous oxide is obtained when ceric oxide is heated with magnesium, or, according to J. Sterba, with zinc; it is, however, not practicable to separate the cerous oxide from the other products of the reaction. A. Burger obtained cerous oxide by reducing ceric oxide with an excess of calcium, and washing out the other products of the reaction with a soln. of ammonium chloride at −10°, or with a soln. of sugar at 0°.

Owing to the difficulty of removing didymia from ceria, and to the ignorance of the early workers as to the complexity of what they considered to be pure ceria, there are some conflicting statements as to the colour of cerous oxide. C. F. Rammelsberg said that it is a bluish-grey powder; A. Burger, yellowish-green; and O. Popp, and L. M. Dennis and W. H. Magee, white. Lanthana is white; praseodymia, yellowish-green or greenish-yellow; neodymia, sky-blue; and samaria, white with a faint yellow tinge. There are some differences of opinion as to the colour of neodymia described by C. A. von Welsbach as being blue; A. Wägner, sky-blue with a violet tint; B. Brauner, pink with an amethyst tint; W. Muthmann and L. Weiss greyish-blue without any yellow or brown tinge; E. Demarçay, violet; H. C. Jones, when hot, "a marked bluish colour, which, however, disappears on cooling"; C. Baskerville and R. Stevenson, brown, rose, black, and violet; and H. Lacombe, sky-blue. The varying statements, said A. Wägner, are probably due to the oxide under investigation having been in many cases contaminated with other rare earths, and particularly with praseodymia. E. T. Wherry attributed the reddish-violet colour of certain minerals to the presence of neodymium compounds. When ceria is exposed to air, oxygen is absorbed and the dioxide is formed, the product usually acquires a yellow tinge; praseodymia likewise absorbs oxygen, forming a brown powder which is probably a mixture of praseodymous and praseodymic oxides. Lanthana resembles quicklime in that it rapidly absorbs water and carbon dioxide when exposed to air; neodymia and samaria are not appreciably oxidized or carbonated on exposure to air. Ceria is unstable in air, forming the dioxide, and, according to A. Burger, even at 200°, it burns to the higher oxide. When praseodymia or neodymia is heated in air a mixture of the sesquioxide with more or less of the higher oxide (*q.v.*) is formed; while lanthana and samaria are not preceptibly peroxidized.

The sesquioxides prepared by the above-described processes are generally described as amorphous. According to A. E. Nordenskjöld, prismatic rhombic crystals of lanthana are obtained by heating the oxide with fused borax. The crystals are said to have a sp. gr. 5·296 at 16°; for the sp. gr. of amorphous lanthana, P. T. Cleve gave 6·53 at 17°; R. Hermann, 5·94; L. F. Nilson and O. Pettersson, 6·480; B. Brauner, 6·41 at 15°; and W. Prandtl, 6·51 at 15°/4°. For the old didymia, R. Hermann gave 6·64; A. E. Nordenskjöld, 5·825 (14°); P. T. Cleve, 7·180 at 13·5°; and L. F. Nilson and O. Pettersson, 6·950. For praseodymia,

C. von Scheele gave 6·88 at 15°; B. Brauner, 7·068; and W. Prandtl, 6·87 at 15°/4°. For samaria, P. T. Cleve gave 8·347 at 13°–15°; and W. Prandtl, 7·43 at 15°/4°. For neodymia, W. Prandtl gave 7·24 at 15°/4°. A. H. White and M. E. Müller demonstrated a loss of ceria by volatilization when thoria mantles with one per cent. of ceric oxide are heated. According to L. F. Nilson and O. Pettersson, the sp. ht. of lanthana is 0·0749, and of didymia, 0·0810 between 0° and 100°. E. Tiede and E. Birnbräuer say that lanthana melts and volatilizes at about 2000°. W. R. Mott gave 4200° for the b.p. of lanthanum oxide at 760 mm. W. Muthmann and L. Weiss' observations on the heats of formation have been described in connection with the metals. H. L. Howes found the cathode ray luminescence spectrum of samarium oxide has eight short series of constant frequency intervals, and the spectrum is unchanged by heat treatment between 600° and 3000°. E. L. Nichols and H. L. Howes studied the luminescent spectra of incandescent oxides of cerium, praseodymium, neodymium, and samarium. W. W. Coblentz found the ultra-red emission spectrum has maxima at 3μ, 4·4μ, and 4·83μ. The magnetic susceptibilities of the oxides have been determined by G. Urbain and G. Jantsch, R. J. Meyer and J. Wuorinen, and S. Meyer. These values are: lanthana, $-0·18\times10^{-6}$; neodymia, $+33·5\times10^{-6}$; samaria, $+6·5\times10^{-6}$ electromagnetic units; hence lanthana is diamagnetic and the other two oxides paramagnetic; praseodymia is also paramagnetic, but less so than neodymia. E. H. Williams measured the magnetic susceptibilities of the oxides of lanthanum, neodymium, and samarium between 20° and −140°, and found the value for samaria to be about 10 per cent. larger at −140° than at 20°. E. Wedekind and P. Hausknecht found the at. magnetism of lanthanum oxide to be $-18·3\times10^{-6}$; praseodymium oxide, $+4740\times10^{-6}$; neodymium oxide, $+5100\times10^{-6}$; and samarium oxide, $+8300\times10^{-6}$. They found that if the values for the at. magnetism of the metals of the rare earths be plotted against at. wt. a graph is obtained which shows a flat maximum at yttrium, and a second maximum in the cerite group, either at neodymium or samarium, according to the value adopted; the curve then descends to europium, and subsequently rises somewhat steeply but regularly through gadolinum and terbium to a high maximum at dysprosium, after which it falls steeply and evenly through holmium, erbium, ytterbium, to lutecium.

All the sesquioxides are soluble in acids, but, as in the case of alumina (*q.v.*), and many other oxides, the reactivity of the rare earth oxides depends upon the temp. of calcination; the higher the temp. of calcination the more slowly are the oxides attacked by acids. According to A. Damour, however, lanthana, even after intense ignition, is readily soluble. Like quicklime, lanthana hisses when sprinkled with water, and forms the hydroxide, but, according to A. E. Nordenskjöld, the crystals of lanthana are not affected by water. The rare earths are fairly strong basic oxides; C. A. Matignon said that they are stronger bases than magnesia, but weaker than the alkaline earths. The rare earths readily form normal salts even with weak acids like carbonic acid, chromic acid, and numerous organic acids. The basicity has been determined qualitatively. The relative order of precipitation from their salt soln. by ammonia and the alkali hydroxides has already been discussed. There are some reversals in the order of basicity when determined by different methods, thus, by ammonia precipitation, gadolina is a stronger base than samaria, but by some other methods the reverse obtains. When tested by the thermal value of the reactions: $R_2O_3+6HCl=2RCl_3+3H_2O+Q_1$ Cals., and by $R_2O_3+3H_2SO_4=R_2(SO_4)_3+3H_2O+Q_2$ Cals., C. A. Matignon found the order to be:

	La	Pr	Nd	Sa
Q_1	160·6	147·8	143·1	128·4
Q_2	138·2	125·7	125·1	113·8
Hydrolysis . . .	6·81	—	11·07	14·20

This order also agrees with S. H. Katz and C. James' observations on the degrees of hydrolysis of aq. soln. of the sulphates, expressed in arbitrary units.

L. Kahlenberg and W. J. Trautmann found cerous oxide, Ce_2O_3, is not reduced by silicon at the temp. of the electric arc furnace.

According to C. Baskerville and G. F. Catlett, when lanthana is fused with alkali carbonates, and washed with alcohol; or when lanthana is digested for a long time with soln. of the alkali hydroxides at 100°, **lanthanates**—*e.g.* sodium lanthanate, $Na_2La_4O_7$; and **metalanthanates**—*e.g. dihydrated lithium enneahydropentalanthanate,* $LiH_9La_5O_{15}.2H_2O$; *tetrahydrated sodium enneahydropentalanthanate,* $NaH_9La_5O_{15}.4H_2O$; *pentadecahydrated potassium enneahydropentalanthanate,* $KH_9La_5O_{15}.15H_2O$; *barium enneahydropentalanthanate,* $Ba(H_9La_5O_{15})_2$, but not the calcium compound —are formed; but the report has not been confirmed, and in view of the very marked basic properties which are indeed comparable with those of calcium oxide, it will be extraordinary if lanthana has the acidic strength to form such compounds. According to F. Zambonini and G. Carobbi, the products reported by C. Baskerville and G. F. Catlett are only mixtures of lanthanum oxide or hydroxide with varying proportions of the hydroxides or carbonates. The alkalies and alkaline earths which were present probably represented adsorption effects by the hydroxide. Double carbonates may also be present. H. von Euler and R. Nilsson studied the adsorptive power of lanthanum and aluminium hydroxides.

When an excess of an ammonium or alkali hydroxide, or ammonium sulphide, is added to a hot dil. soln. of a salt—chloride, nitrate, sulphate, etc.—of the rare earths, the corresponding rare earth hydroxide is precipitated as a gelatinous colloid, insoluble in an excess of the precipitant. If insufficient precipitant be added for complete precipitation, or if cold soln. be used, some basic salt may also be deposited. A. Damiens found the sesquioxides are formed when water acts on the carbides. The colours of **cerous hydroxide,** $Ce(OH)_3$, and of **lanthanum hydroxide,** $La(OH)_3$, are white; the colour of **praseodymium hydroxide,** $Pr(OH)_3$, is green; that of **neodymium hydroxide,** $Nd(OH)_3$, is blue; and that of **samarium hydroxide,** $Sa(OH)_3$, is a very pale yellow. The precipitation is prevented or hindered if citric, tartaric, or other organic hydroxy-acids be present—*vide* analytical reactions; according to A. Müller, glycerol inhibits the precipitation of cerous and neodymium hydroxides; and according to L. de Boisbaudran, J. Sterba, M. Delafontaine, W. Biltz, N. A. Orloff, etc., the hydroxides are but slowly and incompletely precipitated by ammonia in the presence of ammonium acetate. This property has been utilized in separating iron from the rare earths. Cerous hydroxide oxidizes in air whereby the colour changes to violet, forming cerosoceric hydroxides, and finally yellow owing to the formation of ceric hydroxide. Lanthanum hydroxide is soluble enough in water to colour red litmus blue. L. M. Dennis and W. H. Magee, and A. Damiens found that cerous hydroxide can be dried out of contact with air and still retain its white colour, but when the dehydration is pushed further some cerous oxide is converted to ceric oxide by the decomposition of the water. According to J. F. Spencer, the oxidation of cerous to ceric oxide takes place more rapidly in the presence of alkali hydroxides, but in the presence of alkali carbonate a still higher oxide is produced. The oxidation to the peroxide in the presence of air occurs only with cerous hydroxide and not ceric hydroxide. The ready oxidation of cerous hydroxide renders it a strong reducing agent, for, as W. Biltz and F. Zimmermann, and G. A. Barbieri showed, it reduces cupric to cuprous salts; mercuric to mercurous salts, etc. This reducing action of cerous salts distinguishes them from the salts of all the other rare earths, and shows that in this respect they are more nearly allied to the manganous salts. G. A. Barbieri added that it is not quite accurate to state that ceric compounds are unstable, whilst cerous compounds are stable. What is really unstable is the ceric ion $Ce^{\cdot\cdot\cdot\cdot}$, which is readily transformed into the cerous ion $Ce^{\cdot\cdot\cdot}$. In an alkaline medium, in which ceric ions cannot exist, ceric compounds are stable, whilst cerous compounds act as reducing agents. Further, in an acid medium, when the conditions are such as to diminish the conc. of the ceric ions, the oxidation of cerous salts can be effected by nitric acid alone. When neodymium hydroxide is heated to 300°, P. Joye and C. Garnier found that the composition corresponds with the sesquihydrate, $2Nd_2O_3.3H_2O$; at 525°, the monohydrate, $Nd_2O_3.H_2O$; and at a bright red heat, Nd_2O_3. The two hydrated neodymium sesquioxides have different reflection spectra. All the hydroxides are strong bases which react readily with acids to form salts. Indeed, lanthanum hydroxide is the strongest base of all the rare earth hydroxides, and approaches in strength that of calcium hydroxide; while, according to K. A. Vesterberg, its strength is comparable with that of ammonium hydroxide. All the rare earth hydroxides absorb carbon dioxide from air. Lanthanum hydroxide liberates ammonia from ammonium salts. K. C. Sen and N. R. Dhar studied the peptization of cerium hydroxide by sugars, starch, dextrine, gycerol, etc.; and H. von Euler and R. Nilsson, the action of acids and bases.

A well-defined basic oxide, namely, **ceric oxide,** or **cerium dioxide,** CeO_2, is represented by a corresponding series of salts; but salts derived from praseodymic oxide or praseodymium dioxide, PrO_2, have not been reported. There is some evidence of the formation of an unstable neodymium dioxide, NdO_2; but none at all with respect to the corresponding samarium oxide. According to H. Zschiesche,[2] lanthana does not absorb oxygen when heated in air, but, according to R. Marc, if an activating substance like cerium dioxide be present, oxygen is absorbed, and a higher oxide is produced. In conformity with the terms applied to the other rare earths, *ceria* should refer to the sesquioxide, but the term is sometimes applied to the dioxide possibly because zirconium and thorium dioxides are called respectively by zirconia and thoria, and cerium comes between zirconium and thorium in the periodic table. Ceric oxide is obtained as an amorphous powder when cerous or ceric hydroxide, nitrate, sulphate, or salt of a volatile oxy-acid is heated; the oxalate is most commonly used for this purpose. J. Sterba removed the last traces of nitrate by fusing ceric oxide with potassium hydroxide. It is also made by burning the metal in air.

According to H. E. Ives and co-workers, when white or brownish-white ceric oxide is heated in a quartz tube by a Bunsen burner, the colour becomes yellow or brown when the temp. has risen a few hundred degrees, and this also obtains with mixtures of thoria with a low percentage of ceric oxide. The colour change is exhibited by the commercial mantle with one per cent. of ceria, when the flame is burning low. If a fragment of a commercial mantle be heated in the inner part of the flame of Mèker's burner—with less than 0·1 per cent. of oxygen—and allowed to cool in the products of combustion, the colour is dark grey; and if heated in hydrogen, the colour is black. The original colour is restored by heating the material in an oxidizing flame. The ordinary form of the oxide is ceric oxide, CeO_2; the yellow colour acquired in the oxidizing low temp. flame is due to *cerium trioxide,* CeO_3; and the grey-blue or black form is the oxide Ce_4O_7. For the volatilization of ceric oxide, *vide* ceria.

Crystals belonging to the cubic system and exhibiting faces of the cube and octahedron, have been obtained by A. E. Nordenskjöld by fusing the oxide with borax in a porcelain oven, and extracting the cold mass with hydrochloric acid; J. Sterba, L. Grandeau, and P. Didier also prepared the crystals by melting the amorphous oxide with borax, sodium chloride, or potassium hydrosulphate, or by fusing the anhydrous chloride with borax; and in all cases extracting the cold mass with acid as before. K. A. Hofmann and K. Höschele also obtained crystals of ceric oxide by adding anhydrous cerous sulphate to molten magnesium oxide; after slowly cooling, the mass was extracted with hydrochloric acid. If small quantities of neodymium, praseodymium, or erbium sulphate be also added, the crystals have a fine colour. V. M. Goldschmidt and L. Thomassen found the crystals of cerium dioxide, thorium dioxide, and uranous oxide are isomorphous. The X-radiograms agree with a fan-centred cubic lattice of the calcium fluoride type with the edge 5·41 A. The mol. vol. was examined by F. A. Henglein. J. Böhm and H. Niclassen found the hydroxides of cerium, lathanum, and neodymium as first precipitated are amorphous, and slowly crystallize.

R. J. Meyer and H. A. Winter, and B. Brauner made **praseodymium dioxide**, PrO_2, by heating the nitrate to 400°–450°. When praseodymium hydroxide, nitrate, carbonate, or oxalate is heated in air, the resulting black powder was considered by C. A. von Welsbach, and H. C. Jones to have the composition Pr_4O_7, which was doubted by G. P. Baxter and P. C. Griffin; P. Schottländer, and R. J. Meyer gave Pr_6O_{11}; and B. Brauner, Pr_5O_9. C. von Scheele, however, found the composition to be dependent on the mode of preparation, for the product obtained by calcining the oxalate at as low a temp. as possible contains the most oxygen, while that similarly prepared from the nitrate contains least; and the product contains less oxygen the higher the temp. of calcination. If the product be strongly heated, it loses oxygen, but re-absorbs the gas on cooling. P. H. M. P. Brinton and H. A. Pagel found that Pr_6O_4 represented the product of the calcination of the oxalate in air at ordinary press. over a wide range of temp. B. Brauner assumed that the oxide Pr_5O_9 is a compound of the two oxides: $Pr_2O_3+3PrO_2=Pr_5O_9$, but it is doubtful if the products with the composition just indicated are chemical individuals; rather do they represent intermediate stages in the conversion of praseodymium sesquioxide to the dioxide. According to F. M. Jäger, and R. Marc, if small quantities of cerium be present the product approaches nearer the limit PrO_2 because the ceria seems to act as oxygen-carrier; on the contrary, if small quantities of lanthana or neodymia be present, R. J. Meyer and M. Koss found that the formation of the dioxide is adversely affected. C. A. von Welsbach, H. C. Jones, and R. J. Meyer and M. Koss deny that an oxide of neodymium higher than the sesquioxide can be prepared by calcination, but R. Marc, and B. Brauner say that if traces of ceria or praseodymia are present, the product approximates in composition to **neodymium dioxide,** NdO_2. A. Wagner claimed to have made an oxide of the composition Nd_4O_7 by heating the oxalate in oxygen, and he described the reflection spectrum of this product; but P. Joye and C. Garnier have shown that the spectrum is characteristic of the hydrated oxide $Nd_2O_3.H_2O$. R. Hermann, H. Zschiesche, and R. Marc obtained indications of the existence of a higher oxide--possible *lanthanum dioxide*. P. T. Cleve said that *samarium dioxide* has not been made and that this earth forms no oxide higher than Sm_2O_3 when heated in oxygen.

There have been some arguments as to the colour of cerium dioxide. From the position of cerium between zirconium and thorium in the periodic table, it might be anticipated that cerium dioxide, like thorium and zirconium dioxides, would be white. This is the opinion of G. Wyrouboff and A. Verneuil, J. Sterba, C. Wolf, H. Moissan, and J. F. Spencer. B. Brauner attributed the white colour to the presence of silica, but J. F. Spencer prepared the white dioxide free from silica. The presence of other elements of the cerium group—praseodymium and neodymium—impart a salmon-colour, reddish-brown, or brown tint to the oxide, which becomes deeper the larger the amount of these substances present, and the higher the temp. of calcination. J. F. Spencer found that if the white oxide be calcined at a red heat, it becomes pale yellow. The tint depends on the mode of preparation, and G. Wyrouboff and A. Verneuil add that there are several shades of white. The oxide derived from the sulphate is lightest in colour, that derived from the hydroxide is darkest, but the tint of neither is definite enough to be described other than as a particular shade of white. J. Sterba also concluded that ceric oxide can be white or a pale citron-yellow, and that the yellow colour which cannot be attributed to iron, platinum, or other rare earth elements, but it may be due to the presence of a higher oxide than the dioxide. Praseodymium dioxide is black or brownish-black; and the neodymium compound is blue. According to V. M. Goldschmidt and L. Thomassen, the X-radiogram of ceric oxide indicates a cubic lattice with sides $5{\cdot}41\times10^{-8}$ cms. C. J. B. Karsten gave 5·6059 for the sp. gr. of cerium dioxide; R. Hermann, 6·00; A. E. Nordenskjöld, 6·935 at 15·5°, and 7·09 at 14·5°, for the crystals; L. F. Nilson and O. Pettersson, 6·739; and J. Sterba noted that the higher the temp. of formation of the crystals the greater the sp. gr.—thus, by using fused sodium chloride, borax, and potassium sulphate, the sp. gr. were respectively 7·314, 7·415, and 7·995. W. Prandtl gave 6·71 at 15°/4° for the sp. gr. of the black oxide Pr_4O_7. The sp. gr. of praseodymium dioxide is 5·978 at 20°. J. F. Spencer observed that the colour of the white oxide appears yellow when it is heated, but if the temp. has not been too high, the original colour is restored on cooling; praseodymium dioxide passes into the sesquioxide when strongly heated. According to E. Tiede and E. Birnbräuer, ceric oxide does not melt at 1875°, but in vacuo, it volatilizes rapidly at that temp. The oxide readily fuses in the electric arc furnace, and attacks the containing vessel. O. Ruff and co-workers found that cerium dioxide melted at 1930°. W. R. Mott gave for the order of volatility of the oxides: Al_2O_3, Ti_2O_3, Er_2O_3, CeO_2, Nd_2O_3, La_2O_3, ZrO_2, and ThO_2. W. W. Coblentz found the ultra-red emission spectrum of cerium dioxide has a strong emission between 2μ and 3μ, with possible maxima at 4·4μ and 7·5μ Beyond 7μ, H. Rubens found the emissivity approaches that of a complete radiator. According to C. Renz, purified cerium dioxide, which has a pale yellow colour, is unaffected by light, but if mixed with a small quantity of praseodymia or terbia it becomes light-sensitive. Such a mixture, which has a slightly reddish-yellow colour, when exposed to sunlight becomes bluish-grey, but in the dark its original colour is restored. In the cerite earths, cerium is known to have an oxidizing influence on praseodymia, and apparently in sunlight this influence becomes emphasized. E. L. Nichols and H. L. Howes studied the blue glow which occurs when the oxide is heated in the oxy-hydrogen flame. L. F. Nilson and O. Pettersson found the sp. ht. of ceric oxide to be 0·0877 between 0° and 100°. J. Sterba said that the refractive index of the crystals of ceric oxide is high—about 1·9. E. Wedekind and P. Hausknecht found the at. magnetism to be $+74·4\times10^{-6}$.

Ceric oxide is a very stable oxide, but it is weakly basic, forming a series of ceric salts. According to C. Renz, ceric oxide is reduced when exposed to light in the presence of certain organic liquids and reducing soln., particularly glycerol. Crystalline ceric oxide is not attacked by hydrochloric or nitric acid or by alkali hydroxides. According to C. F. Rammelsberg, fused alkali hydroxide has no action on ceric oxide; and L. Marino showed that the amorphous oxide after calcination is not soluble in hydrochloric or nitric acid, but if a reducing agent, like hydrogen dioxide, hydriodic acid, stannous chloride, or hydroquinone, be present, the oxide dissolves as a cerous salt. If ceria earths containing less than 50 per cent. of ceria oxide be treated with hydrochloric or nitric acid, the cerium is dissolved under conditions where ceric oxide alone is not dissolved. G. Wyrouboff and A. Verneuil assume that ceric oxide is a feeble acid, forming with other bases, salts of the type $R_2O_3.2CeO_2$ or $2R_2O_3.3CeO_2$; these salts are assumed to be decomposed by the acid into ceric hydroxide which is soluble as a base in the excess of acid present. K. A. Hofmann and K. Höschele prepared some salts with uranic oxide—$UO_2.2CeO_2$. According to R. Bunsen, warm conc. sulphuric acid converts ceric oxide into ceric sulphate but no dissolution occurs; moderately conc. sulphuric dissolves ceric oxide producing both ceric and cerous sulphates, and liberating a little ozonised oxygen; dil. sulphuric acid has no perceptible action on ceric oxide. Hydriodic acid converts ceric oxide into cerous iodide and iodine. Praseodymium dioxide, said B. Brauner, is not of the peroxide type, but in it, the praseodymium is quadrivalent. According to C. von Scheele, praseodymium dioxide liberates chlorine from hydrochloric acid; iodine from hydriodic acid; and ozonized oxygen from oxy-acids; it oxidizes cerous to ceric salt; manganous to manganic salts; stannous to stannic salts; and ferrous to ferric salts—part of the oxygen also escapes without oxidizing the ferrous or stannous salt. A soln. of strychnine in sulphuric acid is coloured violet by praseodymium dioxide. P. G. Melikoff and B. E. Klimenko say that praseodymium dioxide gives hydrogen dioxide but no ozone when treated with dil. sulphuric acid; with nitric acid it oxidizes manganese sulphate to a permanganate; and with hypochlorous acid it gives rise to the evolution of oxygen and the formation of chloric acid. In this reaction, which proceeds very slowly in the cold, but much mor energetically at higher temp., no ozone is given off, and any which is formed must b at once used up in oxidizing the hypochlorous acid. They add that praseodymium dioxide is not constituted like hydrogen peroxide. J. Sterba found that carbon does not reduce ceric oxide to the metal, but in the electric arc furnace cerium carbide is formed. For the reduction of ceric oxide by aluminium, magnesium, etc., *vide* metallic cerium. According to C. G. Mosander, and A. Beringer, hydrogen from zinc and an acid reduces ceric oxide to the lower state of oxidation. Ceric oxide, said W. S. Chase, readily absorbs gases.

As indicated by J. J. Berzelius and W. Hisinger,[3] and C. G. Mosander, when ammonia or an alkali hydroxide is added to a soln. of a ceric salt, a yellow gelatinous precipitate of **ceric hydroxide**—possibly $Ce(OH)_4$, or $CeO_2.nH_2O$—is formed; it is insoluble in excess. Like most gelatinous precipitates, this hydroxide is liable to be contaminated with basic salt or the entrained salt, as well as adsorbed alkali hydroxide. According to G. Wyrouboff and A. Verneuil, the best procedure is to add ammonia to a cold soln. of ceric ammonium nitrate, and allow the washed precipitate partially to dry at a low temp., and wash again with cold water to remove the ammonium nitrate. When dried over potassium hydroxide, the composition corresponds with $2CeO_2.3H_2O$, or $Ce_2O(OH)_6$. C. F. Rammelsberg, and C. Erk assigned to this compound a similar formula. T. Carnelley and J. Walker obtained different results. They measured the mols of water lost per mol of ceric hydroxide at different temp. They said:

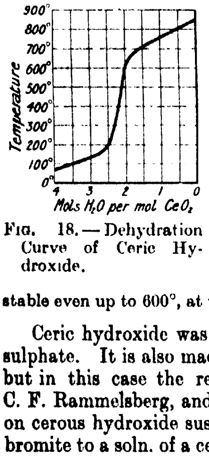

Fig. 18.—Dehydration Curve of Ceric Hydroxide.

> The curve, Fig. 18, after rising almost perpendicularly from 200° to 600°, begins at the latter temp. to curve towards the horizontal, and this continues even up to 815°. The composition at 600°, just before this change occurs, is represented by $CeO_2.2H_2O$. This would seem to be a definite hydrate, for the composition had previously remained nearly constant, the loss of water for 12 hrs. between 385° and 600° not having amounted to more than 0·39 per cent., or for 8 hrs.' heating between 440° and 600°, to 0·23 per cent. Further, the rate of loss which commences at 600° is 20 times as great as the average rate during the previous 220°, and, moreover, at 600° the colour suddenly changes from a light yellow (presumably the colour of the hydrate $CeO_2.2H_2O$) to salmon colour, the latter prevailing until complete dehydration. Finally, at the temp. at which the composition became practically constant (385°), and therefore presumably that at which the hydrate $CeO_2.2H_2O$ was formed, there was a change of colour from brownish-yellow to bright yellow. It is therefore concluded that ceric oxide forms a definite hydrate, $CeO_2.2H_2O$, or normal ortho-ceric hydroxide, H_4CeO_4, or $Ce(OH)_4$, which is very nearly stable even up to 600°, at which temp. rapid dehydration begins.

Ceric hydroxide was made by C. Erk by the action of ammonia on basic ceric sulphate. It is also made by the oxidation of cerous hydroxide by exposure to air, but in this case the reaction is slow. C. G. Mosander, O. Popp, R. Hermann, C. F. Rammelsberg, and M. Stapff oxidized it by the action of chlorine or bromine on cerous hydroxide suspended in water, or by adding alkali hypochlorite or hypobromite to a soln. of a cerous salt. Cerous hydroxide may also be oxidized by treatment with hydrogen dioxide, and, in order to destroy the peroxides, heating the product to 120°, or boiling the product with water. When freshly prepared, or when dried at 120°, ceric hydroxide dissolves in nitric acid, forming a reddish coloured soln. of ceric nitrate; it dissolves in hydrochloric acid with the evolution of chlorine and the formation of cerous chloride; and with sulphuric acid, a mixture of cerous and ceric sulphates is formed and oxygen evolved, but, according to B. Brauner, if platinum be present ceric hydroxide prepared from ceric peroxide furnishes cerous sulphates alone, while ceric hydroxide, prepared by oxidizing cerous hydroxide with chlorine, furnishes ceric sulphate alone. According to G. A. Barbieri, ceric hydroxide obtained by either method gives with dil. sulphuric acid, 93–95 per cent. of the cerium in the quadrivalent form. J. M. Ordway found ceric hydroxide to be insoluble in alkali hydroxides, but soluble in soln. of alkali carbonates, forming, according to A. Job, a perceric carbonate.

W. Biltz prepared a colloidal soln. or **hydrosol of ceric hydroxide** by dialyzing a ten per cent. aq. soln. of ceric ammonium sulphate for four or five days. The colloid is positively charged with respect to water. The soln. is readily coagulated by a few drops of soln. of electrolytes. When the colloidal soln. is evaporated, it leaves a gum-like mass which dissolves to a clear soln. in hot water. The sol was studied by J. E. M. van der Made, H. N. Holmes, and J. Böhm and H. Niclassen; the adsorption of dyes by cerium dioxide, by H. Rheinboldt and E. Wedekind; and the action of radium emanation, by A. Fernau and W. Pauli. The colloid was further investigated by H. R. Kruyt and J. E. M. van der Made.

J. J. Berzelius and W. Hisinger,[4] A. Beringer, J. C. G. de Marignac, L. N. Vauquelin, and C. G. Mosander describe a **cerosoceric oxide** as a lemon-yellow powder obtained by igniting ceric oxide in a current of hydrogen, or by igniting cerous oxalate or carbonate in a retort. A. Beringer gives the formula $Ce_2O_3.16CeO_2$, and J. C. G. de Marignac, $3Ce_2O_3.8CeO_2$. There appears to be something amiss with these observations because, when ceric oxide is heated to redness in a current of dry hydrogen, free from air, it is partially reduced, and it loses about two per cent. in weight. The reduction is more rapid with ceric oxide which has not been strongly ignited, than it is with an oxide which has been strongly ignited; but the former oxide is liable to retain a little water. The product is a blue or bluish-black solid which readily absorbs oxygen from the air, and is sometimes pyrophoric. The dark blue oxide is also obtained by heating ceric oxide in vacuo. It has been described by G. Wyrouboff and A. Verneuil,[5] J. Sterba, W. S. Chase, and R. J. Meyer. The two last-named gave the composition of the cerosoceric oxide, Ce_4O_7, while G. Wyrouboff and A. Verneuil gave Ce_7O_{12}. W. S. Chase found this oxide readily adsorbed gases.

When white cerous hydroxide is exposed to air or to oxygen, it acquires a violet or purple tint and ultimately becomes yellow ceric hydroxide. G. Wyrouboff and A. Verneuil obtained the *violet foncé* product by adding alkali hydroxide to a mixed soln. of cerous and ceric salts. The maximum intensity of tint is obtained when the ratio $CeO_2 : Ce_2O_3 = 2 : 1$. When the material is dried in vacuo, the colour is nearly black. The same product is obtained by precipitating a soln. of cerosoceric sulphate with alkali hydroxide. They also described a cerosoceric oxide, $6CeO_2.Ce_2O_3$, which is not stable, but if the cerous oxide be replaced by one of the other ceria or yttria earths, the product is stable; and a complex $6CeO_2.R_2O_3$ is formed. From a study of the basic ceric salts, G. Wyrouboff and A. Verneuil concluded that they are derived from different polymerized forms of ceric hydroxide; these include what they call the *para-oxides*, $(CeO_2)_{40}.nH_2O$; the *meta-orides*, $(CeO_2)_{56}.nH_2O$; etc. There is very little to support the mol. formulæ so ascribed to these compounds.

The colloidal soln. of ceric hydroxide, made by the dialysis of a soln. of ceric ammonium sulphate, change in a marked manner with time, the ageing being accompanied by a diminution in viscosity, a gradual loss of the faculty of gelatinization, and by a diminution in the sensitiveness towards electrolytes. The change is irreversible, and is accelerated by rise of temperature. It is supposed that the ageing is due to the gradual dehydration of the sol particles. The ageing of ceric hydroxide sols is very largely modified under the influence of β- or γ-rays from radium. The first effect consists in an accelerated rate of diminution of the viscosity, but this effect is succeeded by a second, in which the viscosity of the sol increases to a value very large in comparison with that of the freshly dialyzed sol. The progress of the second stage is not dependent on the continued exposure of the sol to the action of the active rays, for if the exposure be made intermittent, it is found that the course of the viscosity—time curve is quite unchanged. A further curious effect is observed when the source of the radiation is removed before the end of the first stage in the ageing process. Under these circumstances, the second stage in the ageing process sets in, and the viscosity of the sol increases very considerably, attains a maximum value, and subsequently decreases almost as rapidly as it increased before the attainment of the maximum. The jelly obtained when the radiation is allowed to act sufficiently long appears to be perfectly stable. Similar changes in the viscosity are produced by the addition of electrolytes, although the effects are not readily distinguishable. The ageing of sols is supposed to be due to the gradual formation of larger colloidal particles by a process of aggregation, but it is probable that the effects described by the authors are connected with changes in the degree of hydration. It is probable that ceric hydroxide and other metallic hydroxide sols are highly hydrated, and in this way differ from hydrophobic colloids, such as the metallic and the sulphide sols. Under the influence of electrolytes or β- or γ-rays, the electrical charge of the colloidal particles is neutralized, and this is accompanied by a diminution in the degree of hydration, and results in a lowering of the viscosity, gradual when the sol is subjected to β- or γ-rays and immediate when an electrolyte is added. The increase in viscosity in the second state of the ageing process is then due to the aggregation of the electrically neutral particles, a process which takes place with a velocity comparable with that of crystallization and similar processes. The attainment of a maximum viscosity and the subsequent fall which is observed when the added electrolyte is very small in quantity or the time of exposure to the rays is comparatively brief is explained by assuming that this peptization is due to the action of electrically charged colloid particles which are enclosed by the jelly resulting from the aggregation of the electrically neutral particles. In support of this view, it has been found that ceric hydroxide jelly may be readily peptized by the addition of the corresponding sol.

According to R. Hermann,[6] and L. de Boisbaudran, when a soln. of a cerous salt is treated with a mixture of ammonia and hydrogen dioxide, or when a soln. of, say, cerous sulphate is mixed with a slight excess of ammonia, and hydrogen peroxide added, a reddish gelatinous precipitate is obtained. The orange-red precipitate formed when a soln. of cerium acetate is treated with hydrogen dioxide does not contain such a high proportion of oxygen. Cerium compounds are sometimes recognized by mixing the soln. with an alkaline acetate, adding hydrogen dioxide, and heating gently, when an orange-red precipitate is formed. In the case of cerous salts, the precipitate not unfrequently remains white, or at most becomes pale yellow. This precipitate should be moistened with ammonia, and again treated with hydrogen peroxide, when the orange-red colour will be produced. The white precipitate formed by hydrogen peroxide in soln. of cerous acetate does not appear to be more highly oxidized than the sesquioxide. L. de Boisbaudran, and P. T. Cleve assume the orange-red precipitate is a **hydrated cerium trioxide,** $CeO_3.nH_2O$. According to L. Pissarjewsky, the mechanism of the formation of the peroxidized cerium compound is $Ce(OH)_4+HO.OH=Ce(OH)_3.O.OH+H_2O$. The sesquioxides of didymium and samarium were found by P. T. Cleve to yield peroxides of the general formula, $R_4O_9.nH_2O$, or, according to L. Pissarjewsky, hydrated **lanthanum pentoxide,** $R_2O_5.nH_2O$, or $HLaO_3+nH_2O$. P. G. Melikoff and L. Pissarjewsky ascribed the formula $La(OH)_2.(O.OH)$ to lanthanum peroxide. According to B. Brauner, if praseodymium hydroxide be precipitated in the presence of hydrogen peroxide, a hydrated **praseodymium pentoxide,** $Pr_2O_5.nH_2O$, is produced; P. G. Melikoff and B. E. Klimenko assume that the first product of the action is $Pr(O.OH)_3$, which then decomposes to give the product the formula $Pr(OH)_2(O.OH)$. B. Brauner also assumes the existence of a corresponding hydrated **neodymium pentoxide,** $Nd_2O_5.nH_2O$. He also mentions the existence of $(CH_3.CO)_2R.O.O.OR(OH)(CO.CH_3).H_2O$, where R represents Pr or Nd., P. T. Cleve's peroxide $Sa_4O_9.nH_2O$ is probably analogous to the products just described, and in conformity therewith, the compound is called hydrated **samarium pentoxide,** $Sa_2O_5.nH_2O$. P. Mengel found that if sodium dioxide be employed instead of hydrogen dioxide, at ordinary temp., oxyhydroxides are obtained containing more oxygen than the sesquioxide, but less than the P. T. Cleve's peroxide, and the amount of oxygen varies with the conditions of the experiment, especially with the temp. When a soln. of a pure cerium salt is precipitated with sodium dioxide and boiled, whereby a bright yellow precipitate of cerium dioxyhydroxide is obtained, and this is dried at 130°, the percentage of CeO_2 in the precipitate estimated with ferrous ammonium sulphate and permanganate, shows that the oxidation of the cerium is incomplete. If, however, the precipitate be heated over the blowpipe, the theoretical quantity of dioxide is obtained. When a mixture of lanthanum and didymium salts, free from cerium, is treated with sodium dioxide in the cold, it yields a precipitate which gives off oxygen when the mixture is warmed; the precipitate, when dried at 120°, is bluish-white, and contains much carbonic anhydride absorbed from the air, which is eliminated only at a high temp.; when heated at 400°, it becomes dark brown, and on further heating over the blowpipe assumes the characteristic grey colour of the anhydrous sesquioxide. The brown coloration is due to the formation of a higher oxide of praseodymium, and since this higher oxide cannot be obtained by the action of chlorine in alkaline soln., the praseodymium peroxide, like barium peroxide, must belong to the type H_2O_2. The oxalates of lanthanum and didymium do not yield the brown oxide when heated; if, however, the grey oxide which is obtained be moistened with nitric acid and cautiously heated, the brown oxide is obtained.

According to A. Job, cerous salts are more soluble than ceric salts in soln. of alkali carbonates, and the solubility is still further increased if they are peroxidized. If, however, an excess of hydrogen peroxide be added, the solubility is reduced and a precipitate forms, the nature of which has not yet been ascertained. In order to obtain a conc. soln. of cerium peroxide, hydrogen peroxide and ceric ammonium nitrate, in molecular proportion, are added successively to a conc. aq. soln. of potassium carbonate, and the soln. is agitated; a limpid, deep-coloured liquid is thus obtained, and as much as 40 grms. of cerium dioxide may be added per litre if 280 grms. of alkali carbonate be also present. Potassium hydrogen carbonate may be used in place of the normal carbonate, but then the solubility of the cerium salt be less. If to the soln. prepared in the manner just described, hydrogen peroxide is added in slight excess but not in sufficient quantity to produce a precipitate, and the soln. be allowed to remain at the ordinary temp., it at first loses some oxygen, but is afterwards quite stable, the quantity of available oxygen in it corresponding exactly with that required by the formula CeO_3. Ceric salts do not absorb oxygen from the air, but if a soln. of a cerous salt containing also an alkali carbonate be exposed to the air, it is first oxidized to a ceric salt and then continues to absorb oxygen up to a limit that depends on the strength of the soln. E. Baur confirmed the results by A. Job. Cerous sulphate soln. containing potassium carbonate, when shaken with air, are converted into cerium peroxide, and at the same time some ceric salt is formed. A slight alkalinity of the soln. increases the yield of peroxide. When arsenious oxide is used as "acceptor," the cerium is converted to a greater extent into peroxide. The salt, $Ce_2O(CO_3)_2.O_3.4K_2CO_3.10H_2O$, described by A. Job, gives oxygen as well as carbon dioxide when treated with dil. sulphuric acid. More oxygen is liberated than indicated by the equation $2CeO_3+3H_2SO_4=Ce_2(SO_4)_3+O_2+H_2O_2+2H_2O$, and this is due to a spontaneous decomposition of the hydrogen peroxide present. According to L. Pissarjewsky, the peroxidized cerium compound is not stable; it loses oxygen fairly quickly at ordinary temp.; it is rapidly converted into ceric hydroxide when heated with boiling water, or when dried at 100°; and, with dil. acids, it forms a cerous salt, hydrogen dioxide, and ozonized oxygen: $2\{Ce(OH)_3.O.OH\}+3H_2SO_4=Ce_2(SO_4)_3+H_2O_2+O_2+6H_2O$. Carbonic acid also liberates hydrogen dioxide from the peroxidized compound. The peroxides like the sesquioxides have basic properties, and do not combine with the bases to form salts. L. Pissarjewsky gives for the heat of formation $CeO_{3aq.}=CeO_{2aq.}+O+33{\cdot}576$ Cals. The higher oxide of praseodymium, say P. G. Melikoff and B. E. Klimenko, does not convert manganese salts into permanganates in the presence of nitric acid.

§ 14. The Halides of the Cerium Metals

H. Moissan[1] prepared the anhydrous fluorides of the rare earths by the action of fluorine on the carbides ; and W. K. van Haagen and E. F. Smith converted yttrium, lanthanum, and cerium oxides into fluorides by heating them in a stream of hydrogen fluoride.

According to A. Hirsch, the hydrated fluorides can be made by the action of conc. hydrofluoric acid on a hot soln. of the chlorides, acidified with hydrochloric acid. The precipitated fluoride is washed with hot water, then with 95 per cent. alcohol, and the alcohol removed by the centrifuge. If the product be covered with absolute alcohol, evaporated to dryness, and the residue heated first at 100°, and then at 200°, the anhydrous fluoride is formed.

The fluorides of the rare earths crystallize in the cubic system, and they are isomorphous with calcium fluoride. The fluorides of the rare earths are practically insoluble in water and in dil. mineral acids ; they are perceptibly soluble in hot conc. hydrochloric acid, and this the more with the fluorides of the cerium group than with those of the yttrium group. The fluorides of scandium and thorium are much less soluble.

Hydrated cerium tetrafluoride, $CeF_4.H_2O$, occurs with the quartz and albite at Brodbö, Sweden, as the mineral *fluocerite*. B. Brauner prepared hydrated ceric

fluoride, *$CeF_4.H_2O$, as a brown powder by the action of hydrofluoric acid on ceric hydroxide, and drying the product at 100°. When heated this salt gives off water, hydrogen fluoride, and possibly fluorine. B. Brauner claims to have made the salt $3KF.2CeF_4.2H_2O$, in cubic or octahedral crystals insoluble in water, by the* action of potassium hydrogen fluoride on ceric hydroxide, but E. Rimbach and H. F. C. Kilian question the accuracy of B. Brauner's statement; they did not succeed in preparing B. Brauner's salt nor the analogous salts of lithium, sodium, rubidium, cæsium, or ammonium, but they did prepare a series of double salts of the type $MF_2.2CeF_4.7H_2O$, where M denotes Zn, Cd, Cu, Co, or Ni, by the action of a soln. of the metal oxide in an excess of hydrofluoric acid on a soln. of ceric hydroxide in hydrofluoric acid. **Heptahydrated zinc decafluodicerate,** $ZnF_2.2CeF_4.7H_2O$, and **heptahydrated cadmium decafluodicerate** are white, **heptahydrated copper decafluodicerate** is pale blue. These salts are decomposed more or less readily by water. T. Vogt found that fused mixtures of calcium and cerium fluorides give cubic mixed crystals with up to 55·8 per cent. of cerium fluoride; these crystals are called *cerofluorite,* and mixed with yttrofluorite they find a representative in the mineral *yttrocerite.* According to B. Brauner, ceric fluoride is converted into **cerous fluoride,** CeF_3, by heating it to dull redness. S. Jolin made **hemihydrated cerous fluoride,** $2CeF_3.H_2O$, by double decomposition. N. A. Puschin and A. V. Baskoff did not succeed in preparing a double compound with cerous and potassium fluorides; the two chlorides have a eutectic at 660° corresponding with 24 mol per cent. of cerous fluoride. P. R. Bassett studied the electrochemistry of the high intensity arc with the positive electrode having a core of cerous fluoride.

P. T. Cleve, and F. Frerichs and F. Smith have described **hemihydrated lanthanum fluoride,** $2LaF_3.H_2O$, prepared as a white gelatinous precipitate by adding hydrofluoric acid to a soln. of the acetate; and **lanthanum hydrofluoride,** $2LaF_3.3HF$, prepared by adding hydrofluoric acid to a soln. of the sulphate. H. Moissan made the anhydrous fluoride by the action of fluorine on the carbide. W. F. Smith obtained a voluminous precipitate of lanthanum hydrofluoride, $2LaF_3.3HF$. W. F. Smith also precipitated a gelatinous **didymium hydrogen fluoride,** $3HF.DiF_3$; and B. Brauner reported three **potassium fluodidymates,** with the ratios $KF : DiF_3 : H_2O$ as 1 : 2 : 1; 6 : 6 : 2; and 3 : 4 : 3. J. Popovici precipitated gelatinous **praseodymium fluoride,** PrF_3, from an aq. soln. of praseodymium sulphate by hydrofluoric acid. The gelatinous precipitate when warmed forms a mass of yellow glistening crystals which appear green by reflected light. **Neodymium fluoride,** NdF_3, is formed in a similar manner as a pale, lilac-coloured, crystalline powder. P. T. Cleve obtained **hemihydrated samarium fluoride,** $SaF_3.H_2O$, as a gelatinous precipitate by double decomposition by adding hydrofluoric acid to a soln. of a samarium salt.

The classical process of H. C. Oersted [2] is of no practical value for chlorinating the oxides of the rare earths because the resulting chloride is non-volatile. C. A. Matignon and F. Bourion made the anhydrous chlorides of the rare earths by heating the oxide, sulphate or oxalate in a stream of sulphur chloride, S_2Cl_2, followed by the fusion of the chloride in a stream of dry hydrogen chloride; E. Chauvenet heated the oxide in a stream of carbonyl chloride; P. Didier and also C. Baskerville used a mixture of carbon monoxide and chlorine; E. Demarçay, and H. Quantin used carbon tetrachloride; and C. A. Matignon, and O. Pettersson used hydrogen chloride, but in the latter case the reaction is not quantitative, although it is so if the oxalate be used in place of the oxide. F. Hillebrand and A. Norton converted the metals into chlorides by heating them in a stream of chlorine or hydrogen chloride; C. G. Mosander, and W. Muthmann and L. Stützel heated the sulphides in a stream of chlorine or hydrogen chloride; and H. Moissan heated the carbide in a stream of chlorine, O. Pettersson, in hydrogen chloride. The hydrated salts can be dehydrated by heating them to 105°–130° in a stream of dry hydrogen chloride until no more water is evolved. The product is heated to 180°–200° in a stream of the same gas. When water is no longer evolved, the temp.

is raised until the chloride fuses. The solid residue obtained by evaporating an aq. soln. of the chloride can also be dehydrated by heating it in a stream of dry hydrogen chloride and sulphur chloride, S_2Cl_2. W. Heap and E. Newbery treated the oxide or the salt of a weak acid at 350°–400° with carbonyl chloride.

Aq. soln. of the rare earth chlorides are readily made by dissolving the oxides, hydroxides, or carbonates in conc. hydrochloric acid; and when the soln. are evaporated over sulphuric acid; or when the hot sat. soln. is cooled; or when the cold aq. soln. is sat. with hydrogen chloride, crystalline hydrated chlorides are formed. The hydrated salts cannot be dehydrated without decomposition by simply heating them in air. The hydrated salts are usually of the type $MCl_3.6H_2O$, and when heated between 105° and 130° in a stream of dry hydrogen chloride, they are partially dehydrated, forming the monohydrated salts $MCl_3.H_2O$, which are completely dehydrated between 180°–200° in a stream of hydrogen chloride.

The chlorides are all hygroscopic and dissolve in water with the evolution of heat. The aq. soln. are neutral to methyl orange. Cæsium chloride forms double salts with the chlorides of lanthanum, praseodymium and neodymium, and samarium, but other double chlorides of the metals of groups I and II have not been prepared—excepting the chloroaurates. Double chlorides with antimony, bismuth, tin, and platinum have been made. They also form double compounds with mercuric cyanide, and with alcohol, pyridine, and many organic bases.

Crystallized oxychlorides of the rare earths were prepared by C. A. Matignon and F. Bourion by passing a slow current of air or steam along with an inert gas, over the molten anhydrous chloride, and A. Job made them by heating the hydrated or oxalo-chlorides to redness. K. A. Hofmann and K. Höschele prepared them in a crystalline form by adding the oxides or sulphates to molten magnesium chloride; and extracting the soluble salts from the cold mass by dil. acetic or hydrochloric acid. G. Urbain prepared crystalline oxychlorides for spectroscopic examination by dissolving the oxides in hydrochloric acid, adding ammonium and alkali chlorides; the soln. is evaporated to dryness, the residue carefully heated, and, when cold, extracted with water. The residual oxychloride is practically insoluble in water, but slowly soluble in dil. acids. A prolonged ignition converts them into oxides.

According to C. G. Mosander,[3] cerium burns vigorously when heated in chlorine gas, and F. Hillebrand and A. Norton prepared the chloride by igniting cerium in this gas. According to A. Beringer, if chlorine gas be passed over heated ceric oxide, cerium chloride mixed with the oxide is formed, and some oxychloride sublimes. **Cerium trichloride,** or **cerous chloride,** $CeCl_3$, was prepared by F. Wöhler, A. Beringer, and by F. Hillebrand and A. Norton by evaporating a soln. of the carbonate in hydrochloric acid to dryness and igniting the residue, mixed with ammonium chloride, at a red heat. H. Robinson ignited the oxalate in a stream of hydrogen chloride; P. Didier ignited the oxide in a stream of carbon dioxide and chlorine; L. Meyer ignited the oxide in a stream of carbon tetrachloride; and C. G. Mosander heated the sulphide in chlorine—free from oxygen; if all the air be not expelled by the chlorine before the sulphide is heated, a mixture of the chloride and oxide is formed which fuses with great difficulty. Of the general methods described above, F. Bourion's sulphur chloride process is one of the most convenient. The anhydrous chloride forms white deliquescent crystals of sp. gr. 3·92 at 0°—H. Robinson gives 3·88 at 15·5°—the crystals melt at 848°. According to P. Didier, cerium chloride is decomposed by oxygen or steam, forming cerium sesquioxide, Ce_2O_3. The salt is very soluble in water, and, according to L. M. Dennis and W. L. Magee, the aq. soln.—generally prepared by dissolving cerous oxide or ceric hydroxide in conc. hydrochloric acid—when sat. with hydrogen chloride furnishes rhombic crystals of **heptahydrated cerous chloride,** $CeCl_3.7H_2O$, with the axial ratios $a:b:c=0·8083:1:1·4419$; and, according to A. S. Eakle, the rhombic bipyramidal crystals, $CeCl_3.7\frac{1}{2}H_2O$, have the axial ratios $a:b:c=0·6096:1:0·7857$. A. Fock also reported triclinic pinacoidal crystals of

hexahydrated cerium trichloride, $CeCl_3.6H_2O$, with the axial ratios $a:b:c=1\cdot1580:1:0\cdot8635$; and $\alpha=91^\circ\ 2\frac{1}{2}'$; $\beta=114^\circ\ 9'$; and $\gamma=88^\circ\ 11\frac{1}{2}'$. These crystals are said to be isomorphous with hexahydrated lanthanum trichloride. According to T. Lange, cerium dioxide, CeO_2, dissolves in hydrochloric acid only in the presence of a reducing agent—say hydroferrocyanic acid. L. N. Vauquelin's and A. Beringer's products were rose-coloured owing to the presence of impurities; the purer crystals obtained by W. Hisinger and J. J. Berzelius are colourless. According to J. J. Berzelius, when the heptahydrated chloride is heated, water is given off, then hydrogen chloride, as indicated in describing the general properties of these salts. The hydrated salt is also deliquescent, and very soluble in water. R. J. Meyer found the eq. conductivity of aq. soln. of cerium chloride rises from 107·6 with a dilution $v=32$ to 135·2 with $v=1024$, so that the difference $\lambda_{1024}-\lambda_{32}=27\cdot6$, very nearly the value 26 characteristic of strongly basic tervalent cations which do not hydrolyze to any marked degree. From the potential of the cell $H_2 \mid CeCl_3 \mid NH_4NO_3 \mid$ Calomel electrode, H. G. Denham computes that about 0·14 per cent. of the salt is hydrolyzed in a $\frac{1}{32}N$-soln. A. B. Schiotz found that the electrolysis of soln. of cerous chloride in the presence of chloride of mercury, nickel, platinum, zinc, or aluminium gave deposits containing no cerium; the addition of potassium lactate to the soln. of cerous chloride raised the overvoltage to 0·15 volt. With soln. of cerous and ferrous chlorides in the presence of alkali lactate, iron with 62 per cent. of cerium was deposited on the cathode. J. H. Hildebrand titrated cerium, praseodymium, and neodymium chlorides with sodium hydroxide soln., and measured the e.m.f. against the normal hydrogen electrode during the operation. J. J. Berzelius found the colourless aq. soln. becomes brown on exposure to the air owing to the formation of a ceric salt. The alcoholic soln. burns with a green flame. H. Arnold electrolyzed molten cerium trichloride, and he observed a secondary reaction at about 900° so long as there is an excess of water present in the molten mass. The dark brown powder has the composition $CeOCl_2.10H_2O$, **ceric oxychloride,** and it is hydrolyzed by water, forming ceric hydroxide and cerous chloride. It is supposed to be formed from the ceric chloride produced on the anode: $CeCl_4+H_2O=2HCl+CeOCl_2$. W. Biltz and E. Meinecke found cerium trichloride to be insoluble in liquid chlorine.

M. Barre has shown that cerium chloride readily forms additive compounds with ammonia. Gaseous ammonia, when introduced into a tube containing cerium chloride at −80°, combines with the development of heat, and there is a considerable increase in the volume of the mass. By a study of the dissociation pressures, this author has established the existence of five different compounds of cerium chloride with ammonia, and has prepared them in the form of white powders decomposable by water. The compounds are: **cerium icosiamminotrichloride,** $CeCl_3.20NH_3$; **cerium dodecamminotrichloride,** $CeCl_3.12NH_3$; **cerium octamminotrichloride,** $CeCl_3.8NH_3$; **cerium tetramminotrichloride,** $CeCl_3.4NH_3$: and **cerium diamminotrichloride,** $CeCl_3.2NH_3$. G. L. Clark found the temp. of decomposition at 760 mm. press. to be −32° for the icosiamminochloride; −14°, for the dodecachloride; 18°, for the octamminochloride; 67°, for the tetramminochloride; and 98°, for the diamminochloride. E. H. Ducloux prepared crystals of **cæsium tetrachlorocerate,** $CsCl.CeCl_3$, of refractive index 1·58, and recommended the reaction as a microchemical test for cerium. The yellow, dichroic, deliquescent, monoclinic crystals of tridecahydrated **auric hexachlorocerate**—$CeCl_3.AuCl_3.13H_2O$, according to S. Jolin, or $CeCl_3.AuCl_3.10H_2O$, according to M. Holzmann—are deliquescent, and soluble in water and in alcohol. F. Zambonini found that up to 2·19 per cent. of cerous chloride, $CeCl_3.3H_2O$, and barium chloride, $BaCl_2.2H_2O$, form a series of mixed crystals. S. Jolin has prepared hexahedral crystals of decahydrated **mercuric henadecachlorocerate,** $CeCl_3.4HgCl_2.10H_2O$, soluble in water; and J. E. Ahlen, felted needle-like crystals of octohydrated **mercuric hexacyanotrichlorocerate,** $CeCl_3.3HgCy_2.8H_2O$, very soluble in water, by crystallization from a soln. of mercuric cyanide with an excess of cerium chloride

The crystals lose their water of crystallization at 100° or over sulphuric acid. They crystallize only from soln. containing an excess of the chloride.

J. J. Berzelius obtained **cerium oxychloride,** $CeOCl$, as a residue after heating the hydrated chloride in a retort; F. Wöhler, as a by-product in the preparation of cerium from cerium chloride and sodium, when the slag is treated with dil. acid; P. Didier, by the action of water vapour diluted with nitrogen on a molten mixture of cerous and sodium chlorides; C. G. Mosander by the action of a mixture of air and chlorine on heated cerium sulphide; and C. Erk, by the electrolysis of molten cerium chloride. The silver-white, mica-like crystals become yellow when exposed to the air; they form ceric sulphate with sulphuric acid; dissolve slowly in nitric acid; and are scarcely affected by hydrochloric acid. A. Beringer found that the oxychloride forms the oxide when strongly ignited in an open vessel.

Cerium tetrachloride, or **ceric chloride,** $CeCl_4$, has not been isolated. J. J. Berzelius obtained a dark red soln. of a ceric salt in cold conc. hydrochloric acid which is believed to contain the complex **hydrochloroceric acid,** H_2CeCl_6. This soln. decomposes slowly in the cold with the evolution of chlorine, the decomposition is rapid when the soln. is heated, and in either case cerous chloride remains. I. Koppel,[4] and A. J. Grant and C. James have prepared several double compounds of ceric chloride with the organic bases—pyridine, quinoline, etc.—by adding the base to a soln. of ceric chloride in a methyl alcohol soln. of hydrogen chloride. H. Arnold has prepared **ceric oxychloride,** $CeOCl_2$, by the electrolysis of slightly hydrated molten cerous chloride.

Anhydrous **lanthanum chloride,** $LaCl_3$, was prepared by C. G. Mosander[5] by evaporating a soln. of the oxide in hydrochloric acid to dryness, and heating the product in a stream of hydrogen chloride; M. Choubine also prepared it by heating the oxide in a stream of the same gas. The same salt has been prepared by several of the general methods—by heating the oxide in a mixture of sulphur monochloride and chlorine; the sulphide, or carbide in hydrogen chloride; the carbide in chlorine; and by heating the hydrated chloride with ammonium chloride. B. S. Hopkins and F. H. Driggs described the preparation of highly purified lanthanum chloride. The anhydrous chloride forms colourless crystals which, according to F. Bourion, melt at 890°, or, according to C. A. Matignon, at 907°; and solidify to long deliquescent needles recalling aragonite, and which, according to F. Bourion, have a sp. gr. of 3·79 at 0°, or, according to C. A. Matignon, 3·947 at 18°. C. A. Matignon also gives the heat of formation $(La,3Cl)=263$ Cals.; $La_2O_3+6HCl_{aq.}=2LaCl_{3aq.}+3H_2O+114{\cdot}6$ Cals., or $La_2O_3+6HCl=2LaCl_3+3H_2O+160{\cdot}6$ Cals. C. G. Mosander noted that the salt is very soluble in water with the evolution of a large amount of heat; for, according to C. A. Matignon, the heat of soln. is 31·3 Cals. W. W. Coblentz studied the ultra-red transmission spectrum. A. Voigt and W. Biltz measured the electrical conductivity of the fused chloride. According to H. Ley, the aq. soln. is very slightly hydrolyzed; the eq. conductivity rises from 105·8 for a dilution $v=32$ to 131·5 for a dilution $v=1024$, so that $\lambda_{1024}-\lambda_{32}=25{\cdot}7$. The aq. soln. was found by A. Beringer to deposit pale rose-coloured crystals, which, according to J. Watts, are white when quite pure. According to J. C. G. de Marignac, the triclinic crystals of **hexahydrated lanthanum chloride,** $LaCl_3.6H_2O$, have the axial ratios $a:b:c=1{\cdot}1593:1:0{\cdot}8659$; and $\alpha=91°\ 3'$; $\beta=114°\ 28'$; and $\gamma=88°\ 12'$, and are isomorphous with hexahydrated cerium chloride. C. Söderström obtained crystals of heptahydrated praseodymium chloride, $PrCl_3.7H_2O$, of the same form as J. C. G. de Marignac's hexahydrated lanthanum chloride. There is therefore some doubt about the water content of these hydrated salts. The formula $LaCl_3.7\frac{1}{2}H_2O$ has also been assigned to this salt. R. Hermann found that when **hydrated lanthanum chloride** is heated, it loses both water and hydrogen chloride, forming lanthanum oxychloride, $2LaCl_3.3La_2O_3$, as a white residue insoluble in water, and sparingly soluble in hydrochloric and nitric acids, and F. Frerichs obtained the oxychloride, $LaCl_3.La_2O_3$, that is, $LaOCl$, by heating lanthanum oxide to 200° in a stream of chlorine gas. The greyish-white powder yields but a trace of soluble matter when treated with water. The anhydrous and hydrated salts are both soluble in alcohol, and C. A. Matignon's value for the mol. wt. of the chloride by the b.p. method in alcoholic soln. corresponds with $LaCl_3$; according to R. J. Meyer and M. Koss, the alcoholic soln. deposits crystals of $LaCl_3.2C_2H_5OH$. B. J. Dryfuss and C. G. L. Wolf found that dil. soln. of lanthanum chloride have little or no effect on bacteria; and 0·8 per cent. soln. coagulates the proteins in serum; and 0·1 grm. injected hypodermically in guinea-pigs causes convulsions followed by death. Lanthanum chloride unites with a number of other metal chlorides, forming double salts. R. J. Meyer prepared hydrated **cæsium hexachlorolanthanate,** $LaCl_3.3CsCl.4$(or $5)H_2O$; J. C. G. de Marignac, colourless, double refracting crystals of dodecahydrated **mercuric henadecachlorolanthanate,** $LaCl_3.4HgCl_2.12H_2O$, easily soluble in water; J. E. Ahlen, needle-like crystals of octohydrated **mercuric hexacyanotrichlorolanthanate,** $LaCl_3.3HgCy_2.8H_2O$, like the cerium salt.

The properties of *didymium chloride*, $DiCl_3$, were investigated by J. C. G. de Marignac,[6] P. T. Cleve, L. F. Nilson, F. T. Frerichs and E. F. Smith. These became of less importance when it was discovered that didymium is a complex mixture of praseodymium and neodymium. J. O. Perrine found didymium chloride shows no ultra-violet fluorescence. The general methods for the preparation of the chlorides of the rare earths apply to anhydrous **praseodymium chloride,** $PrCl_3$, namely, the action of chlorine on the heated carbide; of hydrogen chloride on the heated sulphide; of a mixture of sulphur monochloride and chlorine on the heated oxide; and of hydrogen chloride on the heated hydrated chloride. Praseodymium chloride forms bluish-green, transparent, hygroscopic, needle-like crystals. The sp. gr. at 0° is given by F. Bourion as 4·07; by C. A. Matignon, at 18°, as 4·017; and by G. P. Baxter and O. J. Stewart, at 25°, as 4·020. According to F. Bourion, it melts at 810°, and, according to T. Vogt, at 818°, to form a black liquid. It is not volatile at 1000°, and, in general, it may be said that the chlorides of the cerium group—cerium, lanthanum, praseodymium, neodymium, and samarium—are less volatile than the metals of the yttrium group. A. Voigt and W. Biltz measured the electrical conductivity of the fused chloride. C. A. Matignon found that at 13·8°, 100 parts of water dissolve 103·9 parts of the anhydrous chloride. The aq. soln. of the chloride, or a soln. of the oxide in hydrochloric acid, furnishes large green crystals of **heptahydrated praseodymium chloride,** $PrCl_3.7H_2O$, which, according to C. von Scheele, have a sp. gr. of 2·251 at 150°, and melt in their water of crystallization at 115°—G. P. Baxter and O. J. Stewart say 111°. At 13·8°, C. A. Matignon says that 100 parts of water dissolve 334·2 parts of the heptahydrated chloride, and that the soln. is in equilibrium with the same salt. According to C. A. Matignon, the heat of the reaction $Pr_2O_3+6HCl=2PrCl_3+3H_2O+147{\cdot}8$ Cals.; and $Pr_2O_3+6HCl_{aq.}=2PrCl_{3aq.}+3H_2O+106{\cdot}2$ Cals. The anhydrous chloride is very soluble in water, and C. A. Matignon gives the heat of soln. $PrCl_3+Aq.=35{\cdot}5$ Cals.; for the heptahydrated chloride, $PrCl_3.7H_2O+Aq.=5{\cdot}3$ Cals.; and for the hydrated chloride, $PrCl_3.H_2O+Aq.=28{\cdot}9$ Cals. C. von Scheele says that the crystals of the heptahydrated chloride do not lose water when allowed to stand over sulphuric acid, but C. A. Matignon says that the crystals effloresce in air, forming **hexahydrated praseodymium chloride,** $PrCl_3.6H_2O$, that this salt can be slowly dehydrated to form **trihydrated praseodymium chloride,** $PrCl_3.3H_2O$; that when heated to 105°–130° in a stream of hydrogen chloride, it forms **monohydrated praseodymium chloride,** $PrCl_3.H_2O$; and that when heated to 180°–200° in the same gas the anhydrous chloride is formed. When heated in air to 115°, hydrogen chloride and water are given off and an oxychloride of indefinite composition remains; G. P. Baxter and O. J. Stewart formed **praseodymium oxychloride,** $PrOCl$, by heating the heptahydrated chloride in oxygen. F. T. Frerichs and E. F. Smith studied the properties of didymium oxychloride. K. A. Hofmann and K. Höschele obtained crystals of the oxychloride from a soln. of the oxide in fused magnesium chloride. The conc.

aq. soln. of praseodymium chloride dissolves considerable amounts of the rare earth oxalates. C. A. Matignon found that when praseodymium chloride is heated with hydrobromic or hydriodic acid the bromide or iodide respectively is formed. B. J. Dryfuss and C. G. L. Wolf find the physiological action is analogous to that of lanthanum chloride. Praseodymium chloride is very soluble in alcohol, and, according to B. Brauner, the mol. wt. in alcoholic soln. agrees with the simple formula $PrCl_3$. C. A. Matignon says that 100 grms. of pyridine dissolve 21·4 grms. of praseodymium chloride at 15°. Praseodymium forms double chlorides in the same way as cerium and lanthanum chlorides.

J. C. G. de Marignac prepared the *didymium mercuric chloride*, $2DiCl_3.9HgCl_2.24H_2O$, in deliquescent cubes; J. E. Ahlen, *didymium mercuric chlorocyanide*, $DiCl_3.3HgCy_2.8H_2O$; P. T. Cleve, *didymium stannic chloride*, $2DiCl_3.2SnCl_4.21H_2O$; L. F. Nilson, *didymium platinous chlorides*, or *didymium chloroplatinites*, $2DiCl_3.3PtCl_2.18H_2O$, and $DiCl_3.2PtCl_2.10H_2O$; P. T. Cleve, *didymium platinic chloride*, $2DiCl_3.2PtCl_4.21H_2O$, which F. T. Frerichs and E. F. Smith said had the composition $2DiCl_3.3PtCl_4.24H_2O$ of sp. gr. 2·41 at 16°; and yellow crystals of **auric hexachloropraseodymate**, *praseodymium chloroaurate*, $PrCl_3.AuCl_3.10H_2O$, which have a sp. gr. 2·60 at 15°, and which are very soluble in water. P. T. Cleve previously had prepared didymium auric chloride, $DiCl_3.AuCl_3.10H_2O$, and F. T. Frerichs and E. F. Smith, $2DiCl_3.3PtCl_4.24H_2O$. C. Soderström says the chloroplatinates of the cerium group are isomorphous crystallizing in tetragonal bipyramids the cerium salt has the axial ratio $a:c=1:1·1272$; and the praseodymium salt, $a:c=1:1·13$. Praseodymium chloride also forms double salts with many organic compounds.

Anhydrous **neodymium chloride,** $NdCl_3$, has been prepared in a similar manner to its companion praseodymium chloride. Neodymium chloride forms rose-pink, transparent, very hygroscopic crystals. F. Bourion[7] found the sp. gr. to be 4·14 at 0°; C. A. Matignon, 4·195 at 18°; and G. P. Baxter and H. C. Chapin, 4·134 at 25°. According to F. Bourion, neodymium chloride melts at 784°, forming a red liquid, although C. A. Matignon says that the salt becomes green in colour below the m.p. A. Voigt and W. Biltz measured the electrical conductivity of the fused chloride. C. A. Matignon found at 13°, 100 parts of water dissolve 96·68 parts of the salt at 13°, and 140 parts of the salt at 100°; in both cases, the soln. is in equilibrium with the hexahydrated chloride. The aq. soln. of the chloride furnishes large, rose-pink, rhombic prisms of **hexahydrated neodymium chloride,** $NdCl_3.6H_2O$, which have a sp. gr. 2·282 at 16·5°, and which are readily soluble in water, for 100 grms. of water at 13° dissolve 246·2 grms., and at 100°, 511·6 grms. The conc. aq. soln. dissolves neodymium oxalate on warming, and as the soln. is cooled crystals of *neodymium chloroxalate* separate out. According to C. A. Matignon, the heat of the reaction: $Nd_2O_3+6HCl_{aq.}=2NdCl_{3aq.}+3H_2O$, is +105·5 Cals.; the heat of soln. of the anhydrous chloride, 35·4 Cals.; and of the hexahydrated chloride, 7·6 Cals. When hexahydrated neodymium chloride is heated to 115° in a stream of hydrogen chloride, it forms **monohydrated neodymium chloride,** $NdCl_3.H_2O$, which loses all its water when the temp. is carried up to 160°, and the anhydrous chloride remains. By heating the hexahydrated chloride in air or steam, C. A. Matignon obtained mauve-coloured leaflets of **neodymium oxychloride,** $NdOCl$, which do not fuse at 1000°. K. A. Hofmann and K. Höschele obtained crystals from a soln. of the oxide in fused magnesium chloride. C. A. Matignon found that acetylene is polymerized catalytically when passed over heated neodymium chloride, graphite being simultaneously deposited. B. J. Dryfuss and C. G. L. Wolf observed that soln. of neodymium chloride have the same physiological action as the salts of praseodymium and lanthanum. Neodymium chloride is soluble in alcohol, and C. A. Matignon reports that 100 parts of this solvent at 20° dissolve 44·5 parts of the salt; the heat of soln. in alcohol is 21·5 Cals.; the mol. wt. in alcoholic soln. corresponds with the formula $NdCl_3$, and the alcoholic soln. deposits crystals of $NdCl_3.3C_2H_5OH$. Similarly, 100 parts of pyridine at 15° dissolve 1·8 parts of the salt, and the soln. deposits crystals of $NdCl_3.3C_5H_5N$. Other compounds with organic bases have been reported.

According to C. A. Matignon and R. Trannoy, when anhydrous neodymium chloride is exposed to the action of gaseous ammonia at a low temp. or is sealed in a tube with liquefied ammonia, it is converted into the additive compound, $NdCl_3.12NH_3$. This, on being gradually heated, dissociates, giving rise to a series of less complex additive products, the formulæ, dissociation temp., and heats of formation (in each case from the preceding compound in the list) of which are as follows: **neodymium monoamminochloride,** *360°, 20·2 Cals.;* **neodymium diamminochloride,** $NdCl_3.2NH_3$, 255°, 16·9 Cals.; **neodymium tetramminochloride,** $NdCl_3.4NH_3$, 157°, 13·7 Cals.; **neodymium pentamminochloride,** $NdCl_3.5NH_3$, 117°, 12·5 Cals.; **neodymium octamminochloride,** $NdCl_3.8NH_3$, 79°, 112 Cals.; **neodymium henadecamminochloride,** $NdCl_3.11NH_3$, 26°, 9·5 Cals.; and **neodymium dodecamminochloride,** $NdCl_3.12NH_3$, −10°, 8·4 Cals. The heats of formation were calculated from the law of the constant change of entropy.[8]

Anhydrous **samarium trichloride,** or *samarium chloride,* $SaCl_3$, can be prepared by the general methods for the anhydrous chlorides of the rare earths. C. A. Matignon,[9] and F. Bourion used the sulphur chloride process. O. J. Stewart and C. James made a highly purified chloride for their at. wt. determinations. Samarium chloride forms a hygroscopic crystalline powder with a faint yellow tinge. F. Bourion gives for the sp. gr. at 0°, 4·27; and C. A. Matignon, 4·465 at 18°. According to F. Bourion, samarium chloride melts at 686° to form a dark brown liquid. C. A. Matignon found the salt dissolves readily in water with a hissing noise, and the aq. soln. deposits large yellow plates of **hexahydrated samarium chloride,** $SaCl_3.6H_2O$, which, according to P. T. Cleve, have a sp. gr. 2·383. When the hexahydrated chloride is heated to 110° in a stream of hydrogen chloride, it forms **monohydrated samarium chloride,** $SaCl_3.H_2O$, which, under similar conditions, at 180°, forms the anhydrous salt. C. A. Matignon gives for the heat of the reaction: $Sa_2O_3+6HCl=2SaCl_3+3H_2O+128·4$ Cals.; for $Sa_2O_3+6HCl_{aq.}=2SaCl_{3aq.}+3H_2O+94·63$ Cals.; and for the heat of soln. of the anhydrous chloride, 37·4 Cals. When the anhydrous chloride is heated in oxygen, it forms **samarium oxychloride,** SaOCl, of sp. gr. 7·017, and P. T. Cleve prepared the same compound by calcining the oxide in chlorine. K. A. Hofmann and K. Höschele obtained crystals of the oxychloride from a soln. of the oxide in fused magnesium chloride. Samarium chloride is soluble in alcohol and in pyridine, and C. A. Matignon found 100 grms. of pyridine at 25° dissolve 6·38 grms. of chloride, and that when the pyridine soln. is heated, a gelatinous compound separates out, and this redissolves when the soln. is cooled. E. Fouard found that soln. of samarium chloride accelerate the oxidation of quinol more than do any of the other rare earth chlorides. C. A. Matignon and R. Trannoy found that when anhydrous samarium chloride is sealed in a tube with liquid ammonia, it is converted into a white, voluminous compound, $SaCl_3$, $11·5NH_3$, which, on being progessively heated, gives off its ammonia at eight different temp., which are the dissociation temp. of the eight compounds which samarium chloride forms with ammonia; the formulæ of the compounds, their dissociation temp. at 760 mm., and heats of formation, are, respectively, as follow: **samarium monoamminochloride,** $SaCl_3.NH_3$, 375°, 20·7 Cals.; **samarium diamminochloride,** $SaCl_3.2NH_3$, 240°, 16·4 Cals.; **samarium triamminochloride,** $SaCl_3.3NH_3$, 200°, 15·1 Cals.; **samarium tetramminochloride,** $SaCl_3.4NH_3$, 155°. 13·7 Cals.; **samarium pentamminochloride,** $SaCl_3.5NH_3$, 105°, 12·1 Cals.; **samarium octamminochloride,** $SaCl_3.8NH_3$, 76°, 11·2 Cals.; **samarium hemienneadecaamminochloride,** $SaCl_3.9\frac{1}{2}$(or 8)NH_3, 40°, 10·0 Cals.; and **samarium hemitricosiamminochloride,** $SaCl_3.11\frac{1}{2}NH_3$, 15°, 9·2 Cals. G. L. Clark discussed this subject. By mixing soln. of the component chlorides, P. T. Cleve prepared deliquescent orange-red prisms of platinic heptachlorosamarate, $SaCl_3.PtCl_4.10\frac{1}{2}H_2O$, of sp. gr. 2·712; and rhombic plates of auric hexachlorosamarate, $SaCl_3.AuCl_3.10H_2O$, of sp. gr. 2·742.

C. A. Matignon and E. Cazes prepared **samarium dichloride,** or *samarous* *chloride*, $SaCl_2$, by heating anhydrous samarium chloride in a current of dry hydrogen or ammonia; and by heating samarium trichloride with powdered aluminium. This compound forms dark reddish-brown crystals of sp. gr. 3·687 at 22°. It dissolves readily in water, forming a reddish-brown soln. which gradually loses its colour as hydrogen is evolved, and samarium hydroxide is precipitated: $6SaCl_2+6H_2O=4SaCl_3+2Sa(OH)_3+3H_2$; the rapidity with which the colour disappears is accelerated by shaking the soln. in air: $12SaCl_2+6H_2O+3O_2=8SaCl_3+4Sa(OH)_3$. Samarium subchloride is insoluble in alcohol, carbon disulphide, and other organic solvents.

Anhydrous **cerium tribromide,** $CeBr_3$, is white hygroscopic crystalline powder which can be made by one of the general methods—W. Muthmann and L. Stützel's,[10] H. Robinson's or F. Bourion's processes. The soln. in water is slightly acid; no definite hydrates have been reported, but a number of double salts have been obtained by S. Jolin, J. Dehnicke, and by G. T. Morgan and E. Cahen: J. Dehnicke made **antimony hexabromocerate,** $CeBr_3.SbBr_3.12H_2O$; **bismuth henicosibromocerate,** $CeBr_3.6BiBr_3.20H_2O$; **bismuth hexabromocerate,** $CeBr_3.BiBr_3.12H_2O$; **stannic heptabromocerate,** $CeBr_3.SnBr_4.10H_2O$; and **auric hexabromocerate,** $CeBr_3.AuBr_3.8H_2O$, was made by S. Jolin in dark brown deliquescent crystals. F. T. Frerichs and E. F. Smith made anhydrous **lanthanum bromide,** $LaBr_3$, by F. Bourion's process; E. Cahen heated lanthanum oxide in bromine vapour, but F. T. Frerichs and E. F. Smith found that **lanthanum oxybromide,** $LaOBr$, is so formed. The resulting white fused mass dissolves in water, producing a soln. which has no action on methyl orange but colours litmus wine red, because the soln. is slightly acid through hydrolysis. The aq. soln. obtained by dissolving lanthanum oxide in hydrobromic acid furnishes colourless crystals of **heptahydrated lanthanum bromide,** $LaBr_3.7H_2O$. These crystals are soluble in water and in alcohol, and form double salts with many metallic bromides; F. T. Frerichs and E. F. Smith made **zinc dodecabromolanthanate,** $2LaBr_3.3ZnBr_2.39H_2O$; and **nickel dodecabromolanthanate,** $2LaBr_3.3NiBr_2.18H_2O$; P. T. Cleve made **auric hexabromolanthanate,** $LaBr_3.AuBr_3.9H_2O$; J. Dehnicke made **bismuth hexabromolanthanate,** $LaBr_3.BiBr_3.12H_2O$; **antimony hexabromolanthanate,** $LaBr_3.SbBr_3.12H_2O$; and **antimony dodecabromolanthanate,** $LaBr_3.3SbBr_3.20H_2O$. F. Bourion prepared anhydrous **praseodymium bromide,** $PrBr_3$, by heating the brown oxide in the vapour of sulphur monochloride and hydrogen bromide. The green crystalline powder resembles the corresponding chloride; it dissolves slowly in water, forming a soln. which is slightly hydrolyzed. The aq. soln. of the oxide in hydrobromic acid furnishes green crystals of **hexahydrated praseodymium bromide,** $PrBr_3.6H_2O$. P. T. Cleve made deliquescent tabular crystals of **zinc enneabromodidymate,** $DiBr_3.3ZnBr_2.12H_2O$, to which F. T. Frerichs and E. F. Smith assigned the formula $2DiBr_3.3ZnBr_3.36H_2O$, and to the corresponding **nickel dodecabromodidymate,** $2DiBr_3.3NiBr_2.18H_2O$. P. T. Cleve made black deliquescent crystals of **auric hexabromodidymate,** $DiBr_3.AuBr_3.10H_2O$, of sp. gr. 3·304. Red crystals of **platinic heptabromopraseodymate,** $PrBr_3.PtBr_4.10H_2O$, of sp. gr. 2·41 at 16°. Anhydrous **neodymium bromide,** $NdBr_3$, was prepared by F. Bourion in a similar manner to the praseodymium salt. The green crystalline substance melts to a dark brown liquid. The aq. soln. is slightly hydrolyzed. Anhydrous **samarium bromide,** $SaBr_3$, was made by F. Bourion by passing the vapour of sulphur bromide and hydrogen bromide over the heated oxide. The yellow fused mass dissolves slowly in water, forming a soln. which is slightly hydrolyzed. According to P. T. Cleve, the aq. soln. obtained by dissolving the oxide in hydrobromic acid forms yellow deliquescent crystals of **hexahydrated samarium bromide,** $SaBr_3.6H_2O$, of sp. gr. 2·971; it also forms with auric bromide, **auric hexabromosamarate,** $SaBr_3.AuBr_3.10H_2O$.

The iodides of the rare earths have been studied even less than the bromides. L. T. Lange[11] made colourless crystals of **enneahydrated cerium iodide,** $CeI_3.9H_2O$, by evaporating in vacuo over sulphuric acid a soln. of cerium dioxide in hydriodic acid. The crystals turn brown when exposed to air owing to the separation of iodine.

Lanthanum iodide has been reported, and the equilibrium conditions in the presence of iodine whereby a polyiodide is produced, have been studied by R. G. van Name and W. G. Brown, but T. F. Frerichs and E. F. Smith prepared **zinc dodecaiodolanthanate,** $2LaI_3.3ZnI_2.27H_2O$, in hygroscopic needle-like crystals. C. A. Matignon has prepared **praseodymium iodide,** PrI_3, and also **neodymium iodide,** NdI_3, by the action of hydrogen iodide on the anhydrous chlorides heated just below their melting points. According to C. A. Matignon, neodymium iodide melts to a black liquid, which at a higher temp. becomes transparent owing to the formation of an allotropic modification. C. A. Matignon also made **samarium triiodide,** SaI_3, in a similar manner to the neodymium salt. The orange-yellow crystals become deeper in colour as the temp. is raised and pass through orange, brick-red, and finally, at 800°, black. When heated to a high temp. in a stream of hydrogen iodide, yellow **samarium diiodide,** SaI_2, is formed. This compound dissolves in water, forming a brown soln. which, on standing, loses its colour and deposits gelatinous samarium hydroxide.

§ 15. The Sulphides of the Cerium Metals

The sulphides of the rare earths have not been prepared in the wet way, *i.e.* by the action of hydrogen sulphide, or of ammonium or alkali sulphide on aq. soln. of the salts. When ammonium or an alkali sulphide is added to an aq. soln. of a salt of the rare earths, the hydroxide is precipitated. Hydrogen sulphide has no perceptible action. In this respect, the rare earth metals resemble aluminium and chromium; but unlike these elements, the cerium metals furnish sulphides which are fairly stable in contact with water at ordinary temp. The normal sulphides are of the sesquisulphide type, R_2S_3; but they also form polysulphides, and some oxysulphides have been reported.

C. G. Mosander[1] made **cerium sulphide,** Ce_2S_3, by heating the metal in the vapour of sulphur, and by passing the vapour of carbon disulphide over heated cerous carbonate. A. Beringer substituted ceric oxide in place of the carbonate. F. T. Frerichs and E. F. Smith also prepared cerium sulphide by this process. P. Didier prepared this sulphide by passing a current of dry hydrogen sulphide over *a fused mixture of sodium chloride and anhydrous cerium chloride, and extracting the soluble salts with cold water. According to C. G. Mosander, when a mixture of ceric oxide (or cerium chloride) with three times its weight of potassium polysulphide (liver of sulphur), is strongly heated in a covered vessel for half an hour, and the potassium sulphide removed by leaching with water, small crystalline scales of cerium sulphide* are formed; they have a yellow or yellowish-green colour like mosaic gold. W. Muthmann and L. Stützel did not succeed in making the gold-yellow crystalline sulphide by this process; and J. Sterba said that C. G. Mosander's crystalline sulphide was really crystalline ferric sulphide. A. Beringer claimed to have made a crystalline variety resembling C. G. Mosander's cerium sulphide by using sodium polysulphide in place of potassium polysulphide; but this is probably a similar mal-observation.

C. G. Mosander also prepared **lanthanum sulphide,** La_2S_3, by the carbon disulphide process. T. Lange, R. Hermann, and F. T. Frerichs and E. F. Smith also prepared lanthanum sulphide by the processes employed for cerium sulphide. W. Muthmann and L. Stützel prepared it by a process similar to that employed for cerium sulphide, namely, by heating the anhydrous sulphate in a stream of hydrogen sulphide. W. Biltz showed that the disulphide, LaS_2, is first formed, and if the temp. exceeds 650°, the latter compound is converted to the sesquisulphide. F. T. Frerichs and E. F. Smith prepared *didymium sulphide* by C. G. Mosander's carbon disulphide process. W. Muthmann and L. Stützel prepared **praseodymium sulphide,** Pr_2S_3, and **neodymium sulphide,** Nd_2S_3, by the same process as that employed for the lanthanum and cerium sulphides. W. Biltz observed that as in the case of lanthanum, praseodymium disulphide is formed if the temp. be not high enough. H. Moissan found that if sulphur vapour be passed over praseodymium carbide at 1000°, a mixture of the sulphide and graphite is formed. H. Erdmann and F. Wirth prepared **samarium sulphide,** Sa_2S_3, by heating the anhydrous sulphate in a stream of dry hydrogen sulphide. H. Moissan made samarium sulphide by the action of sulphur vapour or hydrogen sulphide on samarium carbide heated to a high temp.; and C. A. Matignon made it by passing dry hydrogen sulphide on heated anhydrous samarium chloride.

Cerium sulphide, as prepared by P. Didier, was a porous mass, and vermilion or black according to the temp. of preparation; the crystals he made were red and translucent. W. Biltz said cerium sesquisulphide is red. W. Muthmann and L. Stützel's process furnishes black, or brownish-black, pulverulent cerium sulphide; yellow lanthanum sulphide; chocolate-brown praseodymium sulphide; and olive-green neodymium sulphide; H. Erdmann and F. Wirth's samarium sulphide was a yellow powder. P. Didier's cerium sulphide had a sp. gr. 5·1, and W. Muthmann and L. Stützel's, 5·020 at 11°, while the lanthanum sulphide had a sp. gr. 4·9108 at 11°; praseodymium sulphide, 5·042 at 11°; and neodymium sulphide, 5·179 at 11°; and H. Erdmann and F. Wirth's samarium sulphide, 3·7. All agree that the sulphides are fairly stable in air at ordinary temp., but if heated in air, they burn with a blue flame, forming sulphur dioxide, and a mixture of oxide and sulphate is formed, or, as C. G. Mosander expressed it with respect to cerium sulphide, the product of the combustion is a basic cerium sulphate. W. Muthmann and L. Stützel found that finely divided cerium sulphide ignites spontaneously in air at ordinary temp. J. Sterba said that the spontaneous ignition occurs only when cerium oxysulphide has been produced by using moist hydrogen sulphide. All agree that the sulphides are slowly hydrolyzed by hot water with the evolution of hydrogen sulphide; the hydrolysis is fastest with lanthanum sulphide. The sulphides are dissolved by dil. acids with the evolution of hydrogen sulphide. Cerium sulphide, said P. Didier, dissolves even in acetic acid without the separation of sulphur; and when treated with alkali sulphide it undergoes alteration, but does not become crystalline. C. G. Mosander said that a soln. of potassium hydroxide converts cerium sulphide into a green powder which appears to be an oxysulphide. W. Muthmann and L. Stützel found that dry hydrogen chloride or bromide passed over the dry sulphide furnishes the corresponding cerium, lanthanum, praseodymium, or neodymium halide. According to C. G. Mosander, when cerium sulphide is heated in chlorine gas it is resolved into cerium and sulphur chlorides, but it is not altered by heating it in the vapour of iodine, phosphorus, or potassium.

In 1826, C. G. Mosander said that cerium disulphide had not been isolated, and was known only in combination with electronegative metal sulphides. W. Biltz passed a current of hydrogen sulphide over cerium sulphide at 580°-600°, and found that in about 20 hrs., 2 to 3 grms. of the sesquisulphide were converted into **cerium disulphide,** Ce_2S_4. The progress of the formation of the polysulphide is best followed by weighing from time to time, but since cerium oxysulphide has also been obtained, of approximately the same weight per mol, a complete analysis is necessary to characterize the compound. Cerium disulphide is a dark yellowish-brown crystalline powder, moderately stable in air and in cold water. A 17·7 per cent. soln. of hydrochloric acid dissolves the disulphide in the cold, and an odour of hydrogen persulphide is perceptible, and sulphur is afterwards deposited. This is taken to prove that the disulphide is not a true analogue of the dioxide, but is rather a polysulphide, $Ce_2S_3.S$. The conversion of the disulphide into the sesquisulphide has been examined up to 1200°. The temp. of decomposition is about 720°; the lower sulphide is stable at a red heat, and does not react with hydrogen or nitrogen at that temp., but between 1400° and 1500° it melts and decomposes. The sesquisulphide prepared at 745°, when heated in a current of hydrogen sulphide for thirty hours at 615°, did not reabsorb sulphur. This irreversibility is only apparent, as by heating the disulphide in a current of hydrogen at 400° the sesquisulphide was obtained, and this product reabsorbed 4·2 per cent. sulphur. The heat of soln. of the disulphide, CeS_2, in hydrochloric acid is 32,500 cals.; that of $CeS_{1·5}$, 37,800 cals. (39,500 cals. from the product prepared at 400°). From these figures, the equation $4CeS_2=2Ce_2S_3+2S_{(amorp.)}-18,600$ cals. is calculated. By the use of Nernst's equation for heterogeneous equilibria, the decomposition temp. is calculated to be 793°, whereas that found was roughly 720°.

W. Biltz prepared **lanthanum disulphide,** LaS_2, by heating anhydrous lanthanum sulphate at 580°-600° in a current of hydrogen sulphide. The product behaves as a polysulphide, $La_2S_3.S$, and it decomposes when more strongly heated at about 650°. A comparison of the heat of soln. of the two sulphides in hydrochloric acid gives the result $4LaS_2=2La_2S_3+S_{2(gas)}-43·4$ cals. This gives a theoretical dissociation temp. of 670°, about 100° lower than that of cerium disulphide. The action of hydrogen sulphide on anhydrous praseodymium sulphate results only in the formation of **praseodymium oxysulphide,** Pr_2SO_2. Sulphides free from oxygen are only obtained in the presence of some cerium. In the same way, cerium is known to assist the formation of praseodymium peroxide. **Praseodymium**

disulphide, PrS_2, dissociates at a temp. near that of the lanthanum compound. J. J. Berzelius and W. Hisinger mentioned the formation of an apple-green powder of **cerium oxysulphide** by heating cerous carbonate with sulphur, or in a stream of hydrogen sulphide. A little basic sulphate is usually present. Acids decompose the oxysulphide with the evolution of hydrogen sulphide and the separation of sulphur. C. G. Mosander also mentioned cerium oxysulphide—*vide supra*—but W. Muthmann and L. Stützel could not obtain this product. W. Biltz prepared cerium oxysulphide, $Ce_2S_{2\frac{1}{4}}OS$; and J. Sterba also obtained an oxysulphide by using moist instead of dry hydrogen sulphide in the preparation of cerium sulphide.

§ 16. The Sulphates of the Cerium Metals

J. J. Berzelius and W. Hisinger[1] made anhydrous **cerous sulphate,** $Ce_2(SO_4)_3$, by dissolving the carbonate in cold dil. sulphuric acid. The hydroxide or oxide can be used ; if ceric oxide be used a little reducing agent like hydroquinone is added to reduce ceric to cerous sulphate. P. Berthier dissolved ceric oxide in sulphurous acid. The aq. soln. is evaporated for crystallization, and the crystals are dehydrated by heat. B. Brauner and co-workers, and G. Wyrouboff and A. Verneuil showed that the temp. of dehydration should be 400°–450°—if it exceeds 500°, the sulphate begins to decompose. E. Löwenstein measured the vap. press. of hydrated cerium sulphate, and found evidence of the existence of the octo-, penta-, tetra-, and di-hydrates. M. Stuart found an efflorescence of cerium sulphate on some graphite from Velland, Travancore. Anhydrous cerium sulphate thus prepared is a white hygroscopic powder. Anhydrous **lanthanum sulphate,** $La_2(SO_4)_3$, is also a white hygroscopic powder, and it is prepared in a similar way. B. Brauner and F. Pavlicek, and H. C. Jones showed that the dehydration must be carried out at 600°–650°, for if the temp. be less, the whole of the water will not be expelled, or some acid sulphate will remain undecomposed. E. Löwenstein measured the vap. press. of hydrated lanthanum sulphate, and found evidence of the existence of the ennea-, hexa-, and tri-hydrates. He also obtained the octo-, hexa-, and penta-hydrates of didymium sulphate. The sulphates of the remaining members of the family are hygroscopic powders, and are obtained in a similar manner—anhydrous **praseodymium sulphate,** $Pr_2(SO_4)_3$, is light green ; anhydrous **neodymium sulphate,** $Nd_2(SO_4)_3$, is light red ; and anhydrous **samarium sulphate,** $Sa_2(SO_4)_3$, is pale yellow ; B. D. Keyes and C. James thus describe the preparation of samarium sulphate in the following manner :

> Samarium oxalate was ignited and the oxide dissolved in hydrochloric acid. To the cool soln. there was added a little more sulphuric acid than was required to unite with the samarium present, after which the mixture was poured into a large excess of alcohol. The precipitated sulphate was filtered off, washed with alcohol and rendered anhydrous by heating. The anhydrous sulphate was dissolved in water, filtered, and the filtrate evaporated upon the steam-bath. The purified salt was then dried and very finely powdered.

The sp. gr. of anhydrous cerous, lanthanum, and praseodymium sulphates are respectively 3·91, 3·60, and 3·726 at 15·8°. L. F. Nilson and O. Pettersson gave for the sp. ht. of anhydrous cerous, lanthanum, and didymium sulphates 0·1168, 0·1182, and 0·1187 between 0° and 100° ; and for the corresponding mol. ht., 66·23, 66·90, and 68·96. B. Brauner represented the sp. gr. of soln. of cerous sulphate containing *p* parts of $Ce_2(SO_4)_3$ in 100 parts of water, at 15° :

p	2	4	6	8	10	12	14
Sp. gr.	1·01888	1·03796	1·05691	1·07572	1·09441	1·11296	1·13137

or sp. gr. $=0{\cdot}999665+0{\cdot}0096401p+0{\cdot}0000166p^2$. C. von Scheele gave for anhydrous praseodymium sulphate the sp. gr. 3·720. According to G. Wyrouboff and A. Verneuil, and B. Brauner and A. Batek, cerous sulphate begins to decompose at 500°, and at a white heat it is completely converted into the dioxide. The other sulphates behave similarly, but lanthanum sulphate resists thermal decomposition better than any of the rare earth sulphates. L. Wöhler and M. Grünzweig measured the dissociation press. of some rare earth sulphates between 800° and 1020° with the idea of obtaining a measure of the basicity of the rare earths. The following represents the partial press., *p*, of the sulphur trioxide, and the heats of dissociation, *Q*, at 900°. The values of *Q* were computed from Nernst's theorem.

	La	Pr	Nd	Sa
Press. of SO_3 at 900°	2	5·5	6·0	8·0
Heat of dissociation	59·8	57·4	57·2	56·6

E. Wedekind and C. Hausknecht found the at. magnetism of cerous (Ce^{III}) sulphate to be $+2200\times10^{-6}$; ceric (Ce^{IV}) sulphate, $+37{\cdot}5\times10^{-6}$; lanthanum sulphate, -84×10^{-6}; praseodymium sulphate, $+5100\times10^{-6}$; neodymium sulphate, $+5270\times10^{-6}$. The different observers agree that the rare earth sulphates are completely decomposed only at a white heat ; and when heated between 900° and 1000°—L. Wöhler and M. Grünzweig said between 800° and 850°—the products are often called **basic sulphates,** or oxysulphates, and represented by the formula $R_2O_3.SO_3$, or $R_2O_2SO_4$. C. A. Matignon said that **praseodymium dioxysulphate,** $Pr_2O_2SO_4$, and **neodymium dioxysulphate,** $Nd_2O_2SO_4$, are amorphous powders insoluble in water or cold dil. sulphuric acid, and stable at 1000° ; the former is green, the latter pink ; **samarium dioxysulphate,** $Sa_2O_2SO_4$, has similar properties, and it is pale yellow. L. Wöhler and M. Grünzweig obtained **lanthanum dioxysulphate,** $La_2O_2SO_4$, and **cerous dioxysulphate,** $Ce_2O_2SO_4$.

L. Pissarjewsky gave for the heats of formation of some rare earth sulphates $2\{Ce(OH)_3.O.OH\}+3H_2SO_{4aq}=Ce_2(SO_4)_{3aq}+H_2O_{2aq}+O_2+29{\cdot}95$ Cals. ; C. A. Matignon, $La_2O_3+3H_2SO_4=La_2(SO_4)_3+3H_2O+138{\cdot}2$ Cals. ; and $La_2(SO_4)_3+Aq.=La_2(SO_4)_{3aq.}+34{\cdot}6$ Cals. ; $Pr_2O_3+3H_2SO_4=Pr_2(SO_4)_3+3H_2O+125{\cdot}7$ Cals. ; and $Pr_2(SO_4)_3+Aq.=Pr_2(SO_4)_{3aq.}+36{\cdot}0$ Cals. ; $2Nd+3S+6O_2=Nd_2(SO_4)_3+928{\cdot}2$ Cals. ; $2Nd+3S+6O_2+8H_2O=Nd_2(SO_4)_3.8H_2O+946{\cdot}8$ Cals ; $Nd_2O_3+3H_2SO_4=Nd_2(SO_4)_3+3H_2O+125{\cdot}1$ Cals. ; $Nd_2O_3+3H_2SO_{4aq.}=Nd_2(SO_4)_{3aq.}+3H_2O+106{\cdot}4$ Cals. ; $Nd_2(SO_4)_3+Aq.=Nd_2(SO_4)_{3aq.}+36{\cdot}5$ Cals. ; $Nd_2(SO_4)_3.5H_2O+Aq.=Nd_2(SO_4)_{3aq.}+8{\cdot}3$ Cals. ; and $Nd_2(SO_4)_3.8H_2O+Aq.=Nd_2(SO_4)_{3aq.}+6{\cdot}7$ Cals. ; $Sa_2O_3+3H_2SO_4=Sa_2(SO_4)_3+3H_2O+113{\cdot}8$ Cals. ; and $Sa_2(SO_4)_3+Aq.=Sa_2(SO_4)_{3aq.}+38{\cdot}8$ Cals. The electrical conductivities of aq. soln. of cerous sulphate have been determined by A. Aufrecht and K. Holmberg. The eq. conductivities of soln. of a gram eq. of the salts in *v* litres of water at 25° are as follow :

$Ce_2(SO_4)_3$	v	33	66	132	264	528	1056
	λ	45·66	53·71	63·63	74·09	87·17	100·90
$La_2(SO_4)_3$	v	33·86	67·72	135·44	270·88	541·76	1083·25
	λ	43·58	50·30	58·49	68·89	80·93	96·26
$Pr_2(SO_4)_3$	v	3·46	13·84	55·36	110·72	442·88	885·76
	λ	26·46	36·12	49·14	58·41	67·40	92·70
$Nd_2(SO_4)_3$	v	33·47	66·94	133·88	267·76	535·52	1071·04
	λ	40·61	48·15	—	62·23	80·21	95·95
$Sa_2(SO_4)_3$	v	31·35	62·70	125·40	250·80	501·60	1003·2
	λ	31·17	43·49	51·59	61·39	72·76	89·24

Those of praseodymium sulphate were measured by H. C. Jones and H. M. Reese, C. von Scheele and A. Aufrecht; those of lanthanum sulphate, by K. Holmberg, A. A. Noyes and J. Johnston, A. Aufrecht; those of neodymium sulphates, by H. C. Jones and H. M. Reese, A. Aufrecht; and those of samarium sulphates, by A. Aufrecht, A. A. Noyes and J. J. Johnston gave for the percentage ionization of soln. of lanthanum sulphate :

v	5	10	20	80	500	∞
Percentage ionization .	13·2	15·8	19·10	27·8	45·0	100

A. Aufrecht calculated the degrees of ionization of soln. of neodymium and of praseodymium sulphates from the lowering of the f.p. of aq. soln., and found for v=2·54 and 92·61, the percentage ionization of praseodymium sulphate in aq. soln. was respectively 29 and 88 ; with soln. of neodymium sulphate, v=4·65 and 5·72, the percentage degree of ionization was 40 and 72 respectively. According to S. H. Katz and C. James, aq. soln. of samarium sulphate are slightly hydrolyzed.

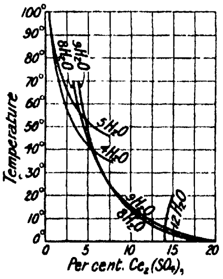

FIG. 19.—Solubility of Cerous Sulphate in Water.

The hydrated forms of these sulphates are best considered in connection with the solubility curves, *i.e.* the equilibrium conditions in connection with the binary system, $R_2(SO_4)_3-H_2O$. F. J. Otto showed that when anhydrous cerous sulphate is sprinkled with water, much heat is evolved, and the mixture cools to a solid mass which dissolves with difficulty. The early observers noted that if a soln. of the salt in cold water be heated, pale red crystals of a hydrate—they thought sesquihydrate—are deposited, and the crystals redissolve as the liquid cools. The solubility of cerous sulphate in cold water is greater than that of magnesium sulphate, and it exhibits a very different behaviour from that shown by the alkaline earth sulphates. The phenomenon is related with that shown by thorium sulphate investigated by H. W. B. Roozeboom. Measurements of the solubility of cerous sulphate in water made by B. Brauner, H. Bührig, F. Wirth, W. Muthmann and H. Rölig, and by G. Wyrouboff, were shown by J. Koppel to be inaccurate. There are at least five definite hydrates, and the ranges of stability and transition points are indicated in Fig. 19. The *dodecahydrate*, $Ce_2(SO_4)_3.12H_2O$, was obtained as a mass of felted needle-like crystals, by W. Muthmann and H. Rölig, G. Wyrouboff, and J. Koppel, by the evaporation of a sat. soln. of the anhydrous salt, at 0°, over sulphuric acid; by S. Jolin, by evaporating a soln., at 0°, in air; or, by stirring the lower hydrates with ice-cold water. The solubilities of the dodecahydrate at 0°, 18·8°, and 19·2° are respectively 14·20, 14·91, and 15·04 grms. of $Ce_2(SO_4)_3$ per 100 grms. of soln. At 16°, the dodecahydrate slowly passes into the octohydrate, although it is stable in contact with the soln. only between 0° and 3°. The *enneahydrate*, $Ce_2(SO_4)_3.9H_2O$, was prepared by C. M. Marx, J. J. Berzelius and W. Hisinger, L. N. Vauquelin, M. H. Klaproth, C. Czudnowitz, R. Hermann, E. H. Kraus, J. C. G. de Marignac, F. J. Otto, G. Wyrouboff, etc. According to J. Koppel, the enneahydrate is obtained by the slow evaporation of a sat., but not supersat., soln. of the sulphate at 40° to 45°, and seeding with a crystal of the enneahydrate. If the soln. be not seeded, a mixture of the octo- and ennea-hydrates will be obtained. The percentage solubilities of the enneahydrate, *i.e.* the number of grams of $Ce_2(SO_4)_3$ per 100 grms. of soln., are as follow :

	0°	15°	21°	31·6°	45·6°	50°	60°	65°
$Ce_2(SO_4)_3$ . .	17·35	10·61	8·863	6·686	4·910	4·465	3·73	3·47

The enneahydrate is stable in contact with the soln. between 33° and 41°, Fig. 19. The *octohydrate*, $Ce_2(SO_4)_3.8H_2O$, was described by R. Hermann, J. C. G. de Marignac, A. des Cloizeaux, G. Wyrouboff, etc. According to J. Koppel, the octohydrate is obtained by crystallization from soln. between 30° and 70°. The percentage solubility of the octohydrate is:

	0°	15°	20·5°	40°	60°
$Ce_2(SO_4)_3$	15·95	9·95	8·69	5·613	3·88

The octohydrate is stable in contact with the soln. between 3° and 33°, Fig. 19, and at the transition point 70°, it passes spontaneously into the pentahydrate. R. Hermann, and S. Jolin reported a *hexahydrate*, but neither W. Muthmann and H. Rölig, nor J. Koppel were able to confirm this. G. Wyrouboff suggested that the alleged hexahydrate is a mixture of the octohydrate and pentahydrate. F. J. Otto, C. Czudnowitz, S. Jolin, R. Hermann, C. Wolf, C. H. Wing, J. Thomsen, W. Muthmann and H. Rölig, etc., made the *pentahydrate*, $Ce_2(SO_4)_3.5H_2O$, by heating an aq. soln. of cerium sulphate, and pouring off the liquid from the crystals which separate. The percentage solubility is:

	45°	60°	80°	100·5°
$Ce_2(SO_4)_3$	8·116	3·145	1·19	0·46

The pentahydrate is stable in contact with the soln. between 56° and 100·5°, Fig. 19. G. Wyrouboff noticed that the crystals of the octohydrate become opaque at 100° or more slowly on a summer's day, owing to the formation of a *tetrahydrate*, $Ce_2(SO_4)_3.4H_2O$. The crystals were obtained by J. Koppel by heating the enneahydrate with a little water at 70° or by evaporating a one per cent. soln. on the water-bath, and sowing with crystals of the tetrahydrate. The percentage solubility is:

	35°	40°	50°	65°	82°	100·5°
$Ce_2(SO_4)_3$ . . .	7·8	5·71	3·31	1·85	0·98	0·42

The tetrahydrate is stable in contact with a soln. between 41° and 100·5°.

According to W. Ostwald, the solubility of the different solids which a substance can form with the same solvent in corresponding soln. is inversely as their stability, so that the most stable form has the smallest solubility, and the least stable form the greatest solubility. Suppose that at a given temp., the stable octohydrate had a greater solubility than the labile pentahydrate, then a sat. soln. of the latter could still dissolve some of the former. Suppose that a soln., saturated with respect to the octohydrate, and supersaturated with the pentahydrate, be sown with the pentahydrate, that hydrate separates out until the soln. is sat. with respect to the pentahydrate. It is thus possible to convert the octohydrate into the pentahydrate without the consumption of energy. This, however, is contrary to the original assumption that the pentahydrate is the labile form, and hence the solubility of the pentahydrate must be greater than that of the octohydrate. J. Koppel has given a general demonstration of the original proposition. The solubility determinations by J. Koppel are in agreement with this rule, but this is not the case with the determinations of W. Muthmann and H. Rölig.

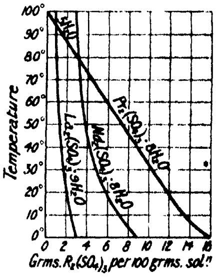

FIG. 20.—The Solubility of Lanthanum, Neodymium, and Praseodymium Sulphates.

C. F. Rammelsberg, P. A. Bolley, and C. G. Mosander prepared crystals of lanthanum sulphate. The last-named found that 100 parts of water dissolve 16·67 parts of *enneahydrated lanthanum sulphate*, $La_2(SO_4)_3.9H_2O$, at 2°; 2·35 parts at 23°; and 1·89 parts at 100°. W. Muthmann and H. Rölig gave for the percentage solubility:

	0°	14°	30°	50°	75°	100°
$La_2(SO_4)_3$ . . .	2·91	2·53	1·86	1·47	0·95	0·68

with the enneahydrate as solid phase, Fig. 20. The enneahydrate is readily made by warming a 15 per cent. ice-cold soln. of lanthanum sulphate to 30°. According to B. Brauner and F. Pavlicek, fine needles of the *hexadecahydrate*, $La_2(SO_4)_3.16H_2O$, separate from the ice-cold sat. soln. This hydrate is unstable and decomposes at 0°; F. T. Frerichs and E. F. Smith said that the *hexahydrate*, $La_2(SO_4)_3.6H_2O$, separates from a strongly acid soln. of lanthanum sulphate. According to G. Eberhard, and C. von Scheele, 100 parts of water dissolve 23·64 parts of praseodymium sulphate at 0°; and 17·7 parts at 20°. W. Muthmann and H. Rölig found the percentage solubility to be:

	0°	18°	35°	55°	75°	85°	95°
$Pr_2(SO_4)_3$ . .	16·5	12·3	9·4	6·6	4·1	1·5	1·0
Solid phase . .	$Pr_2(SO_4)_3.8H_2O$					$Pr_2(SO_4)_3\ 5H_2O$	

The results are plotted in Fig. 20. C. von Scheele found the hydrate, $Pr_2(SO_4)_3.15\frac{1}{2}H_2O$, to be formed by the crystallization of a dil. soln. at ordinary temp., and W. Muthmann and H. Rölig, the *dodecahydrate*, $Pr_2(SO_4)_3.12H_2O$, at temp. in the vicinity of 0°, and it resembles the corresponding cerium sulphate; at ordinary temp. it passes into the *octohydrate*, $Pr_2(SO_4)_3.8H_2O$, which separates from aq. soln. between 0° and 75°. Near 75°, it changes to the *pentahydrate*, $Pr_2(SO_4)_3.5H_2O$, which crystallizes from the soln. between 90° and 100°. B. Brauner mentioned a *hexahydrate*, $Pr_2(SO_4)_3.6H_2O$, but this has not been confirmed. W. Muthmann and H. Rölig found the percentage solubility of neodymium sulphate to be:

	0°	16°	30°	50°	80°	108°
$Nd_2(SO_4)_3$	8·7	6·6	4·7	3·5	2·6	2·2

The solid phase is the *octohydrate*, $Nd_2(SO_4)_3.8H_2O$, Fig. 20. C. A. Matignon mentioned a *pentahydrate*, $Nd_2(SO_4)_3.5H_2O$, but this has not been confirmed. The octohydrate, $Sa_2(SO_4)_3.8H_2O$, is the only known hydrate of samarium sulphate. F. Wirth gave for the percentage solubility of octohydrated samarium sulphate, 3·426 grms. of anhydrous sulphate in 100 grms. of liquid at 25°. F. Wirth gives for the percentage solubilities, *i.e.* the number of grams of the anhydrous sulphate in 100 grms. of soln. at 25°, the following:

$La_2(SO_4)_3,9H_2O$	$Ce_2(SO_4)_3.8H_2O$	$Pr_2(SO_4)_3.8H_2O$	$Nd_2(SO_4)_3.8H_2O$	$Sa_2(SO_4)_3.8H_2O$
2·483	7·600	11·110	5·30	3·426

The crystals of the dodecahydrates have not been obtained in a form suitable for measurement. The hexagonal bipyramidal crystals of enneahydrated cerium sulphate were measured by J. C. G. de Marignac, and E. H. Kraus; the former gave for the axial ratio $a : c = 1 : 0·73100$; and the latter, 1 : 0·72958. The crystals of enneahydrated lanthanum sulphate were measured by J. C. G. de Marignac, H. Töpsöe, and E. H. Kraus. They are isomorphous with those of the corresponding cerium salt, and, according to the last-named, have the axial ratio $a : c = 1 : 0·7356$. E. H. Kraus examined the corrosion figures of both salts; and showed that the double refraction is feebly positive. H. Töpsöe gave 2·827 for the sp. gr. of the lanthanum salt, and E. H. Kraus, 2·821. G. Wyrouboff gave 2·841 for the sp. gr. of the cerium salt, and E. H. Kraus, 2·831. P. T. Cleve gave 3·898 for the sp. gr. of the samarium salt at 18·3°.

The hydrated crystals and aq. soln. of cerous and lanthanum sulphates are colourless; those of praseodymium sulphate are green; those of neodymium sulphate are rose-red; and those of samarium sulphate are yellow. J. C. G. de Marignac regarded the crystals of octohydrated cerium sulphate as combinations of bipyramidal rhombic crystals; B. Brauner, and A. des Cloizeaux agreed with this, but G. Wyrouboff showed that the crystals are pseudorhombic, and are really twinned triclinic crystals, devoid of all elements of symmetry, with axial ratios $a : b : c = 1·0650 : 1 : 1·1144$, and $\alpha = 90° 52'$, $\beta = 90° 40'$, and $\gamma = 91° 45'$. The double refraction is strongly negative. G. Wyrouboff gave 2·886 for the sp. gr. of the crystals. Octohydrated cerous sulphate is dimorphous. C. F. Rammelsberg treated a soln. of cerosoceric sulphate with hot water; the filtrate from the basic ceric sulphate furnished monoclinic prismatic crystals of octohydrated cerous sulphate with the axial ratios $a:b:c=2{\cdot}9398:1:2{\cdot}0302$, and $\beta=117°\ 15'$. E. H. Kraus, B. Brauner, and H. Dufet examined the crystals of octohydrated praseodymium sulphate. The monoclinic prisms, said E. H. Kraus, have the axial ratios $a:b:c=2{\cdot}9863:1:1{\cdot}9995$, and $\beta=118°\ 0'$; he also studied the corrosion figures. E. H. Kraus gave 2·819 for the sp. gr.; and C. von Scheele, 2·882. The double refraction is feebly positive, and the crystals exhibit a feeble anomalous dispersion. H. Dufet gave for the indices of refraction for Li-, Na-, and Tl-light respectively $\alpha=1{\cdot}5366$, 1·5399, and 1·5430; $\beta=1{\cdot}5459$, 1·5494, and 1·5525; and $\gamma=1{\cdot}5573$, 1·5607, and 1·5641. He also studied the absorption spectrum of the salt. For monoclinic prismatic crystals of octohydrated neodymium sulphate H. Dufet gave the axial ratios $a:b:c=2{\cdot}9835:1:1{\cdot}9968$, and 118° 8·5′. B. Brauner also studied the crystals. E. H. Kraus gave 2·850 for the sp. gr. The double refraction is positive, and it exhibits an anomalous dispersion. H. Dufet gave for the indices of refraction for Li-, Na-, and Tl-light, respectively $\alpha=1{\cdot}5379$, 1·5413, and 1·5441; $\beta=1{\cdot}5469$, 1·5505, and 1·5534; and $\gamma=1{\cdot}5583$, 1·5621, and 1·5652. The pleochroism is weak. H. Dufet studied the absorption spectrum of the salt. H. Dufet found the axial ratios of the monoclinic prisms of octohydrated samarium sulphate to be $a:b:c=3{\cdot}0030:1:2{\cdot}0022$, and $\beta=118°\ 16'$. A. Fock also examined the crystals. According to S. H. Katz and C. James, the sp. gr. is 2·930 at 18·3°. The double refraction is positive. H. Dufet gave for the indices of refraction for Li-, Na-, and Tl-light respectively $\alpha=1{\cdot}5395$, 1·5427, and 1·5458; $\beta=1{\cdot}5486$, 1·5519, and 1·5551; and $\gamma=1{\cdot}5594$, 1·5629, and 1·5663. He also studied the absorption spectrum. The monoclinic crystals of the octohydrates of praseodymium, neodymium, samarium, gadolinium, yttrium, and erbium are isomorphous with one another, and also with the corresponding selenates, and with the monoclinic form of octohydrated cerous sulphate. The isomorphous crystals of octohydrated didymium sulphate were investigated by J. C. G. de Marignac, H. Becquerel, P. T. Cleve, R. Bunsen, J. Schabus, and C. F. Rammelsberg. According to G. Bodman, the hydrates of bismuth sulphate are isomorphous with those of lanthanum—$(Bi,La)_2(SO_4)_3.9H_2O$; $(Bi,La)_2(SO_4)_3.5H_2O$; $(Bi,Di)_2(SO_4)_3.8H_2O$; etc.

The crystals of pentahydrated cerous sulphate, $Ce_2(SO_4)_3.5H_2O$, were examined by A. des Cloizeaux, G. Wyrouboff,[2] and E. H. Kraus; the last-named found the axial ratios of the monoclinic prisms to be $a:b:c=1{\cdot}4656:1:1{\cdot}1264$, and $\beta=102°\ 40'$, and he studied the corrosion figures. E. H. Kraus gave 3·160 for the sp. gr.; G. Wyrouboff, 3·176; and L. F. Nilson and O. Pettersson, 3·220. The crystals have a negative double refraction. For the monoclinic prismatic crystals of the isomorphous pentahydrated praseodymium sulphate, E. H. Kraus gave $a:b:c=1{\cdot}4450:1:1{\cdot}1157$, and $\beta=101°\ 16'$; and the sp. gr. 3·173. The crystals have a strong double refraction.

P. T. Cleve found the 100 c.c. of a sat. soln. of potassium sulphate dissolved 0·05 eq. of Sa_2O_3; and 100 c.c. of a sat. soln. of sodium sulphite dissolved 0·24 grm. of sodium samarium sulphate, $SaNa(SO_4)_2.nH_2O$. A. A. Noyes and F. G. Falk found the percentage ionization of soln. of lanthanum sulphate at 18° to be for soln. containing 2, 10, and 50 millieq. per litre, respectively 46·4, 28·9, and 19·8. F. Wirth measured the solubility of cerous, lanthanum, and samarium sulphates in sulphuric acid. The order of solubility is quite different from what it is in water. The results are shown in Fig. 21. Expressing the data in grams of $R_2(SO_4)_3$ per 100 grms. of sat. soln. at 25°, he found with sulphuric acid of normality N:

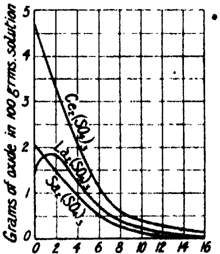

FIG. 21.—Solubility of Cerous, Lanthanum, and Samarium Sulphates in Sulphuric Acid.

G. Wyrouboff found that the hydrated and anhydrous varieties of the lower cerium oxide dissolve in conc. sulphuric acid, and the soln. on evaporation, deposits small, brilliant, transparent needles. When the evaporation is continued until no more sulphuric anhydride is evolved, care being taken that the temperature of decomposition of the salt is not reached, a crystalline **cerous hydrosulphate,** $Ce(HSO_4)_3$, is obtained. The salt is quite stable in dry air, and is very hygroscopic. B. Brauner and J. Picek found that in the above process of preparation, some sulphuric acid adheres very tenaciously to the acid salt, but it can be separated by heating the salt under reduced press. at a temp. not sufficiently high to decompose the sulphate—say 130°, but not above 180°. They prepared this salt by dissolving normal cerium sulphate in ice-cold water and then adding an excess of sulphuric acid. The acid salt which separates may occasionally be contaminated with the hydrate of the normal salt, which is, however, readily converted into the acid salt by heating. The acid salt was freed from sulphuric acid in a Sprengel vacuum at 130° ; it forms colourless, glistening needles. The corresponding **lanthanum hydrosulphate,** $La(HSO_4)_3$, was obtained by a similar process in colourless silky needles; so also in green silky needles of **praseodymium hydrosulphate,** $Pr(HSO_4)_3$; rose-red silky needles of **neodymium hydrosulphate,** $Nd(HSO_4)_3$; and golden-yellow silky needles of **samarium hydrosulphate,** $Sa(HSO_4)_3$. C. A. Matignon prepared neodymium hydrosulphate either by evaporating down a soln. of the neodymium salt of a volatile acid with excess of sulphuric acid or by dissolving the normal sulphate in the boiling reagent and allowing the soln. to cool. It crystallizes in long, silky, deliquescent, pink needles, which have an oblique extinction inclined at 12° to the principal axis. This form, however, rapidly becomes hydrated and changes into an aggregate of small, anisotropic crystals ; finally, the normal salt with $8H_2O$ is obtained mixed with excess of dil. sulphuric acid. One hundred parts of boiling conc. sulphuric acid dissolve 1·30 parts of the acid salt. The heats of dissolution of the acid and normal sulphates in water at 17° are 64·20 and 37·2 Cals. respectively, the heat of formation of the former from the latter being 26·3 Cals. Praseodymium hydrosulphate, prepared in a similar manner, is isomorphous with this substance, separating in slender needles having oblique extinction ; 100 parts of boiling conc. sulphuric acid dissolve only 1·02 parts of the compound. The heats of dissolution of the acid and normal sulphates in water at 16° are 65·5 and 36·0 Cals. respectively, the heat of formation of the former from the latter being 24·2 Cals. The acid praseodymium salt is less stable than its neodymium analogue, and is more readily decomposed on heating. He also obtained samarium hydrosulphate by evaporating at 200° a sulphuric acid soln. of the normal sulphate or by allowing the boiling soln. to cool, when the salt forms thin needles, less soluble than the corresponding salts of praseodymium or neodymium. B. Brauner and J. Picek heated the hydrosulphates in the vacuum of the mercury pump, and found the percentage decomposition to be :

		Ce	La	Pr	Nd	Sa
180°	3½ hrs.	2·5	6·0	2·8	1·3	6·6
	7 hrs.	3·2	12·0	4·1	2·3	7·7

	7 hrs.	92·7	95·8	94·7	79·7	88·5

E. Kunheim studied the action of carbon on cerium sulphate in the electric arc furnace.

Complex salts.—M. Barre[3] has examined the lowering of the solubility of cerous and lanthanum sulphates in water by the presence of alkali sulphates, and, expressing the results in grams of anhydrous salt in soln. per 100 grms. of water, he found with sodium sulphate :

19°	Na_2SO_4	0	0·33	1·09	1·39	1·70	3·59
	$Ce_2(SO_4)_3$	9·65	0·64	0·09	0·06	0·03	0·01
18°	Na_2SO_4	0	0·40	0·77	1·14	2·48	5·55
	$La_2(SO_4)_3$	2·13	1·00	0·30	0·13	0·04	0·02

with potassium sulphate:

	$La_2(SO_4)_3$	2·13	0·39	0·25	0·28	0·14	0·01

The solid phase is not stated, but it is known that double or complex salts are produced. The subject is in an empirical stage; it has not yet been illumined by the phase rule. M. Barre, for example, found that a sat. soln. of sodium sulphate precipitates **sodium dicerous sulphate,** $Na_2SO_4.Ce_2(SO_4)_3.2H_2O$, from a soln. of cerous sulphate, and at the b.p. precipitation is virtually complete. The same complex salt is obtained if crystalline sodium sulphate is added to a soln. of cerous sulphate. C. Czudnowicz, and S. Jolin reported **sodium dicerous hexasulphate,** $3Na_2SO_4.Ce_2(SO_4)_3.2H_2O$; and A. Beringer, **sodium tetracerous enneasulphate,** $3Na_2SO_4.2Ce_2(SO_4)_3$. P. T. Cleve, and M. Barre also obtained **sodium lanthanum sulphate,** $Na_2SO_4.La_2(SO_4)_3.2H_2O$, and P. T. Cleve **sodium samarium sulphate,** $Na_2SO_4.Sa_2(SO_4)_3.2H_2O$, in a similar way. D. B. Keyes and C. James' solubility curve, Fig. 22, shows the existence of only the complex salt, $3Na_2SO_4.2Sa_2(SO_4)_3.6H_2O$, at 25°.

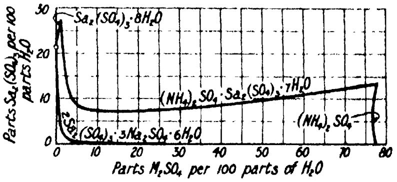

FIG. 22.—Solubility Curves of Samarium Sulphate in Solutions of Sodium and Ammonium Sulphates at 25°.

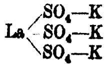
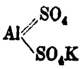
J. J. Berzelius noted that a double salt is precipitated when a conc. soln. of a cerous salt is mixed with a soln. or with crystals of potassium sulphate. If any iron sulphate be present, T. Scheerer said that it is carried down with the double salt and imparts to it a yellow tint. The double salt which is precipitated by the solid potassium sulphate, said A. Beringer, contains a slight excess of potassium sulphate which is not entirely separated by washing and recrystallization. The double salt can be purified by washing with cold water, dissolving in boiling water, and cooling the soln. Small colourless crystals are thereby obtained. The properties of the double salt were described by J. J. Berzelius, A. Beringer, C. G. Mosander, etc. From this, it appears that the salt fuses at a red heat; it is decomposed by fusion with alkali carbonate, and when the fused mass is extracted with water, ceric oxide remains. Cerous hydroxide is precipitated by potassium hydroxide or carbonate from a hot aq. soln. of the double salt, but some basic sulphate or other sulphate will be entrained with the precipitate unless the mixture is digested or boiled for a considerable time. Sulphuric acid dissolves the double salt, forming potassium hydrosulphate. The double salt is soluble in other acids; it is freely soluble in boiling water; sparingly soluble in cold water; and virtually insoluble in a sat. soln. of potassium carbonate. According to J. J. Berzelius and W. Hisinger, and W. Muthmann and H. Rölig, the double sulphates are very conveniently brought into soln. by heating them with conc. nitric acid, and pouring the whole into boiling water, or, according to G. Urbain, by dissolving them in a conc. soln. of ammonium acetate. C. von Scheele found that they are directly converted into hydroxides by heating them with alkali hydroxide; and C. A. von Welsbach converted them into oxalates by prolonged heating with an aq. soln. of oxalic acid. According to P. E. Browning and P. L. Blumenthal, and L. M. Dennis and F. H. Rhodes, when the double sulphates are heated for about an hour with four times their weight of powdered charcoal, they are almost completely reduced to sulphides, soluble in hydrochloric acid.

C. Czudnowicz, S. Jolin, and M. Barre obtained **potassium cerous sulphate,** $K_2SO_4.Ce_2(SO_4)_3.2H_2O$. Crystals of potassium lanthanum sulphate were made by M. Choubine, T. Scheerer, and C. G. Mosander. M. Barre made **potassium lanthanum sulphate,** $K_2SO_4.La_2(SO_4)_3.2H_2O$. C. Baskerville and H. Holland made **potassium praseodymium sulphate,** $Pr_2(SO_4)_3.K_2SO_4.4H_2O$; **cæsium praseodymium sulphate,** $Pr_2(SO_4)_3.Cs_2SO_4.2H_2O$, and $Pr_2(SO_4)_3.Cs_2SO_4.4H_2O$; lavender blue crystals of **cæsium neodymium sulphate,** $Cs_2SO_4.Nd_2(SO_4)_3.3H_2O$. According to S. Jolin, R. Hermann, and C. Czudnowicz, when a conc. soln. of potassium sulphate is added to one of cerous sulphate, at ordinary temp., **potassium dicerous hexasulphate,** $3K_2SO_4.Ce_2(SO_4)_3$, is precipitated; at 50°, R. Hermann obtained **potassium dicerous pentasulphate,** $2K_2SO_4.Ce_2(SO_4)_3.2H_2O$. According to R. Hermann and C. Czudnowicz, if the soln. contains one part of potassium sulphate to two or more parts of cerous sulphate, crystals of **potassium tetracerous enneasulphate,** $3K_2SO_4.2Ce_2(SO_4)_3$, are formed, and M. Barre obtained the octohydrate, $3K_2SO_4.2Ce_2(SO_4)_3.8H_2O$, as well as **potassium dicerous octosulphate,** $5K_2SO_4.Ce_2(SO_4)_3$, and **potassium dilanthanum octosulphate,** $5K_2SO_4.La_2(SO_4)_3$. R. Hermann and P. T. Cleve made **potassium dilanthanum hexasulphate,** $3K_2SO_4.La_2(SO_4)_3$. C. Baskerville and E. G. Moss made **rubidium hexalanthanum henasulphate,** $2Rb_2SO_4.3La_2(SO_4)_3$; and **cæsium hexalanthanum henasulphate,** $2Cs_2SO_4.3La_2(SO_4)_3$. C. von Scheele made **potassium dipraseodymium hexasulphate,** $3K_2SO_4.Pr_2(SO_4)_3.H_2O$, as a heavy crystalline precipitate of sp. gr. 3·275. P. T. Cleve prepared **potassium samarium pentadecasulphate,** $2Sa_2(SO_4)_3.9K_2SO_4.3H_2O$.

Lanthanum in the aluminium group might be expected to form a series of alums like those of aluminium. J. Locke stated that if an element will form an alum at all, it does so more readily with cæsium sulphate than with any other alkali sulphate. According to C. Baskerville and co-workers, when equi-mol. mixtures of lanthanum and cæsium sulphates are evaporated on a water-bath, enneahydrated lanthanum sulphate, $La_2(SO_4)_3.9H_2O$, separates; if the evaporation is conducted under diminished press., crystals of $3La_2(SO_4)_3.2Cs_2SO_4$ were formed. Similarly with rubidium salts, crystals corresponding with $La_2(SO_4)_3.2R_2SO_4.2H_2O$ were obtained by electrolysis, where R represents cæsium, rubidium, potassium, or sodium. The anhydrous salts $La_2(SO_4)_3.2R_2SO_4$ are formed by the evaporation of soln. at about 50°. The property possessed by lanthanum sulphate of forming the enneahydrate with a slight elevation of temp., interferes with the formation of the alum. F. W. Clarke suggests that while aluminium very readily forms the alum type: $SO_4{=}Al{-}SO_4{-}K$, lanthanum is more inclined to give salts of the type: $La_2(SO_4)_3.3K_2SO_4$; or, graphically,





Similar attempts to form praseodymium and neodymium alums have not been successful.* The former furnishes crystals of $Pr_2(SO_4)_3.Cs_2SO_4.2H_2O$, resembling the gadolinium sulphate, $Gd_2(SO_4)_3.K_2SO_4.2H_2O$. The evaporation of mixed soln. of praseodymium and cæsium sulphates under reduced press., or the application of the electrolytic process for alums, furnishes crystals of $Pr_2(SO_4)_3.Cs_2SO_4.4H_2O$. Neodymium and cæsium sulphate soln. evaporated under reduced press. furnish $Nd_2(SO_4)_3.Cs_2SO_4.3H_2O$.

According to C. Czudnowicz, and S. Jolin, when a mixed soln. of ammonium and cerous sulphates is boiled, octohydrated **ammonium cerous sulphate,** $(NH_4)_2SO_4.Ce_2(SO_4)_3.8H_2O$, separates in monoclinic prismatic crystals, which, according to E. H. Kraus, have the axial ratios $a:b:c=0{\cdot}3598:1:0{\cdot}9340$, and $\beta=97° 15'$. Observations on the crystals have been also made by G. Wyrouboff and A. Verneuil; and on the corrosion figures by E. H. Kraus. The double refraction is feeble and positive; and the dispersion very weak. E. H. Kraus gave 2·523 for the sp. gr. H. Wolff found that a mol of the salt loses 6 mols of water at 100°, and it becomes anhydrous at 150°; but, in contact with its sat. soln., the salt becomes anhydrous at 45°; the solubility expressed in grams of $(NH_4)_2SO_4.Ce_2(SO_4)_3$ per 100 grms. of water is:

	22·3°	35·1°	45·2°	45°	55·3°	75·4°	82·2°
$(NH_4)_2SO_4.Ce_2(SO_4)_3$.	5·331	5·184	4·993	2·994	2·240	1·482	1·184
Solid phase . . .	Octohydrate			Anhydrous salt			

The corresponding octohydrated **ammonium lanthanum sulphate,** $(NH_4)_2SO_4.La_2(SO_4)_3.8H_2O$, was prepared by J. C. G. de Marignac, E. H. Kraus, and G. Wyrouboff and A. Verneuil. It is isomorphous with the cerous salt. The axial ratios of the monoclinic prisms are $a:b:c=0{\cdot}3509:1:0{\cdot}9145$, and $\beta=97° 36'$. The corrosion figures were studied by E. H. Kraus. The double refraction is feeble; the sp. gr. 2·516. M. Barre also made the dihydrate. P. T. Cleve reported the octohydrated **ammonium samarium sulphate,** $(NH_4)_2SO_4.Sa_2(SO_4)_3.8H_2O$, but D. B. Keyes and C. James inferred from the solubility curve at 25°, Fig. 22, that the salt is really heptahydrated. P. T. Cleve, and C. Morton, and J. C. G. de Marignac studied the corresponding didymium salt. M. Barre prepared **ammonium dicerous octosulphate,** $5(NH_4)_2SO_4.Ce_2(SO_4)_3$; **ammonium dilanthanum octosulphate,** $5(NH_4)_2SO_4.La_2(SO_4)_3$; and **ammonium tetralanthanum henasulphate,** $5(NH_4)_2SO_4.2La_2(SO_4)_3$. C. von Scheele made **ammonium dipraseodymium hexasulphate,** $3(NH_4)_2SO_4.Pr_2(SO_4).8H_2O$, in large crystals of sp. gr. 2·532; the crystals do not change in air or over conc. sulphuric acid, but they become anhydrous at 170°.

A. Kolb prepared **cerium pyridine sulphate,** $Ce_2(C_5NH_6)_6(SO_4)_6.3H_2O$, in needle-like crystals; **cerium quinoline sulphate,** probably $Ce_2(SO_4)_3.6C_9NH_7.4H_2SO_4.17H_2O$; **cerium hydrazine sulphate** in lustrous crystals; **cerium hydroxylamine sulphate** in microscopic leaflets; **lanthanum pyridine sulphate,** $La_2(C_5NH_6)_6(SO_4)_6.4H_2O$, in lustrous, columnar crystals; **lanthanum quinoline sulphate** in small, columnar crystals, and **lanthanum hydrazine sulphate** in small leaflets. R. J. Meyer and U. Müller prepared lanthanum hydrazine sulphate, $La_2(SO_4)_3.(N_2H_5)_2SO_4.3H_2O$, in sparingly soluble, colourless crystals on warming a soln. of the mixed sulphates to 75°; and **neodymium hydrazine sulphate,** $Nd_2(SO_4)_3.(N_2H_5)_2SO_4.3H_2O$, in reddish-violet crystals, by warming a soln. of the mixed sulphates.

According to G. Wyrouboff, **cadmium cerous sulphate,** $CdSO_4.Ce_2SO_4.6H_2O$, is obtained by mixing eq. proportions of the component salts, adding sulphuric acid which precipitates some cerium sulphate on evaporation of the soln., the double salt crystallizes in rhombic prisms with axial ratios $a:b:c=1{\cdot}1336:1:0{\cdot}7535$. According to H. Zschiesche, and G. Wyrouboff, **thallous cerous sulphate,** $Tl_2SO_4.Ce_2(SO_4)_3.4H_2O$, crystallizes from a soln. of the mixed salts in monoclinic prisms with axial ratios $a:b:c=1{\cdot}309:1:0{\cdot}7059$, and $\beta=91° 53'$. By mixing cold conc., or warm dil. soln. of thallic and cerous sulphates, the double salt $3Tl_2SO_4.Ce_2(SO_4)_3.H_2O$ is precipitated. According to F. Zambonini, didymium and barium sulphates are immiscible when crystallized from hot conc. sulphuric acid.

When a soln. of ceric oxide or hydroxide is warmed with sulphuric acid, some oxygen is evolved because part of the ceric sulphate is reduced to the cerous state; when the soln. is evaporated, orange-red or dark-red hexagonal prisms, or masses of acicular crystals are produced. Similar crystals are formed when a soln. of cerous sulphate is mixed with an excess of ceric sulphate and sulphuric acid, and evaporated. R. J. Meyer, and A. Aufrecht, and B. Brauner added a definite amount of sulphurous acid to the acid soln. of ceric sulphate and evaporated the product. The mother liquor furnished, on evaporation, pale yellow crystals of ceric sulphate. The orange-red hexagonal crystals are regarded as **cerosoceric hydrosulphate,** $[Ce^{IV}(SO_4)_4]Ce_4^{III}.44H_2O$. Many attempts have been made to find the composition of the crystals. The results are complicated by the fact that the degree of oxidation —*i.e.* the ratio Ce(ous) : Ce(ic)—of the salt varies with the mode of preparation—*e.g.* B. Brauner[4] found the less the acidity of the soln., the less the sulphuric acid and the more the tervalent cerium in the product; and recrystallization from dil. acid gives still more cerous oxide, and the crystals retain an excess of sulphuric acid very tenaciously. R. J. Meyer has recalculated the different formulæ which have been proposed on the assumption that the at. wt. of cerium is 140.

One set of determinations has $3Ce(SO_4)_2.Ce_2(SO_4)_3.nH_2O$—R. Hermann (1843), C. F. Rammelsberg (1859), and C. Czudnowicz gave $n=27$; C. F. Rammelsberg (1873) gave $n=31\cdot5$; and S. Jolin, $n=31$. Another set of determinations has $2Ce(SO_4)_2.Ce_2(SO_4)_3.nH_2O$—D. I. Mendeléeff and B. Brauner gave $n=24$; and W. Muthmann and L. Stützel, $n=20$. Another set of determinations has $2Ce(SO_4)_2.Ce_2(SO_4)_3.mH_2SO_4.nH_2O$—R. Hermann (1864) gave $m=2, n=25$. Another set has $2Ce(SO_4)_2.Ce_2(SO_4)_3.mH_2SO_4.nH_2O$—B. Brauner (1895) gave $m=1\cdot5$, and $n=26$; R. J. Meyer and A. Aufrecht, $m=1, n=26$; and B. Brauner, $m=1, n=24$; H. Zschiesche gave $2Ce(SO_4)_2.1\frac{1}{3}Ce_2(SO_4)_3.H_2SO_4.26H_2O$; and G. Wyrouboff and A. Verneuil, $3Ce(SO_4)_2.2Ce_2(SO_4)_3.1\cdot5H_2SO_4.42H_2O$.

G. Wyrouboff and A. Verneuil showed that the actual analyses—particularly in the ratio Ce(ous) : Ce(ic)—often agree as well with one formula as with another. In consequence, the formula for cerosoceric sulphate is still *sub judice.* Cerosoceric sulphate thus contains both cerous and ceric sulphates, and the colour of cerosoceric sulphate is darker than that of ceric sulphate even though about half the cerium is present as cerous sulphate, a colourless salt. It is therefore inferred that the two sulphates are chemically combined as a complex. The fact that the sulphuric acid cannot be eliminated at 130° in vacuo led B. Brauner to regard cerosoceric hydrosulphate as the cerous salt of a complex acid—**cerous sulphatocerate,** $Ce_4'''[Ce(SO_4)_4]_3.12H_2O$; where the **hydrosulphatoceric acid** is symbolized $H_4Ce(SO_4)_4$. This is rendered the more probable by the existence of the corresponding salts; **lanthanum sulphatocerate,** $LaH[Ce(SO_4)_4]_3.12H_2O$; **praseodymium sulphatocerate,** $PrH[Ce(SO_4)_4]_3.12H_2O$; and **neodymium sulphatocerate,** $NdH[Ce(SO_4)_4].12H_2O$, which B. Brauner obtained by crystallization from an acid soln. of ceric sulphate mixed with an eq. proportion of lanthanum, praseodymium, or neodymium sulphate. It will be observed too that the rare earth hydrosulphates are symbolized, $H_3R(SO_4)_3$—*vide supra*—so that cerous hydrosulphate becomes $H_3Ce'''(SO_4)_3$, and the ceric salt of this would be $Ce_3''''[Ce_3'''(SO_4)_3]_4$, or $3Ce''''(SO_4)_2.2Ce_2(SO_4)_3$, where the ratio of Ce(ic) : Ce(ous) is the same as that given by G. Wyrouboff and A. Verneuil. B. Brauner has stated that the four sulphatocerates are isomorphous, crystallizing in hexagonal prisms. The axial ratio of the lanthanum salt is $a:c=1:2\cdot3349$; that of the cerous salt, $1:2\cdot3081$; that of the praseodymium salt, $1:2\cdot1771$; and that of the neodymium salt, $1:2\cdot6669$. The double refraction is negative. The crystals of the cerous salt were examined by J. Schabus and C. F. Rammelsberg. The cerous salt is reddish-yellow and pleochroic—ω dark yellow, ϵ citron-yellow; the praseodymium salt is greenish-yellow; and the neodymium salt—ω yellowish-green, ϵ pale-green.

W. H. Magee and A. S. Eakle have described three other dicerosoceric sulphates: **dicerosoceric sulphate,** $Ce_2[Ce(SO_4)_5].16\frac{1}{2}H_2O$, is obtained from a sulphuric acid soln. of red ceric hydroxide; **dicerosotetraceric sulphate,** $Ce_2[Ce_4(SO_4)_{11}].16H_2O$, obtained from a mixed sulphurous-sulphuric acid soln. of yellow ceric hydroxide; and **diceroso-octoceric sulphate,** $Ce_2[Ce_8(SO_4)_{19}].45H_2O$, from a sulphuric acid soln. of ceric hydroxide. The crystals are monoclinic prisms with axial ratios and angles respectively $a:b:c=0·7159:1:1·3296$, and $\beta=94°\ 1'$; $1·6023:1:1·89784$, and $\beta=111°\ 8'$; and $1·5122:1:1·5166$, and $\beta=105°\ 13'$.

Anhydrous **ceric sulphate,** $Ce(SO_4)_2$, is produced when a mixture of ceric oxide and conc. sulphuric acid is warmed on a sand-bath; the sulphate does not dissolve; and the change is quantitative. The deep yellow crystalline powder is washed with ice-cold water or glacial acetic acid, and dried over caustic alkali. Ceric sulphate can also be made by fusing ceric oxide with potassium hydrosulphate. D. I. Mendeléeff, and C. F. Rammelsberg prepared the tetrahydrate, $Ce(SO_4)_2.4H_2O$, in yellow needles from the mother liquor remaining after the deposition of cerosoceric hydrosulphate; and from the liquid obtained by dissolving basic ceric sulphate in sulphuric acid. The soln. is concentrated over sulphuric acid. The evaporation of a conc. soln. of the anhydrous salt in dil. sulphuric acid, or, as W. Hisinger and J. J. Berzelius showed, of ceric hydroxide in the same medium, furnishes the yellow crystals. While B. Brauner represents the crystals as those of a tetrahydrate, G. Wyrouboff and A. Verneuil represent them by the formula $Ce(SO_4)_2.3\frac{1}{2}H_2O$. According to B. Brauner, the tetrahydrate furnishes rhombic pyramids with axial ratios $a:b:c=0·717:1:0·471$. According to J. F. Spencer, when the anhydrous salt is heated in air, there is a slight loss in weight at 155°; and when heated at 195° until the weight is constant, the basic salt **ceric oxytetrasulphate,** $Ce_3O_2(SO_4)_4$, or $2Ce(SO_4)_2.CeO_2$, $3CeO_2.4SO_3$, is produced; more sulphur trioxide is lost at 250°, and at 300°, sulphur trioxide is continuously lost until ceric oxide remains. L. and P. Wöhler and W. Plüddemann found that heat converts ceric into cerous sulphate with the loss of oxygen. B. Brauner showed that in the presence of slightly dil. sulphuric acid, ceric sulphate undergoes autoreduction to an appreciable extent. The ready reduction of soln. of ceric salts is explained on the ionic hypothesis by the high oxidation potential of the ceric ion, $Ce^{\cdot\cdot\cdot\cdot}$. This has been measured by E. Baur and A. Glässner, and E. Mühlbach. The potential is greater than that of oxygen, so that acid soln. behave as if they were supersaturated with oxygen; in alkaline soln., ceric soln. are not so readily reduced to the cerous condition, but cerous salts are readily oxidized to ceric salts. According to G. A. Barbieri, in the cold, ceric sulphate, and ceric salts generally, oxidize nitrites without the evolution of gas: $2Ce(SO_4)_2+KNO_2+H_2O=Ce_2(SO_4)_3+KNO_3+H_2SO_4$. A volumetric process for the determination of nitrites has been based on the reaction. The end-point is attained when the soln. becomes yellow with the first drop of the standard ceric sulphate.

Ceric sulphate is very soluble in water, and it forms a yellowish-brown soln. The salt readily hydrolyzes so that the soln. is acidic, and when diluted or boiled, a pale yellow amorphous solid is precipitated. C. G. Mosander said that water dissolves only one part of the basic salt in 25,000. R. J. Meyer and A. Aufrecht say that basic sulphate contains some cerous salt, but J. F. Spencer could find none. The speed of the hydrolysis is increased by raising the temp. Owing to hydrolysis, the colour of an aq. soln. of the ceric salt fades perceptibly. A freshly made soln. of ceric sulphate darkens immediately when sulphuric acid is added, because the hydrolytic action is reversed; but with an old soln. the reversion takes place more slowly—possibly because the ageing of the product of the hydrolysis has made it less reactive. For a similar reason, the addition of hydrogen dioxide immediately decolorizes a freshly prepared soln. of a ceric salt, but, as R. J. Meyer and R. Jacoby showed, with an old soln. a dark red intermediate product is formed, and this is reduced more slowly. A. Benrath and K. Ruland discussed the oxidation of formic acid, methyl alcohol, acetic acid, tartaric acid and anthracene, by soln. of ceric sulphate; oxalic acid: $H_2C_2O_4+2Ce(SO_4)_2=2CO_2+Ce_2(SO_4)_3+H_2SO_4$; hydrazine: $2N_2H_4+2Ce(SO_4)_2=N_2+(NH_4)_2SO_4+Ce_2(SO_4)_3$; hydroxylamine forms nitrogen and nitrous oxide; sodium thiosulphate forms the tetrathionate:

$2Na_2S_2O_3 + 2Ce(SO_4)_2 = Ce_2(SO_4)_3 + Na_2SO_4 + Na_2S_4O_6$; sulphurous acid forms sulphuric and dithionic acid; and hypophosphorous acid forms phosphorous acid.

R. Hermann reported the basic sulphates: $CeO(SO_4).H_2O$, and later $8CeO_2.7SO_3.15H_2O$, and $6CeO_2.5SO_3.5H_2O$; J. C. G. de Marignac, $8CeO_2.7SO_3.12H_2O$; C. F. Rammelsberg, $4CeO_2.3SO_3.7H_2O$, and $3Ce(SO_4)_2.5Ce(OH)_4$. C. Erk made some observations on this subject; he was able to extract all the sulphuric acid from the precipitate by the action of boiling water. O. Hauser and F. Wirth have described two basic sulphates, $4CeO_2.3SO_3.12H_2O$, as a pale yellow crystalline substance obtained by keeping a dil. ice-cold soln. of ceric sulphate at 0° for 24 hrs., and $2CeO_2.3SO_3.4H_2O$, by similarly treating a sat. soln. of ceric sulphate. The latter product is readily soluble in water. J. F. Spencer varied the proportion of the acid and the conc. of the soln., and obtained only one solid phase—**ceric oxysulphate,** $CeO(SO_4).2H_2O$—which is a yellow amorphous powder, stable in contact with $0{\cdot}02N$- to $0{\cdot}37N$- sulphuric acid, but is further hydrolyzed by water apparently to the limit, ceric hydroxide. The compound is sparingly soluble in water. With soln. of greater acidity it is probable that autoreduction occurs. Attempts to make ceric oxysulphate by the action of acid on ceric oxide were not successful.

Ceric sulphate forms a number of complex salts. W. Hisinger and J. J. Berzelius[5] observed that when a little potassium hydroxide or potassium sulphate is added to a soln. of ceric sulphate, an orange-yellow precipitate is obtained which dissolves in water with difficulty. A hot, aq. soln. furnishes dark yellow crystals of **potassium ceric sulphate,** $2K_2SO_4.Ce(SO_4)_2.2H_2O$. The salt was also made by C. F. Rammelsberg, R. Hermann, J. C. G. de Marignac, etc. T. Scheerer found that the sulphur-yellow double salt is precipitated when potassium sulphate is added to a soln. of ceric nitrate, but if the ceric nitrate soln. be previously boiled or mixed with hydrochloric acid, the precipitate is white. According to J. C. G. de Marignac, the monoclinic prisms have the axial ratios $a : b : c = 1{\cdot}2160 : 1 : 2{\cdot}0925$, and $\beta = 100° 40'$. According to W. Hisinger and J. J. Berzelius, when potassium hydroxide is added to a soln. of the salt, ceric hydroxide is precipitated, while ammonia, ammonium carbonate, or potassium carbonate precipitates ceric hydroxide mixed with some sulphate. When an acid soln. of ceric and ammonium sulphates is evaporated, the soln. deposits a crop of small yellow crystals, followed by a crop of monoclinic prisms, and both salts are **ammonium ceric sulphates.** According to C. F. Rammelsberg, and D. I. Mendeléeff, the formula of the yellow salt is $3(NH_4)_2SO_4.2Ce(SO_4)_2.3H_2O$—a recalculation of the analysis gave $2(NH_4)_2SO_4.Ce(SO_4)_2.2H_2O$—and that of the orange-yellow salt, $3(NH_4)_2SO_4.Ce(SO_4)_2.4H_2O$. G. Geipel found the axial ratios of the monoclinic prisms to be $a : b : c = 0{\cdot}6638 : 1 : 0{\cdot}7838$, and $\beta = 96° 44'$. Observations were also made by J. Schabus. The double refraction is positive. V. Cuttica made **sodium ceric sulphate,** $2Na_2SO_4.Ce(SO_4)_2$, in orange-yellow prismatic crystals. No signs of a lithium salt were observed. M. E. Pozzi-Escot obtained an orange-yellow crystalline precipitate of **silver ceric sulphate,** $3Ag_2.SO_4.5Ce(SO_4)_2$, by adding silver nitrate to a strongly acid soln. of ceric sulphate. The salt slowly hydrates, forming the dihydrate, and it is decomposed by boiling water. V. Cuttica obtained the same salt; also orange-red, prismatic crystals of **thallium ceric sulphate,** $2Tl_2SO_4.Ce(SO_4)_2$; and a complex salt with guanidine sulphate. **Cerous ceric sulphate,** and B. Brauner's **lanthanum ceric sulphate, praseodymium ceric sulphate,** and **neodymium ceric sulphate,** are described above as derivatives of hydrosulphatoceric acid.

§ 17. The Carbonates of the Cerium Metals

The high basicity of the rare earths is shown by the ready formation of their carbonates. The hydroxides of the rare earths absorb carbon dioxide from the atm., and from water, thereby forming granular powders. L. N. Vauquelin [1] found that the precipitate produced in cerous salts by the addition of an alkali carbonate, is, when dried, a white voluminous powder with a silvery lustre; and A. Beringer, S. Jolin, and C. Czudnowicz showed that the white amorphous flakes, which are precipitated by ammonium carbonate, after standing in the liquid for about three days, change into shining crystalline scales. Analyses by L. N. Vauquelin, M. H. Klaproth, W. Hisinger, and A. Beringer correspond with pentahydrated **cerous carbonate**, $Ce_2(CO_3)_3.5H_2O$. P. T. Cleve also obtained the rare earth carbonates in a crystalline form by passing a current of carbon dioxide through water in which the rare earth hydroxide is suspended. J. Preiss and A. Dussik found that the normal carbonates of this family can be obtained only by precipitation of a soln. of the salt with a soln. of alkali hydrocarbonate sat. with carbon dioxide; the normal alkali carbonates furnish basic salts. C. G. Mosander produced shining crystalline scales of **lanthanum carbonate**, $La_2(CO_3)_3.3H_2O$, by a process similar to that employed by A. Beringer for cerium carbonate. P. A. Bolley said that crystalline scales are precipitated from a hot soln., while in the cold, a horny gelatinous mass, resembling aluminium oxide, is produced; when dried at 100°, the composition is $La_2(CO_3)_3.H_2O$. This carbonate was also obtained by R. Hermann, and P. T. Cleve. The octohydrate occurs in nature as lanthanite, $La_2(CO_3)_3.8H_2O$, *q.v.* C. von Scheele made **praseodymium carbonate**, $Pr_2(CO_3)_3.8H_2O$, in green silky plates, by the action of carbon dioxide on the hydroxide suspended in water, or by precipitation with ammonium carbonate. R. J. Meyer made light red **neodymium carbonate** in a similar way; and P. T. Cleve prepared yellow needle-like crystals of **samarium carbonate**, $Sa_2(CO_3)_3.3H_2O$, by the action of carbon dioxide on the hydroxide, suspended in water; but not by the addition of alkali carbonates to a soln. of a samarium salt, because double carbonates are precipitated. Samarium carbonate is insoluble in water, and loses $2H_2O$ at 100°. J. Preiss and co-workers studied the thermal dissociation of the praseodymium, neodymium, and lanthanum carbonates, and found a step by step dissociation from the normal carbonate, $M_2(CO_3)_3$, to the **oxydicarbonate,** $M_2O(CO_3)_2$, between 350° and 550° and to the **dioxymonocarbonate,** $M_2O_2O_3$, between 800° and 905°.

The properties of *lanthanite* have already been discussed. The mineral *bastnäsite* (*q.v.*) is regarded as **lanthanum fluocarbonate.** P. T. Cleve, and C. Morton have also discussed the preparation and properties of *didymium carbonate*, $Di_2(CO_3)_3.8H_2O$. According to W. Hisinger and J. J. Berzelius, cerous carbonate can be gently ignited without decomposition, but at a higher temp., cerosoceric oxide, carbon monoxide and dioxide are formed; and, if ignited with access of air, ceric oxide is formed. C. G. Mosander said that the carbon dioxide can be all expelled from lanthanum carbonate by long-continued ignition. L. N. Vauquelin noted that cerous carbonate is insoluble in water and in aq. carbon dioxide. P. H. M. P. Brinton and C. James measured the hydrolysis of many of the carbonates of the rare earths by boiling them with water for different periods of time, and measuring the ratio of the amount of carbon dioxide given off to the total carbon dioxide originally present in the system:

Hours boiling	0·5	1·0	1·5	2·0	2·5	3·0	3·5	4·0
$La_2(CO_3)_3$	27·9	27·9	28·0	–	–	–		
$Ce_2(CO_3)_3$	28·9	28·9	29·0	–	–	–	–	
$Pr_2(CO_3)_3$	23·2	27·4	29·5	30·9	31·9	32·6	33·3	–
$Nd_2(CO_3)_3$	26·6	30·3	32·7	34·4	35·5	36·4	37·1	–
$Sa_2(CO_3)_3$	31·8	35·4	37·8	39·5	40·8	42·4	43·2	44·2

which shows that the order of basicity is in accord with Pr, Nd, La, Ce, and Sa. Lanthanum and cerous carbonates behave abnormally. When the precipitated carbonates are allowed to stand in contact with a conc. soln. of an alkali carbonate, they are transformed into double carbonates; and the double carbonates can be precipitated by adding, drop by drop, a conc. soln. of a rare earth salt to a cold conc. soln. of an alkali carbonate.

S. Jolin described **sodium cerous carbonate,** $2Na_2CO_3.Ce_2(CO_3)_3.2H_2O$, as an amorphous powder obtained by pouring a soln. of a cerous salt into a boiling soln. of sodium hydrocarbonate. R. J. Meyer, and W. Hiller poured a conc. soln. of cerous chloride into a cold sat. soln. of sodium carbonate, and obtained a gelatinous precipitate which, after standing in contact with the mother liquid, acquired a crystalline structure. The composition was $3Na_2CO_3.2Ce_2(CO_3)_3.24H_2O$. The salt decomposed in contact with a dil. soln. of sodium carbonate, and is virtually insoluble in a conc. soln. W. Hiller, R. J. Meyer, and C. Arnold showed that, in general, the double carbonates of the cerium earths are slightly soluble in conc. soln. of sodium or ammonium carbonate, but readily soluble in a conc. soln. of potassium carbonate; the order of increasing solubility is La, Pr, Ce, and Nd. R. J. Meyer prepared gelatinous **sodium lanthanum carbonate,** $3Na_2CO_3.2La_2(CO_3)_3.20H_2O$, by adding an aq. soln. of lanthanum chloride to one of the alkali carbonate; similarly also with amorphous **sodium praseodymuim carbonate,** $3Na_2CO_3.2Pr_2(CO_3)_3.22H_2O$; amorphous pale red **sodium neodymium carbonate,** $3Na_2CO_3.2Nd_2(CO_3)_3.22H_2O$; and, according to P. T. Cleve, with hydrated **sodium samarium carbonate,** $Na_2CO_3.Sa_2(CO_3)_3.16H_2O$. F. Zambonini and G. Carobbi found these five double carbonates are easily obtained crystalline, with the general formula $M_2(CO_3)_3.Na_2CO_3.12H_2O$.

Owing to the solubility of the double carbonates of the rare earths in a conc. soln. of potassium carbonate, the potassium salts are best made by adding the rare earth chloride to an excess of a conc. soln. of potassium carbonate, warming to dissolve the precipitate, cooling, and diluting slightly. R. J. Meyer prepared **potassium cerous carbonate,** $K_2CO_3.Ce_2(CO_3)_3.3H_2O$, by a somewhat similar process. S. Jolin reported needle-like crystals of the trihydrate, $K_2CO_3.Ce_2(CO_3)_3.3H_2O$, to be formed by pouring a cerous salt soln. into a boiling soln. of potassium hydrocarbonate. R. J. Meyer said that the salt becomes pale yellow on exposure to air. He also made silky crystals of **potassium lanthanum carbonate,** $K_2CO_3.La_2(CO_3)_3.12H_2O$; small needle-like crystals of **potassium praseodymium carbonate,** $K_2CO_3.Pr_2(CO_3)_3$

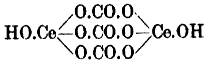
$12H_2O$; and rosette groups of needles of **potassium neodymium carbonate,** $K_2CO_3.Nd_2(CO_3)_3.12H_2O$, in a similar way. The potassium salts of praseodymium and neodymium carbonates were also obtained in needle-like crystals by the slow evaporation of their soln. in one of potassium carbonate. P. T. Cleve made **potassium samarium carbonate,** $K_2CO_3.Sa_2(CO_3)_3.12H_2O$, in a similar way.

R. J. Meyer, and W. Hiller prepared **ammonium cerous carbonate,** $(NH_4)_2CO_3.Ce_2(CO_3)_3.6H_2O$, as a voluminous precipitate, by treating a soln. of cerous chloride with an excess of a soln. of ammonium carbonate; on standing in *contact with the mother liquid for some time, the salt* becomes crystalline. The *double salt is only slightly* soluble in an excess of the precipitant; and it acquires a yellow colour on exposure to air. They also obtained crystalline **ammonium lanthanum carbonate,** $(NH_4)_2CO_3.La_2(CO_3)_3.4H_2O$; bright green crystals of **ammonium praseodymium carbonate,** $(NH_4)_2CO_3.Pr_2(CO_3)_3.4H_2O$; and regular prisms of **ammonium neodymium carbonate,** $(NH_4)_2CO_3.Nd_2(CO_3)_3.4H_2O$. P. T. Cleve also obtained crystalline **ammonium samarium carbonate,** $(NH_4)_2CO_3.Sa_2(CO_3)_3.16H_2O$, in a similar way. The mineral *parisite* (*q.v.*) can be regarded as a **calcium lanthanum carbonate.**

It has not yet been possible to make **ceric carbonate.** W. Hisinger obtained a yellow gelatinous precipitate of what is thought to be basic ceric carbonate, by double decomposition between a ceric salt and an alkali carbonate. The precipitate dissolves in a conc. soln. of potassium carbonate; the yellow soln. is stable in air, but, according to A. Job, may be oxidized with hydrogen dioxide. C. Engler and co-workers represent the formula graphically:

$$\mathrm{Ce}\left\langle\begin{matrix}\mathrm{O.CO.O}\\ \mathrm{O.CO.O}\\ \mathrm{O.CO.O}\end{matrix}\right\rangle\mathrm{Ce}$$

Cerous carbonate.

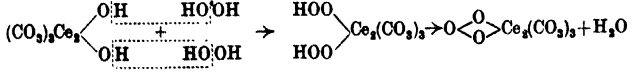


$$\mathrm{HO.Ce}\left\langle\begin{matrix}\mathrm{O.CO.O}\\ \mathrm{O.CO.O}\\ \mathrm{O.CO.O}\end{matrix}\right\rangle\mathrm{Ce.OH}$$

Basic ceric carbonate.

A. Job also reported that two **ceric oxycarbonates,** $2CeO_2.3CO_2$, and $2CeO_2.CO_2$—contaminated with potassium carbonate—are obtained by heating potassium perceric carbonate to 240° and 360° respectively. When hydrogen dioxide is added to a soln. of cerous carbonate in a conc. soln. of potassium carbonate, oxidation occurs, and a blood-red colour is developed. With increasing proportions of hydrogen dioxide, the intensity of the coloration increases to a maximum, further additions weaken the tint, and deposit an orange-yellow or reddish-brown precipitate. All the cerium may be so removed from the soln. A similar soln. can be obtained from ceric carbonate by oxidation with hydrogen peroxide. The precipitate is thought to be an unstable *cerium tetroxide*, CeO_4, but it has not yet been studied in detail. When covered with a conc. soln. of potassium carbonate, oxygen is slowly evolved, and blood-red crystals of **perceric potassium carbonate,** $Ce_2O_3(CO_3)_3.4K_2CO_3.12H_2O$, are produced. E. Baur attributes the formula $Ce_2O_4(CO_3)_2.4K_2CO_3.10H_2O$ to the crystals.

The red soln. is supposed to contain perceric carbonate, a derivative of cerium trioxide, CeO_3, and when the colour has acquired its maximum intensity all the cerium is thought to be in the perceric form. C. Engler and co-workers represent the formation of the perceric carbonate by the equation:



$$(CO_3)_3Ce_2\left\langle\begin{matrix}\mathrm{O\,\boxed{H \quad HO}\,OH}\\ +\\ \mathrm{O\,\boxed{H \quad HO}\,OH}\end{matrix}\right. \rightarrow \left.\begin{matrix}\mathrm{HOO}\\ \mathrm{HOO}\end{matrix}\right\rangle Ce_2(CO_3)_3 \rightarrow O{<}\begin{matrix}O\\ O\end{matrix}{>}Ce_2(CO_3)_3+H_2O$$

A. Job prepared the soln. by the interaction of ceric ammonium nitrate and hydrogen dioxide in a conc. soln. of potassium carbonate. He found that the soln. can be kept several months without alteration; and, by spontaneous evaporation at ordinary temp., it furnishes blood-red crystals of potassium perceric carbonate. When this substance is dissolved in dil. sulphuric acid, it yields carbon dioxide, oxygen, hydrogen dioxide, and potassium cerous sulphate. A brown liquid having

all the characteristics of a soln. of a perceric salt is obtained on dissolving the double carbonate in a dil. soln. of potassium carbonate. The crystals of the double carbonate become anhydrous when heated to 110°, but undergo no further decomposition when the temp. is raised to 200°; at 210°, evolution of oxygen commences, and as the temp. rises, the rate of evolution increases; at 300°, carbon dioxide is liberated, and the decomposition is complete in one hour at 360°; the residue then consists of a yellow ceric potassium carbonate having the composition $Ce_2O_3.CO_3.4K_2CO_3$. The double perceric carbonate is also produced, together with the yellow ceric salt by agitating a soln. of cerous nitrate and potassium carbonate in the presence of atm. oxygen. C. C. Meloche modified the method of preparation. Instead of working in conc. potassium carbonate soln., he found it advantageous to pass a stream of carbon dioxide through the potassium carbonate soln. until a large part of the potassium was removed as the hydrocarbonate. The filtered liquid, when kept at 5° for 24 hrs., deposited ruby-red crystals. His analysis corresponded with $Ce_2O_4(CO_3)_2.4K_2CO_3.12H_2O$. This product loses part of its water when exposed to dry air; and may be almost completely dehydrated at 110°–120° without losing available oxygen.

In alkaline soln., the potassium perceric carbonate has three gram-atoms of available oxygen for two gram-atoms of cerium, but in acid soln., only one-third this amount of oxygen is available. C. C. Meloche hence infers that it is impossible for perceric compounds to exist in soln. with free mineral acids, and he found that in contact with water the salt is rapidly hydrolyzed. He infers that in order to make the oxygen available in the nascent form when in the presence of an acid, contact is necessary as in the case of the nascent hydrogen liberated by the action of metals on dil. hydrochloric acid. The loss of oxygen by the acid treatment is explained by representing the reaction: $2CeO_3+3H_2SO_4=Ce_2(SO_4)_3+O_2+H_2O_2+2H_2O$; where the production of oxygen by autoreduction is regarded as an intramolecular process, so that oxygen is evolved in the molecular, and not in the atomic state. It is inferred that there are two atoms of peroxide oxygen in perceric compounds because if three atoms were present more than one molecule of hydrogen peroxide would probably remain in soln. after treatment with cold dil. sulphuric acid. If only one atom of peroxide oxygen were present, it is improbable that any hydrogen peroxide would remain after treatment with acid, since the following reaction takes place quantitatively: $2Ce(SO_4)_2+H_2O_2=Ce_2(SO_4)_3+O_2+H_2SO_4$. The presence of peroxide oxygen is indicated qualitatively by the following reactions: When a 10 per cent. soln. of the perceric potassium carbonate in 23 per cent. potassium carbonate soln. was treated with a conc. potassium carbonate soln. of potassium ferricyanide, potassium permanganate, potassium manganate, potassium hypochlorite, or potassium hypobromite, a lively evolution of oxygen was observed. Likewise, when a 10 per cent. soln. of the same compound in sat. potassium bicarbonate soln. was treated with lead dioxide, oxygen was evolved. It is inferred that the peroxide oxygen in potassium perceric carbonate is not present as hydrogen peroxide because of the stability of the compound at 110°–120°.

While a soln. of ceric carbonate in one of potassium carbonate is stable in air or oxygen, an aq. soln. of cerous carbonate is autoxidized, for it absorbs oxygen and forms perceric, not ceric, carbonate: $Ce_2(CO_3)_3+2H_2O+O_2=Ce_2(CO_3)_3(OH)_2+H_2O_2$. The perceric carbonate so produced reacts with the unchanged cerous carbonate, forming ceric carbonate. C. Engler and co-workers showed that by varying the conditions, the relative speeds of the two reactions can be modified. Cerous carbonate may thus act as a catalytic agent or as a carrier of oxygen in the oxidation of various substances by air. In this reaction the acceptor should be able to reduce both the perceric and ceric carbonates to the cerous states; if it can reduce only the perceric carbonate to the ceric state, the reaction ceases when all the cerous salt has been oxidized to the ceric state.

C. C. Meloche prepared ruby-red crystals of **rubidium perceric carbonate** by a method similar to that employed for the potassium salt, but the salt was not analyzed. The rubidium salt is less readily hydrolyzed than the potassium salt; and oxygen is liberated by its soln. in contact with lead dioxide. A soln. of **ammonium perceric carbonate** was obtained by a similar process, but the salt could not be crystallized from the liquid. The soln. is less stable than that of the potassium compound, and decomposes when kept with the formation of a yellow deposit—presumably a ceric oxycarbonate. It was not possible to prepare **sodium perceric carbonate** by the method used for the potassium compound—presumably owing to the lower solubility of the sodium carbonate—but if the dark red soln. of perceric ammonium carbonate is treated with excess of solid sodium carbonate and the soln. evaporated slowly in vacuo, well-formed crystals of perceric sodium carbonate of the composition $Ce_2O_4(CO_3)_2.4Na_2CO_3.30H_2O$, are obtained. It is only sparingly soluble in cold water and effloresces in dry air. Contact with moisture above 0° results in hydrolysis, and with larger quantities of water the crystals are completely decomposed with the formation of a gelatinous, orange-red precipitate.

§ 18. The Nitrates of the Cerium Metals

The nitrates of the rare earths are readily obtained in soln. by dissolving the sesquioxides, hydroxides, or carbonates in nitric acid; or by the oxidizing action of hot conc. nitric acid on the oxalates. As a rule, the evaporation of the aq. soln. furnishes the hexahydrated salt. J. J. Berzelius [1] prepared colourless tabular crystals of **cerous nitrate**, $Ce(NO_3)_3.6H_2O$, by evaporating a soln. to a syrupy consistency; A. Beringer could not get his soln. to crystallize; and L. N. Vauquelin obtained crystals only from acidified soln. S. Jolin, and T. Lange prepared a soln. of cerous nitrate by double decomposition of cerous sulphate and barium nitrate; and if cerous oxide or oxalate and nitric acid is used, they recommend the addition of some hydrogen peroxide as reducing agent. A mol of the hexahydrate loses three mols of water at 100°, and at 200° it begins to decompose. In general, when the attempt is made to prepare the anhydrous rare earth nitrates by heat, basic nitrates are produced. E. Löwenstein measured the vap. press. of cerium nitrate crystals and found evidence of the hexa-, tetra-, and mono-hydrates. J. C. G. de Marignac and C. G. Mosander prepared large crystals of **lanthanum nitrate**, $La(NO_3)_3.6H_2O$, by the spontaneous evaporation of the aq. soln.; a mol of the salt loses five mols of water when confined over conc. sulphuric acid. E. Löwenstein measured the vap. press. of lanthanum nitrate crystals and found evidence of the hexa-, tetra-, and mono-hydrates. By similar processes, C. von Scheele prepared large green needles of **praseodymium nitrate**, $Pr(NO_3)_3.6H_2O$; G. Bodman, **neodymium nitrate**, $Nd(NO_3)_3.6H_2O$; and P. T. Cleve, **samarium nitrate**, $Sa(NO_3)_3.6H_2O$, of sp. gr. 2·375 at 20·4°.

The hexahydrates all crystallize in the triclinic system; according to A. Fock, the axial ratios and angles of the cerous salt are $a:b:c=0·8346:1:0·6242$, and $\alpha=78° 54'$, $\beta=102° 9'$, and $\gamma=92° 3'$; for the lanthanum salt, J. C. G. de Marignac gave $a:b:c=0·8345:1:0·6215$, and $\alpha=79° 12'$, $\beta=101° 58'$, and $\gamma=92° 18'$; and H. Töpsöe gave for the didymium salt, $a:b:c=2·4035:1:1·8597$, and $\alpha=69° 6'$, $\beta=97° 30'$, and $\gamma=92° 47\frac{1}{2}'$. Hexahydrated lanthanum and neodymium nitrates were shown by G. Bodmann to be isodimorphous with bismuth nitrate. J. C. G. de Marignac said that the crystals of cerous nitrate are deliquescent, but S. Jolin said this is not the case. K. Jauch found the sp. ht. of soln. of N eq. of lanthanum and samarium nitrates to be:

N	0·5	1·0	2·0	3·0	4·0
Sp. ht. La salt . .	0·9395	0·8880	0·8036	0·7321	0·6688
Sp. ht. Sa salt . .	0·9435	0·8960	0·8166	0·7510	..

W. W. Coblentz studied the ultra-red transmission spectra of the nitrates of lanthanum, praseodymium, and neodymium. W. Muthmann measured the electrical conductivity, λ, of soln. containing a gram-eq. of the salt, $\frac{1}{3}La(NO_3)_3$, in v litres, and found, at 25°:

v . .	32	64	128	256	512	1024
λ . .	98·6	105·4	112·8	118·1	124·1	126·5

where the value $\lambda_{1024}-\lambda_{32}=28$. A. A. Noyes and J. Johnston found for the percentage ionization, α, at 35°:

v . .	5·00	10·00	20·00	80·00	500·0	∞
α . .	58·6	64·4	70·0	80·4	90·4	100

A. A. Noyes and K. G. Falk, and G. N. Lewis and G. A. Linhardt studied the ionization of soln. of lanthanum nitrate.

A. Heydweiller gave the sp. gr. and electrical conductivities of soln. of lanthanum and samarium nitrates. G. N. Lewis and M. Randall calculated the activity coeff. of soln. of lanthanum nitrate. A. C. Neish and J. W. Burns measured the hydrogen ion conc. of $\frac{1}{100}N$-soln. of the nitrates of some rare earths, and found the order to to be thorium, cerium(ic), neodymium, praseodymium, cerium(ous), and lanthanum. J. H. Hildebrand titrated soln. of praseodymium and neodymium nitrates with soln. of sodium hydroxide, and measured the e.m.f. of the soln. during the operation against a normal hydrogen electrode. These nitrates are all readily soluble in water; according to C. James and C. F. Whittemore, 100 grms. of water at 25° dissolve 151·1 grms. of hexahydrated lanthanum nitrate, and, according to C. James and J. E. Robinson, 152·9 grms. of neodymium nitrate. According to O. L. Barneby, these nitrates are also soluble in acetone, and in alcohol; according to L. N. Vauquelin, 100 parts of alcohol dissolve 50 parts of cerous nitrate. The solubilities are usually diminished by the addition of nitric acid, and the pentahydrates usually separate from nitric acid of sp. gr. 1·4. E. Demarçay gave 78°–79° for the m.p. of the yellow needles of hexahydrated samarium nitrate. C. James and C. F. Whittemore measured the solubility of lanthanum nitrate in aq. soln. of lanthanum oxalate; H. Freundlich and E. Löning studied its effect on a colloidal silver soln. G. L. Clark made **lanthanum hexamminonitrate**, $La(NH_3)_6(NO_3)_3$, by the action of ammonia at 43° on the hexahydrated nitrate.

According to G. Wyrouboff and A. Verneuil, crystals of **cerous sulphatonitrate**, $Ce(NO_3)(SO_4).H_2O$, separate when a soln. of cerous sulphate in conc. nitric acid is evaporated on a steam-bath. C. James and C. F. Whittemore studied the ternary system, lanthanum oxalate, lanthanum nitrate, and water at 25°, and found that the henahydrated lanthanum oxalate, $La_2(C_2O_4)_3.11H_2O$, is not stable at this temp. in contact with the nitrate; the solubility curves show the existence of the *octohydrate, the pentahydrate, and the trihydrate,* but no *lanthanum oxalatonitrate* appears to be stable at this temp. though one might exist at a higher temp. The observed results are summarized in Fig. 23. A similar examination by C. James and J. E. Robinson of the ternary system, neodymium oxalate, neodymium nitrate, and water, at 25°, shows the existence of henahydrated neodymium oxalate, and **neodymium oxalatonitrate** with $Nd_2(C_2O_4)_3.2(\text{or } 2\frac{1}{2})Nd(NO_3)_3.24H_2O$, as illustrated in *Fig. 24.*

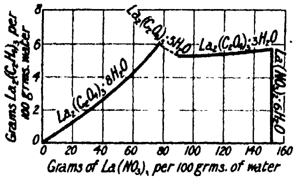

FIG. 23.—Mutual Solubility of Lanthanum Oxalate and Nitrate.

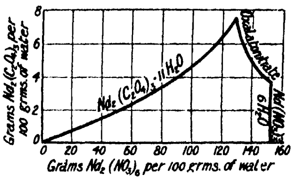

FIG. 24.—Mutual Solubility of Neodymium Oxalate and Nitrate.

The cerium family of metals forms double nitrates with many other metals. The general method of preparation is to dissolve the two nitrates in conc. nitric acid, and evaporate until crystals are formed. G. Wyrouboff found that with the exception of the sodium salt, if soln. of the double nitrates with the alkali metals are evaporated over 70°, the anhydrous salt is obtained, but G. Jantsch and S. Wigdoroff could not confirm this observation. According to T. Lange, when a mixed soln. of cerous and sodium nitrates is evaporated, slender needle-like crystals of **sodium cerous nitrate,** $2NaNO_3.Ce(NO_3)_3.H_2O$, are formed. G. Jantsch and S. Wigdoroff found that double salt is not completely dehydrated at 150°. The sp. gr. is 2·65 at 0°/4°. The last-named also made **sodium lanthanum nitrate,** $2NaNO_3.La(NO_3)_3.H_2O$, in white slender needles of sp. gr. 2·63 at 0°/4°; and the salt is not completely dehydrated at 150°. G. Wyrouboff said that the monoclinic crystals have the axial ratios $a:b:c=1·9970:1:0·7678$, and $\beta=90°\ 32'$. C. von Scheele said that sodium praseodymium nitrate, $2NaNO_3.Pr(NO_3)_3.H_2O$, crystallizes in small deliquescent needles. T. Lange made **potassium cerous nitrate,** $2KNO_3.Ce(NO_3)_3.2H_2O$, and found that the crystals are completely dehydrated at 180°. According to A. Fock, the formula is $2KNO_3.Ce(NO_3)_3.1\frac{1}{2}H_2O$; and the crystals are rhombic pyramids with axial ratios $a:b:c=0·5227:1:0·5704$. Similarly for **potassium lanthanum nitrate,** A. Fock gave $2KNO_3.La(NO_3)_3.1\frac{1}{2}H_2O$, and found the rhombic crystals to have the axial ratios $a:b:c=0·5220:1:0·5712$. G. Jantsch and S. Wigdoroff found the white, slender, hygroscopic needles are dihydrated; they have a sp. gr. 2·54 at 0°/4°; and are dehydrated at 60°. G. Wyrouboff, and G. Jantsch and S. Wigdoroff made **rubidium cerous nitrate,** $2RbNO_3.Ce(NO_3)_3.4H_2O$. It forms hygroscopic, needle-like crystals belonging to the monoclinic system, with axial ratios $a:b:c=1·2298:1:0·9910$, and $\beta=101°\ 16'$; the sp. gr. is 2·497 at 0°/4°; the m.p. is 70°; and the crystals are dehydrated at 60°. G. Wyrouboff, and G. Jantsch and S. Wigdoroff obtained **rubidium lanthanum nitrate,** $2RbNO_3.La(NO_3)_3.4H_2O$, by evaporation from a soln. containing lanthanum and rubidium nitrates in the molar proportions 1 : 4. The monoclinic crystals have the axial ratios $a:b:c=1·2349:1:0·9888$, and $\beta=101°$; the sp. gr. is 2·497 at 0°/4°; the m.p. 86°; and the crystals are dehydrated at 60°. If the lanthanum and rubidium nitrates be in the molar proportion 1 : 2, colourless plates of **rubidium lanthanum hydronitrate,** $RbNO_3.La(NO_3)_3.HNO_3.6H_2O$, appear in colourless plates which lose their nitric acid, and five-sixths the water at 120°; the product $RbNO_3.La(NO_3)_3.H_2O$ is not dehydrated at 200°, and its sp. gr. is 2·377 at 0°/4°. C. von Scheele, and G. Jantsch and S. Wigdoroff made **rubidium praseodymium nitrate,** $RbNO_3.Pr(NO_3)_3.4H_2O$, in green, hygroscopic, monoclinic crystals; which have a sp. gr. 2·50 at 0°/4°; and m.p. 63·5°; and are dehydrated at 60°. Similarly

rubidium neodymium nitrate, $RbNO_3.Nd(NO_3)_3.4H_2O$, furnishes bright reddish-violet plates which, according to G. Wyrouboff, have the axial ratios $a:b:c=1\cdot2276:1:1\cdot0153$, and $\beta=100° 29'$. The sp. gr. is 2·56 at 0°/4°; and the m.p. 47°. The salt is dehydrated at 60°. The temp. at which the above compounds melt in their water of crystallization decrease with increasing at. wt. of the rare earth metal. According to G. Wyrouboff, the nitrates of the type $2M'NO_3.R(NO_3)_3.4H_2O$, are isomorphous. G. Jantsch and S. Wigdoroff, and G. Wyrouboff prepared **cæsium cerous nitrate,** $2CsNO_3.Ce(NO_3)_3.2H_2O$, in monoclinic prisms, with axial ratios $a:b:c=1\cdot2052:1:0\cdot9816$, and $\beta=103° 41'$; similarly, **cæsium lanthanum nitrate,** $2CsNO_3.La(NO_3)_3.2H_2O$, forms small, tabular, monoclinic crystals with axial ratios $a:b:c=1\cdot3052:1:0\cdot9663$, and $\beta=103° 26'$; the sp. gr. is 2·827 at 0°/4°.

H. Wolff prepared **ammonium cerous nitrate,** $2NH_4NO_3.Ce(NO_3)_3.4H_2O$, by crystallization from a mixed soln. of ammonium and cerous nitrates. This double salt is stable in the interval of temp. between 9° and 65°, and it can be recrystallized from water with change. A. des Cloizeaux, J. C. G. de Marignac, A. Fock, and G. Wyrouboff have examined the crystals. According to A. Fock, the monoclinic crystals have the axial ratios $a:b:c=1\cdot2321:1:2\cdot1695$, and $\beta=112° 45'$, and they are isomorphous with the corresponding salts of lanthanum and didymium. The double refraction is negative. The salt melts in its water of crystallization at 74°. According to H. Wolff, 100 grms. of water dissolve

	25°	45°	60°	65·06°
Grms. $2NH_4NO_3.Ce(NO_3)_3$ . .	296·8	410·2	681·2	817·4

and if w denotes the percentage amount of the anhydrous salt, the solubility at $\theta°$ between 25° and 65° is $w=68\cdot7+172\theta+0\cdot002\theta^2$. M. Holzmann obtained $3NH_4NO_3.2Ce(NO_3)_3.12H_2O$ by crystallizing a soln. of the component salts at 0°. According to H. Wolff, when this salt is recrystallized from water, it furnishes $2NH_4NO_3.Ce(NO_3)_3.4H_2O$. J. C. G. de Marignac, A. des Cloizeaux, H. Dufet, E. H. Kraus, and G. Wyrouboff prepared **ammonium lanthanum nitrate,** $2NH_4NO_3.La(NO_3)_3.4H_2O$, and found the monoclinic, prismatic crystals were isomorphous with those of cerium (ous) and didymium. E. H. Kraus gave for the axial ratios $a:b:c=1\cdot2475:1:2\cdot1863$, and $\beta=112° 36'$; and the sp. gr. 2·135. The double refraction is strongly negative. O. Holmberg found that 100 grms. of water at 15° dissolve 181·14 grms. of $2NH_4NO_3.La(NO_3)_3$. C. von Scheele prepared **ammonium praseodymium nitrate,** $2NH_4NO_3.Pr(NO_3)_3.4H_2O$, in large deliquescent crystals of sp. gr. 2·155; and C. A. von Welsbach, **ammonium neodymium nitrate,** $2NH_4NO_3.Nd(NO_3)_3.4H_2O$.

A. Kolb and co-workers reported complex salts of cerous nitrate with pyridine, quinoline, and piperidine; and of lanthanum nitrate with pyridine, antipyrine, and quinoline. G. A. Barbieri and F. Calzolari made a complex salt of lanthanum and neodymium nitrates and hexamethylenetetramine.

G. Jantsch and S. Wigdoroff prepared **thallous cerous nitrate,** $2TlNO_3.Ce(NO_3)_3.4H_2O$, in hygroscopic crystals of sp. gr. 3·326 at 0°/4°, and m.p. 64·5°. The salt is dehydrated at 60°. They also made hygroscopic crystals of **thallous lanthanum nitrate,** $2TlNO_3.La(NO_3)_3.4H_2O$, of sp. gr. 3·318, and m.p. 72°. The salt is dehydrated at 100°.

The magnesium, zinc, manganese, cobalt, and nickel rare earth nitrates of the general formula $3M''(NO_3)_2.2R(NO_3)_3.24H_2O$, have been investigated by many. They form an extended isomorphous series crystallizing in the trigonal system. They are also isomorphous with the corresponding bismuth complex salts. While the double nitrates of the alkali metals are obtained from acidified soln., these salts, with the exception of the gadolinium series, can be obtained from neutral soln. T. Lange, M. Holzmann, and C. F. Rammelsberg prepared **magnesium cerous nitrate,** $3Mg(NO_3)_2.2Ce(NO_3)_3.24H_2O$, in trigonal crystals with the axial ratio $a:c=1:1\cdot5378$. The crystals were also examined by A. des Cloizeaux, L. Carius,

C. F. Rammelsberg, and G. Geipel. The double refraction is feebly negative. G. Jantsch gave for the magnesium series:

	La	Ce	Pr	Nd	Sa
Sp. gr. (0°/4°)	1·988	2·002	2·019	2·020	2·088
Mol. vol.	768·3	764·2	758·0	761·2	742·4
Melting point	113·5°	111·5°	111·2°	109·0°	96·2°
Molar solubility	0·0418	0·0382	0·0503	0·0635	0·0583

where the molar solubility refers to the mols of salts dissolved by a litre of nitric acid of sp. gr. 1·325 at 16°/4°. M. Holzmann prepared **magnesium lanthanum nitrate,** $3Mg(NO_3)_2.2La(NO_3)_3.24H_2O$; and G. Jantsch, large leek-green crystals of **magnesium praseodymium nitrate,** $3Mg(NO_3)_2.2Pr(NO_3)_3.24H_2O$; E. Demarçay prepared **magnesium neodymium nitrate,** $3Mg(NO_3)_2.2Nd(NO_3)_3.24H_2O$; and **magnesium samarium nitrate,** $3Mg(NO_3)_2.2Sa(NO_3)_3.24H_2O$. T. Lange, and H. Zschiesche prepared **zinc cerous nitrate,** $3Zn(NO_3)_2.2Ce(NO_3)_3.24H_2O$, in deliquescent trigonal crystals which, according to A. Fock, have the axial ratio $a:c=1:1·5677$. The double refraction is negative. G. Jantsch gave for the zinc series:

	La	Ce	Pr	Nd	Sa
Sp. gr. (0°/4°)	2·161	2·188	2·215	2·208	2·283
Mol. vol.	763·8	755·5	751·0	750·0	732·8
Melting point	98·0°	92·8°	91·5°	88·5°	76·5°
Molar solubility	0·0751	0·0675	0·0888	0·1066	0·2179

vide supra for the term molar solubility. A. Damour and H. St. C. Deville prepared **zinc lanthanum nitrate,** $3Zn(NO_3)_2.2La(NO_3)_3.24H_2O$. G. Jantsch made **zinc praseodymium nitrate,** $3Zn(NO_3)_2.2Pr(NO_3)_3.24H_2O$, in large, tabular, yellowish-green crystals; **zinc neodymium nitrate,** $3Zn(NO_3)_2.2Nd(NO_3)_3.24H_2O$, in small reddish-violet crystals; and **zinc samarium nitrate,** $3Zn(NO_3)_2.2Sa(NO_3)_3.24H_2O$, in large violet crystals; and another zinc samarium nitrate, $3Zn(NO_3)_2.Sa(NO_3)_3.24H_2O$, in large topaz-yellow crystals.

Normal **ceric nitrate,** $Ce(NO_3)_4$, has not been prepared. When a soln. of ceric hydroxide in conc. nitric acid in the presence of calcium nitrate, is evaporated, V. von Lang and L. Haitinger obtained red monoclinic prisms with axial ratios $a:b:c=1·7834:1:1·0465$, and $\beta=90° 48'$. The favourable action of calcium nitrate on the crystallization is probably due to its lowering the solubility. The composition of the red crystals corresponds with **ceric hydroxynitrate,** $Ce(OH)(NO_3)_3.4\frac{1}{2}H_2O$, or, according to R. J. Meyer and R. Jacoby, $Ce(OH)(NO_3)_3.3H_2O$. When this salt is dissolved in water, the yellow liquid has an acid reaction, and in consequence of a progressive hydrolysis, the colour gradually deepens; by adding nitric acid to a freshly prepared soln., the colour becomes dark red, but a soln. which has stood a long time at ordinary temp., or one which has been boiled, is only gradually darkened by nitric acid. When hydrogen dioxide is added to a freshly prepared soln. of ceric nitrate, the salt is immediately reduced and the soln. decolorized; but with an old soln. or one that has been boiled, the liquid first acquires a deep red colour owing to the formation of a higher oxidized salt, and it is then slowly decolorized by reduction. R. J. Meyer and R. Jacoby add that this behaviour is characteristic of ceric salts.

In the old soln. or in soln. which have been boiled, hydrolysis has presumably made considerable progress, and a hydrosol is formed which coagulates when nitric acid is added, and virtually all the cerium can be precipitated as a hydrogel by adding sufficient acid. When the hydrogel is dried over potassium hydroxide, an amber-coloured, horny, translucent mass is formed. Its composition is $4CeO_2.N_2O_5.5H_2O$; and in contact with sufficient water, a greenish soln. is obtained; if less water is used the liquid may appear opalescent. When the hydrosol is dialyzed nitric acid is lost, but the decomposition ceases when the ratio is about $28Ce(OH)_4 : N_2O_5$. If hydrochloric acid be added to the hydrosol, the precipitated hydrogel has the composition $4CeO_2.2HCl.34H_2O$; and with sulphuric acid, $4CeO_2.SO_3.5H_2O$. The basic chloride resembles the basic nitrate, but the basic sulphate does not form the hydrosol when treated with water, although about half the sulphuric acid is washed away. Similar colloids have been prepared with lanthanum, praseodymium, etc., in place of cerium.

When ammonia is added to the nitrate hydrosol, a hydrogel with the composition $8CeO_2.11H_2O$ is formed. G. Wyrouboff and A. Verneuil regard these colloids as derivatives of polymerized or condensed ceric hydroxides, which they liken to metastannic acid and metatungstic acid, and called *metaceric oxide*, $Ce_{21}O_{15}(OH)_{60}(OH)_6$, in which only the $(OH)_6$ is capable of reacting with acids. When ceric oxide is obtained by calcining cerous oxalate in air at as low a temp. as possible, it is indifferent towards conc. nitric acid, but when digested for some hours at 100° with 3 per cent. nitric acid, and separated from the liquid by decantation, the product is soluble in water. The turbid soln. contains a hydrosol which may be precipitated as a hydrogel by adding 2 per cent. nitric acid, or ammonium nitrate. When dried at 100°, it forms a horny translucent mass with the composition $20CeO_2.N_2O_5.5H_2O$. It is soluble in water. Basic chlorides, sulphates, etc., may be similarly prepared. If cerous hydroxide, precipitated by ammonia from a cerous salt soln., is oxidized to ceric hydroxide by a current of air, the product is almost entirely insoluble in boiling conc. nitric acid, but the soluble portion is colloidal and with water forms a soln. of *paraceric oxide*.

C. F. Rammelsberg, and R. J. Meyer and R. Jacoby prepared **potassium ceric nitrate,** $K_2Ce(NO_3)_6$, by evaporating a mixed soln. of the component salts in conc. nitric acid, sp. gr. 1·25, over potassium hydroxide and conc. sulphuric acid. M. Holzmann also reported this double salt to be a sesquihydrate, but this is possibly due to contamination with the hydrated cerous salt, or with the basic nitrate. The colour of double nitrates of this type is like that of the dichromates. According to A. des Cloizeaux, the potassium salt furnishes monoclinic crystals with axial ratios $a:b:c=1\cdot2455:1:1\cdot9170$, and $\beta=91°\ 12'$. The double refraction is negative. G. Wyrouboff said the crystals of M. Holzmann are hexagonal with the axial ratio $a:c=1:1\cdot400$, and the double refraction is negative. R. J. Meyer and R. Jacoby prepared in a similar way **rubidium ceric nitrate,** $Rb_2Ce(NO_3)_6$, readily soluble in water, sparingly soluble in nitric acid; and **cæsium ceric nitrate,** $Cs_2Ce(NO_3)_6$, which is not so readily soluble as the rubidium salt. M. Holzmann prepared **ammonium ceric nitrate,** $(NH_4)_2Ce(NO_3)_6$, and he regarded it as a sesquihydrate; W. Muthmann supposed it to be monohydrated; and P. Schottländer, anhydrous. The work of R. J. Meyer and R. Jacoby has shown that the salt is anhydrous. G. Plancher and G. A. Barbieri prepared the salt by the anodic oxidation of cerous ammonium nitrate in a compartment cell. This is one of the most important of the ceric salts, and it is employed as a means of preparing pure ceria. A. Sachs found that the monoclinic crystals have the axial ratios $a:b:c=2\cdot4668:1:2\cdot3901$, and $\beta=129°\ 52'$. A. des Cloizeaux gave $a:b:c=1\cdot1690:1:1\cdot9260$, and $\beta=90°\ 21'$. The double refraction is negative. The hygroscopic crystals readily dissolve in water, forming yellow soln. H. Wolff found the percentage solubility to be:

	25°	35·2°	45·3°	64·5°	85·6°	(122°)
$(NH_4)_2Ce(NO_3)_6$	58·49	62·79	64·51	66·84	69·40	(88·03)

and he represented the results at θ° between 25° and 85° by the formula $S=52\cdot07+0\cdot314\theta-0\cdot0013\theta^2$; but with soln. above 60° there is a partial reduction of ceric salt to cerous salt; and at about the b.p. of the sat. soln., say 122°, after 3 hrs.' boiling about 9·8 per cent. of the salt was found to be in the cerous state. The soln. in alcohol is dark red. The salt is not very soluble in nitric acid, and it forms dark red soln., which become nearly black when heated. The salt can be recrystallized from water without decomposition. J. Koppel found the double compounds of ceric salts with the organic bases to be more stable than the inorganic double salts. C. H. G. Williams prepared a compound of ceric nitrate with quinoline.

Ceric nitrate also forms an isomorphous series of double salts of the type

$M(NO_3)_2.Ce(NO_3)_4.8H_2O$, in which M represents an atom of bivalent magnesium, zinc, nickel, cobalt, or manganese. The crystals are also isomorphous with the corresponding thorium salts. These salts are very easily reduced, and they must be prepared from conc. nitric acid; the salts are decomposed when dissolved in water, and they do not lose their water of crystallization when dried over sulphuric acid. R. Bunsen and J. Jegel, and M. Holzmann prepared **magnesium ceric nitrate,** $MgCe(NO_3)_6.8H_2O$, but H. Zschiesche, and C. F. Rammelsberg believed the product to be a mixture of ceric nitrate and magnesium cerous nitrate. R. J. Meyer and R. Jacoby prepared the salt in the presence of conc. nitric acid, and showed the idea that the salt does not exist to be based on the fact that it is very easily reduced. It is deliquescent in air; more soluble in water and nitric acid than the alkali salts; and when heated it melts in, and is decomposed by, its water of crystallization. G. Geipel found the axial ratios of the monoclinic, dark red crystals to be $a:b:c=1{\cdot}032:1:1{\cdot}586$, and $\beta=96° 43'$. M. Holzmann prepared **zinc ceric nitrate,** $ZnCe(NO_3)_6.8H_2O$. C. F. Rammelsberg and H. Zschiesche denied the existence of this salt, but as in the case of the magnesium salt, R. J. Meyer and R. Jacoby showed how it can be prepared. M. Holzmann thought the salt was an enneahydrate. G. Geipel found the axial ratios of the monoclinic dark red crystals to be $a:b:c=0{\cdot}978:1:1{\cdot}339$, and $\beta=100° 0'$.

§ 19. The Phosphates of the Cerium Metals

Several phosphates of the rare earths occur in nature. These have already been discussed. W. Hisinger and J. J. Berzelius[1] precipitated a cerium phosphate by adding phosphoric acid or an alkali phosphate to a soluble cerous salt. S. Jolin, and W. N. Hartley showed that the white powder so obtained is dihydrated **cerous orthophosphate,** $CePO_4.2H_2O$. F. V. C. Radominsky fused the precipitated phosphate with cerous chloride, and extracted the cold mass with water and dil. nitric acid; the crystals of cerous orthophosphate, $CePO_4$, resembled monazite. L. V. R. Ouvrard also obtained the anhydrous phosphate in yellow rhombic prisms by fusing ceric oxide with potassium metaphosphate; H. Grandeau obtained similar greenish-yellow, needle-like crystals. H. Holm obtained a similar product by fusing cerous sulphate with sodium metaphosphate. M. Choubine, P. T. Cleve, and R. Hermann made **lanthanum orthophosphate,** $LaPO_4$, by adding phosphoric acid or disodium hydrophosphate to a soln. of lanthanum acetate or sulphate. F. T. Frerichs and E. F. Smith say that the amorphous precipitate obtained with the sulphate soln. has the composition $La_2(HPO_4)_3$. L. V. R. Ouvrard, and H. Grandeau obtained the crystalline orthophosphate by melting lanthana with potassium metaphosphate. P. T. Cleve made crystals of **samarium orthophosphate,** $SaPO_4$, by fusing samaria with sodium metaphosphate, and leaching the cold mass with water.

According to H. Grandeau, the sp. gr. of the crystals of cerium orthophosphate is 5·22 at 14°; and, according to P. T. Cleve, that of samarium phosphate is 5·828 at 17·5°. W. Hisinger and J. J. Berzelius said that cerous orthophosphate is slightly soluble in nitric and hydrochloric acids; M. Choubine also noted that lanthanum orthophosphate is soluble in acids; and P. T. Cleve, that samarium orthophosphate is insoluble in water. C. G. Mosander said that when cerous phosphate is ignited in a carbon crucible, it is neither fused nor reduced, but merely sinters together. L. V. R. Ouvrard saturated molten potassium orthophosphate or pyrophosphate with ceric oxide, and, on cooling, obtained prismatic crystals of **potassium cerous orthophosphate,** $K_3Ce_2(PO_4)_3$, or $K_3PO_4.2CePO_4$, of sp. gr. 3·8 at 20°; and similarly also with **sodium cerous orthophosphate,** $Na_3Ce_2(PO_4)_3$; and with **potassium lanthanum orthophosphate,** $K_3La_2(PO_4)_3$, of sp. gr. 3·5 at 20°. F. Zambonini obtained *cerium apatite* and *didymium apatite* by fusing and slowly cooling a mixture of calcium orthophosphate and chloride, and cerium phosphate, $CePO_4$. The crystals contained up to 13 per cent. $CePO_4$; similarly, crystals with 3 per cent. of $DiPO_4$ were made; and also crystals of *didymium spodiosite* with up to 9 per cent. $DiPO_4$.

A. Rosenheim and T. Triantaphyllides prepared **cerous pyrophosphate,** $Ce_4(P_2O_7)_3.12H_2O$, by adding a cerous salt to an excess of a soln. of sodium pyrophosphate. It is readily soluble in mineral acids. S. Jolin made microscopic needles of **cerous hydropyrophosphate,** $CeHP_2O_7$, from a sat. soln. of cerous carbonate in pyrophosphoric acid. P. T. Cleve prepared **lanthanum hydropyrophosphate,** $LaHP_2O_7.3H_2O$, by adding a lanthanum salt to a soln. of sodium pyrophosphate until the white precipitate first formed redissolves. On allowing the soln. to stand, needle-like crystals of this salt are formed. He also made **samarium hydropyrophosphate,** $SaHP_2O_7.3\frac{1}{2}H_2O$, from a soln. of samarium hydroxide in pyrophosphoric acid. K. A. Wallroth prepared **sodium cerous pyrophosphate,** $CeNaP_2O_7$, from a soln. of the oxide in molten sodium metaphosphate or sodium ammonium phosphate; he also made in a similar way **sodium lanthanum pyrophosphate,** $LaNaP_2O_7$, isomorphous with the cerous salt.

C. F. Rammelsberg obtained **cerous metaphosphate,** $Ce(PO_3)_3$, by evaporating cerous hypophosphite with nitric acid, and calcining the residue; and K. R. Johnson obtained microscopic crystals by the action of anhydrous cerous sulphate on fused metaphosphoric acid. The sp. gr. of the salt is 3·272, and it is insoluble in acids. F. T. Frerichs and E. F. Smith precipitated **lanthanum metaphosphate,**

$La(PO_3)_3$, from a soln. of sodium metaphosphate by means of lanthanum sulphate; and K. R. Johnson obtained the acid metaphosphate, $La_2O_3.5P_2O_5$, by dissolving the sulphate in molten metaphosphoric acid, and extracting the mass with *water. The monoclinic crystals had the axial ratios* $a : b : c = 1·44604 : 1 : 0·95897$, $\beta = 89° 28' 20''$, *and sp. gr. 3·241.* P. T. Cleve similarly prepared **samarium metaphosphate,** $Sa_2O_3.5P_2O_5$. The crystals had a sp. gr. 3·487 at 28·8°.

According to W. N. Hartley, when sodium phosphate is added to a slightly acid soln. of a ceric salt, a yellowish precipitate is obtained, which, when dried in vacuo over sulphuric acid, has the composition of **ceric hydro-orthophosphate,** $2Ce_2H(PO_4)_3.25H_2O$; R. J. Carney and E. de M. Campbell, and A. Rosenheim and T. Triantaphyllides obtained **ceric pyrophosphate,** $CeP_2O_7.nH_2O$, by warming a soln. of cerous pyrophosphate in hydrochloric acid mixed with bromine.

§ 20. Yttrium

Yttrium occurs in virtually all the rare earths, but more particularly in gadolinite, xenotime, euxenite, polycrase, samarskite, and these minerals are common enough to act as a source of this earth—gadolinite from Hittero, for example, has been reported with 46·5 per cent. of yttrium earths; that from Colorado, 9–14 per cent.; xenotime from Hittero, 58 per cent., that from Minas Geraes, 64 per cent., that from Colorado, 67·8 per cent.; samarskite from Colorado, 17 per cent., and that from Urals, 21 per cent.; polycrase from Hittero, 32 per cent.; euxenite from Arendal, 30 per cent. Monazite has but 0·4 to 4·5 per cent. of yttria earths, but the by-product remaining after the extraction of thoria and ceria earths is a convenient source of yttria earths. Minerals rich in yttrium earths are more abundant than those rich in cerium earths. The cerium minerals are poor in yttrium earths, while the yttrium minerals are poor in cerium earths. It is, however, probable that although yttrium is the most abundant of the rare earths in the yttrium family, any one of the cerium elements, excluding samarium, is more abundant than yttrium. As previously indicated, yttria was discovered by J. Gadolin [1] in 1794, and afterwards studied by A. G. Ekeberg, M. H. Klaproth, L. N. Vauquelin, J. J. Berzelius, and N. J. Berlin.

J. J. Berzelius employed the following process of extraction: Powdered gadolinite is dissolved in aqua regia; the soln. evaporated to dryness; the mass extracted with hot water acidulated with hydrochloric acid; the soln. filtered from the silica; mixed with a sufficient quantity of potassium sulphate, which must project above the surface of the liquid; and left to stand for a space of 24 hrs.; potassium cerous sulphate is then precipitated in the form of a white powder. The whole is then passed through a filter and washed two or three times with water saturated with potassium sulphate; the filtrate and washings are neutralized with ammonia; and the ferric oxide precipitated by ammonium succinate. The filtered liquid treated with ammonia yields a precipitate consisting of basic yttrium sulphate mixed with a small quantity of mangnese oxide; it is repeatedly digested, while still moist, with fresh quantities of a dil. soln. of ammonium carbonate, well shaken, and allowed to stand. The yttrium carbonate dissolved in this liquid is precipitated on boiling the filtrate, and is then ignited. If after ignition it exhibits a brown instead of a greyish-yellow colour, it contains manganese. To eliminate this impurity, the salt is dissolved in nitric acid, evaporated to dryness, and heated in a sand-bath to the m.p. of tin, by which means the manganese nitrate is decomposed. The mass is then dissolved in a very small quantity of water: the almost syrupy liquid filtered through paper; diluted; mixed with ammonia; and the resulting hydrate exposed to a red heat. The residue on the filter containing manganese, yields, by washing with more water, a brown soln., which may be again evaporated and heated to separate the manganese. T. Scheerer discussed the separation of iron oxide from yttria.

In 1842, C. G. Mosander discovered that the earth yttria is not really simple because it can be resolved into three others. The name yttria was reserved for the most basic one, and the other two received the names erbia and terbia. The following is the procedure employed by C. G. Mosander:

When ammonia is added in small quantities at a time to a soln. of ordinary yttria in hydrochloric acid, and the precipitate produced by each addition is separately collected, washed, and dried, basic salts are obtained, the last of which are colourless, and consist of pure *yttria*. Proceeding from these last in the reverse order, we find that the precipitates become reddish and nearly transparent, and contain a larger and larger quantity of *terbia*, while the precipitates first formed contain the largest quantity of *erbia*, mixed, however, with terbia and yttria. When a soln. of crude yttria in nitric acid is treated in the same manner, and the several precipitates separately heated, the first precipitate yields an oxide of a deep yellow colour; and the colour of those which follow becomes continually lighter, till at length a colourless oxide is obtained, consisting mainly of yttria mixed with a small quantity of terbia. In these experiments, it is important that the crude yttria should be perfectly free from iron, uranium, etc. It is better, therefore, to precipitate it from the original soln. by a dil. soln. of ammonium sulphide; and, when the precipitate ceases to exhibit a bluish-green tinge, to filter the soln., and proceed with the filtrate as above. Or, better still: to add a portion of free acid to the soln. of yttria, and then to drop it gradually into a soln. of potassium oxalate, stirring constantly, till the precipitate no longer redissolves. In a few hours a precipitate is deposited; this must be separated by filtration, and the clear liquid again treated with acid oxalate, as long as a precipitate continues to form. The filtrate, on being neutralized with an alkali, yields a small quantity of nearly pure yttrium oxalate. The precipitates first obtained are crystalline, and rapidly fall to the bottom of the vessel; whereas the last, which is pulverulent, is slowly deposited. The first contain the largest quantity of erbia mixed with terbia and yttria; the next, chiefly terbia contaminated with erbia and yttria; and the last, nearly pure yttria. The first precipitates are always reddish; the last colourless. If the mixture of the earths be precipitated by an oxalate, and the precipitate digested in very dil. sulphuric acid (1 : 49), the acid first dissolves out the yttria, properly so called; and on treating the residue with sucessive portions of fresh acid, the quantity dissolved becomes less and less; and at the same time, the undissolved portion becomes more and more yellow by calcination. When the yttria has been thus removed, the residual oxalate is to be washed and ignited; the earth which remains, dissolved in nitric acid; and the soln.—which should not be too dil.—mixed to saturation with pounded potassium sulphate. By this means the erbia is precipitated in the form of a potassium erbium sulphate, which is nearly insoluble in water saturated with potassium sulphate, but dissolves easily in pure water. The potassium terbium sulphate remains in soln. The liquid having been filtered, and the precipitate washed, the potassium erbium sulphate may be dissolved in water, and the erbia precipitated by potassium hydroxide, then washed and ignited. The terbia may also be precipitated by treating the filtrate with potassium hydroxide.

Gadolinite is much more complex than the earlier chemists supposed. In the modern process of extracting yttrium, the rare earths sulphates, which have a low solubility in a sat. soln. of an alkali sulphate, are first separated; and the remaining earths are converted into bromates or ethyl sulphates and fractionated. The fraction between that with the least and that with the greatest solubility contains yttrium contaminated with dysprosium, holmium, and erbium. Various methods of fractionation have been used—*e.g.* fractional hydrolysis of the phthalates; fractional precipitation with potassium ferrocyanide; fractional crystallization of the double alkali sulphates; fractional precipitation of the chromates; fractional precipitation of the basic nitrates; etc. These methods have been previously described in the first purification. L. de Boisbaudran[2] fractionally precipitated with ammonia; P. T. Cleve fractionally crystallized the oxalate from nitric acid; R. J. Meyer and

J. Wuorinen fractionally precipitated the iodate from nitric acid, and they found that the chromate process separates yttrium from terbium and gadolinium, but is most applicable to mixtures from which the greater part of the terbium has been removed by other methods. They found that the fractional crystallization of the ethyl sulphates is tedious, but is suitable for large quantities. Precipitation with potassium ferrocyanide gives nearly pure yttria, but the yield is small, and the precipitates are not readily filtered. The crystallization of the double ammonium tartrates is unsuccessful, as is also the fractional hydrolysis of these salts by water, ammonia, or magnesia. E. W. Engle and C. W. Balke purified yttria by the chromate method; C. James and L. A. Pratt, by the basic nitrate method; and B. S. Hopkins and C. W. Balke, by the sodium nitrate method. J. P. Bonardi and C. James said the most rapid method for separating yttria from the yttria earths is by fractional precipitation with potassium cyanocobaltate. E. Wickers and co-workers found the nitrate method rather more efficient than the cyanocobaltate process. The subject has been discussed by C. C. Kiess and co-workers; and by H. C. Fogg and C. James.

C. James and L. A. Pratt proceeded with the basic nitrate method as follows: The fraction containing the yttria was precipitated as the hydroxide and well washed with boiling water. The hydroxides were next converted into the nitrates, and the latter subjected to fractional decomposition. This was carried out by evaporating the soln. and fusing until a portion had decomposed. The evolution of red fumes was allowed to proceed until the surface acquired a peculiar steely appearance. This point was easily ascertained by experience. The decomposition was allowed to continue until the mass became creamy. The fused mass was then poured into cold water. Great care was required in order to prevent spattering. The result of this operation was a nicely granulated product, which rapidly disintegrated upon boiling. Under the best conditions, the entire mass went into soln.; especially was this true of the yttrium end of the series. Upon cooling, the basic nitrates separated out in a crystalline form. At the opposite end—the least basic portion—of the fractions there always remained an insoluble basic nitrate, unless the decomposition was stopped at an earlier stage, *i.e.* when there was a copious evolution of red fumes.

In case a precipitate remained, it was highly important that it should be well agitated by thorough boiling. After cooling, the precipitate was filtered off, redissolved in nitric acid and again fused. The filtrate was also boiled down, and fused. This second series gives two filtrates and two precipitates. About 40 series of operations were carried out. The nitrate was dissolved in water, heated, and precipitated by means of oxalic acid. The resulting oxalate was filtered off, well washed, dried, and ignited. Some of the yttria still contained a little erbium and holmium. It was put through a modified chromate method. This yielded a supply of yttrium oxide of such a purity that, when converted into a conc. soln. of the nitrate, it showed no absorption bands through a layer of about 5 cms.

Yttrium metal has been obtained only in a more or less impure condition. H. Davy said that the old yttria at a white heat is but imperfectly decomposed by the vapour of potassium, and J. J. Berzelius stated that potassium yttrium fluoride appears to be decomposed by potassium, but on adding water, the yttrium is re-oxidized. F. Wöhler obtained the metal by the following process:

Yttrium chloride and flattened globules of potassium are arranged in alternate layers in a platinum crucible, the quantity of potassium not being quite sufficient to decompose the whole of the yttrium chloride; the cover is then fastened down by a wire, and the crucible heated. The reduction is effected in a moment, and with such violent disengagement of heat that the crucible becomes white hot. When the whole has become perfectly cold, the cover is taken off, and the crucible thrown into a large glass of water, in which the fused potassium chloride dissolves, with evolution of a small quantity of impure hydrogen gas having a fœtid odour; and the yttrium is collected on a filter, washed thoroughly, and dried.

P. T. Cleve and co-workers obtained it by the action of sodium on the anhydrous chloride; J. F. G. Hicks, by the same method, or by electrolyzing the fused chlorides; and C. Winkler, by the action of magnesium on the oxide at a high temp. E. W. von Siemens and J. G. Halske made yttrium by heating, in the absence of air, yttrium nitride, or other compound of yttrium with the elements of the nitrogen family. J. F. Bahr and R. Bunsen, and F. Wöhler obtained yttrium by the electrolysis of a molten mixture of sodium and yttrium chlorides. F. Wöhler, and O. Popp described the metal as a shining powder consisting of small scales with a metallic lustre, and of an iron-grey colour; when burnished, the colour and lustre of the metal resemble those of iron. P. T. Cleve and O. Höglund found that the metal is readily oxidized in air, and is converted into the hydroxide by boiling with water. When burnt in air, said F. Wöhler, yttrium oxide is formed. W. Kettembeil found that when soln. of the rare earths are electrolyzed with mercury cathodes, there is no formation of amalgam at the cathode. According to W. Nernst, a complex ion, MH_2, separates during the electrolysis of alkali salts at about 1·4 volts cathodic potential. Above this potential, with one-third of the current, the formation of amalgam should occur. Below this point to that where the metal ion itself separates, no formation of amalgam could be obtained, even in a freezing mixture, but evolution of hydrogen took place. It is supposed that the amalgam is formed, but is decomposed with such rapidity as to escape detection.

J. Missenden observed that, superficially, yttrium is iron-grey powder when freshly obtained, and is apt to assume a darkish appearance when kept for an appreciable time. This phenomenon is not to be explained by the combination of the metal with oxygen, as the oxide is white, and precisely the same effect is observed when the metal is placed in vacuo. The change is probably due to the energetic action of light, the darkening process being considerably retarded by preservation in a box from which all light has been excluded. W. Guertler and M. Pirani gave 1490° for the m.p. of the metal. W. R. Mott gave 1250° for the m.p., and 2500° for the b.p. of yttrium. The spark spectrum of yttrium has been investigated by R. Thalén,[3] O. Lohse, R. Bunsen, and F. Exner and E. Haschek. The more important lines are 3600·90, 3710·44, 3774·51, 4177·68, 4375·11, and 4883·95. The arc spectrum has been studied by F. Exner and E. Haschek, C. C. Kiess and co-workers, H. Kayser, G. Eberhard, L. F. Yntema and B. S. Hopkins, and J. M. Eder and E. Valenta. The most characteristic lines are 3216·83, 3242·42, 3328·02, 3600·92, 3611·20, 3621·10, 3633·28, 3664·78, 3710·47, 3774·52, 3788·88, 3950·52, 3982·79, 4077·5, 4102·57, 4128·50, 4143·03, 4302·45, 4309·79, 4318·93, 4375·12, 4883·89, 6191·91, and 6435·27. W. J. Humphreys studied the effect of press. on the spectral lines of yttrium; and B. E. Moore, the effect of a magnetic field in producing the Zeeman effect. F. G. Wick studied the effect of press. on the absorption spectrum. H. G. J. Moseley, D. Coster, E. Hjalmar, and E. Friman studied the high frequency or X-ray spectrum of yttrium. F. C. Blake and W. Duane, and M. Siegbahn gave for the K-series, $\alpha_2\alpha'=0{\cdot}840$; $\alpha_1\alpha=0{\cdot}835$; $\beta_1\beta=0{\cdot}746$; and $\beta_2\gamma=0{\cdot}733$; and for the L-series, D. Coster, E. Hjalmar, and M. Siegbahn gave $\alpha_1\alpha=6{\cdot}4349$; $\alpha_3\alpha''=6{\cdot}4065$; and $\beta_1\beta=6{\cdot}1984$. M. Muthmann, E. Baur, and R. Marc showed that yttrium compounds do not give the cathodic phosphorescent spectrum when highly purified; the results obtained by W. Crookes were caused by the presence of impurities. Soln. of yttrium salts give no absorption spectrum in the visible region.

The analytical reactions of yttrium.—Yttrium salts are colourless. With a soln. of yttrium nitrate as typical salt, the addition of aq. **ammonia,** or of **sodium or potassium hydroxide** precipitates the white hydroxide, insoluble in excess. The hydroxide precipitated from hot soln. is gelatinous, but is not difficult to filter, while that precipitated in the cold, is slimy and difficult to filter. If tartaric, citric, or other oxy-acid is present, no hydroxide is precipitated, but in the case of ammonia and tartaric acid, an ammonium yttrium tartrate is precipitated, and with alkalies, the tartrate is precipitated on boiling. The addition of **ammonium sulphide** soln. to the yttrium salt precipitates the hydroxide, insoluble in excess. The addition of **ammonium carbonate,** or an **alkali carbonate** gives a white precipitate of yttrium carbonate, soluble in excess; and the soln. after standing some time becomes turbid owing to the separation of the double salt. Unlike aluminium, thorium, and the cerium elements, **barium carbonate** gives no precipitate in the cold, and only an incomplete precipitation with hot soln. With **oxalic acid,** and **ammonium oxalate,** an amorphous oxalate is precipitated; the precipitate is almost insoluble in water; insoluble in an excess of oxalic acid; sparingly soluble in hydrochloric acid; but appreciably soluble in ammonium oxalate. A soluble double salt is formed with **potassium sulphate**; no precipitation occurs with **sodium thiosulphate.** White amorphous yttrium fluoride is precipitated by **hydrofluoric acid**; and the precipitate becomes pulverulent when warmed. It is insoluble in water and in *hydrofluoric acid. With* **hydrogen peroxide** *in alkaline soln.*, an unstable *peroxide is precipitated. A soln. of* **turmeric** *does not change colour.* With **iodic acid,** *no* precipitate is formed in nitric acid soln.; and with **sodium hypophosphate** no precipitation occurs in soln. strongly acidified with hydrochloric acid. W. Kettembeil could not make *yttrium amalgam* by electrolyzing an aq. soln. of a salt of yttrium using a mercury cathode.

The atomic weight of yttrium.—The individuality of yttrium is now considered to be definitely settled, and the high frequency spectrum fits the assumption that its **atomic number** is 39. In J. J. Berzelius'[4] at. wt. tables of old, yttrium appeared as 96·4 calculated for the tervalent element. In 1860, N. J. Berlin also gave 89·55. O. Popp analyzed yttrium sulphate, and from the ratio $Y_2(SO_4)_3 : 3BaSO_4$ calculated 102·3; and from the ratio $Y_2(SO_4)_3 : Y_2O_3$ obtained 102·0. M. Delafontaine for the same ratio obtained in 1865, 91·1 and 87·8. J. F. Bahr and R. Bunsen calculated 92·63 from the ratio 92·63; P. T. Cleve and O. Höglund (1873) obtained 89·57; P. T. Cleve (1883), 89·11; J. C. G. de Marignac, 88·95; H. C. Jones, 88·96; G. and E. Urbain, 88·6. R. J. Meyer and J. Wuorinen, 88·6; and R. J. Meyer and M. Weinheber, 88·71 to 88·76—average, 88·7. W. Feit and C. Przibylla, from the ratio $Y_2O_3 : 3H_2SO_4$, obtained 89·40. In 1913, J. E. Egan and C. W. Balke objected to the sulphate method because the value obtained varies with the time and temp. of the ignition of the yttrium oxide; and the octohydrate is too unstable for accurate work; they determined the ratio $Y_2O_3 : 2YCl_3$, and obtained 90·12; and B. S. Hopkins and C. W. Balke, 88·9. The values deviated from 88·80 to 89·06. H. C. Fogg and C. James obtained 89·03 from the ratio $YCl_3 : 3Ag$; and H. C. Kremers and B. S. Hopkins, 89·33. The International table for 1921 gives 88·7 as the best representative value for the at. wt. of yttrium. This number is probably rather low. F. W. Aston observed no **isotopes** by the positive ray analysis.

Yttrium forms white basic *yttria* or **yttrium oxide,** Y_2O_3, by the ignition of the hydroxide, oxalate, or nitrate. A. Duboin[5] prepared it in a crystalline form by fusing the oxide with calcium chloride. Yttria, said C. G. Mosander, is a colourless earth which is milk-white after ignition; but when not quite free from other earths it may have a yellowish colour. P. T. Cleve gave 5·028 for the sp. gr.; L. F. Nilson, 5·046; S. M. Tanatar and I. Voljansky, 5·326; and W. Muthmann and C. R. Böhm, 4·84. R. J. Meyer and J. Wuorinen gave 4·48 at 15°, and they suggested that the yttria used previously was impure. L. F. Nilson, and O. Pettersson said the sp. ht. is 0·1026 between 0° and 100°; and S. M. Tanatar and I. Voljansky gave 0·11729. W. R. Mott gave 4300° for the b.p. of yttrium oxide at 760 mm.; O. Ruff and coworkers gave 2410° to 2415° for the m.p. of yttria, and they found a vigorous vaporization occurs at 2350° and 15 mm. press. Yttria is feebly diamagnetic. The magnetic susceptibility of yttrium oxide was found by E. H. Williams to fall slightly from 20° to −140°. The value is less than 1×10^{-6}, and the experimental error large. E. Wedekind and P. Hausknecht found the at. magnetism of yttrium oxide to be $+8·7\times10^{-6}$. R. J. Meyer and J. Wuorinen gave for the magnetic susceptibility, $-0·14\times10^{-6}$ units. H. von Wartenberg and co-workers found yttria to be reduced by hydrogen at about 2000° if another metal be present—*e.g.* tungsten. P. T. Cleve found that yttria readily absorbs ammonia from the air; and it is a strong base capable of expelling ammonia from ammonium salts. When heated with conc. acids, said C. G. Mosander, yttria becomes hot and dissolves, but not so quickly as in dil. acids. It dissolves rapidly in hot acids. Its neutral sols taste sweet at first, and afterwards astringent. W. W. Coblentz found that yttrium oxide had a deep red colour at temp. between 900° and 1000°. The ultra-red emission spectrum has maxima at 2μ, 2·76μ, 3μ, 3·6μ, 4·6μ, and 6·9μ. The reflecting power for light of wave length $\lambda=0{\cdot}60\mu$ is 73·8 per cent.; for $\lambda=4{\cdot}4\mu$, 34·4 per cent.; for $\lambda=8{\cdot}8\mu$, 11·1 per cent.; and for $\lambda=24\mu$, 10 per cent. P. T. Cleve obtained **yttrium hydroxide,** $Y(OH)_3$, as a white gelatinous precipitate by adding ammonia or alkali hydroxide to a soln. of an yttrium salt. It dries to a white powder which absorbs carbon dioxide from the air. B. Szilard described **colloidal yttrium hydroxide**—*vide* thorium hydroxide. J. Böhm and H. Niclassen studied the X-radiograms of the sol and gel of the hydroxide. A. B. Schiotz found the oxide dissolves in formic acid, and is precipitated from this soln. by acetic acid. If an yttrium salt is precipitated by ammonia in the presence of hydrogen peroxide, hydrated **yttrium peroxide,** $Y_4O_9.nH_2O$, is produced.

P. T. Cleve prepared hemihydrated **yttrium fluoride,** $YF_3.\frac{1}{2}H_2O$, as a white gelatinous precipitate, by adding hydrofluoric acid, or an alkali fluoride to a soln. of an yttrium salt. H. Moissan and A. Étard prepared the anhydrous salt by the action of fluorine on the carbide. Yttrium fluoride occurs in nature as yttrocerite (*q.v.*). C. G. Mosander prepared a radiating mass of crystals, of **yttrium chloride,** which, according to P. T. Cleve, are hexagonal prismatic crystals of the hexahydrate, $YCl_3.6H_2O$, and are obtained by slowly concentrating the aq. soln. These crystals deliquesce in air and are readily soluble in water and in alcohol, but not in ether. According to C. A. Matignon, a mol of the salt loses five mols of water at 110°, forming the monohydrate, $YCl_3.H_2O$, which melts between 156° to 160°; the anhydrous salt is formed at 170°–180°, but owing to hydrolysis, some oxide is formed at the same time. P. T. Cleve made the anhydrous salt by heating an intimate mixture of ammonium chloride and the hexahydrate; C. A. Matignon, by evaporating a soln. of the oxide in hydrochloric acid to dryness, and heating the product in a mixture of hydrogen chloride and sulphur chloride; A. Duboin, by heating the oxide in a mixture of carbon dioxide and chlorine; F. V. Radominsky, by heating the hexahydrate in a stream of hydrogen chloride; and H. Moissan and A. Étard, and O. Pettersson, by heating the carbide in a stream of hydrogen chloride. H. C. Kremers and B. S. Hopkins, and H. C. Fogg and C. James have discussed the preparation of the pure salt.

According to C. A. Matignon, the sp. gr. of the anhydrous salt is 2·80 at 18°, it melts below 686°, and solidifies to shining white leaflets which volatilize at a high temp. W. W. Coblentz studied the ultra-red transmission spectrum. He also found that the heat of soln. of anhydrous yttrium chloride in water is 45·3 Cals., and that the aq. soln. is neutral to methyl orange. Further, the anhydrous salt is very soluble in alcohol, and pyridine: 100 grms. of alcohol at 15° dissolve 60·1 grms. of the chloride, and the soln. deposits crystals of the complex $YCl_3.C_2H_5OH$; and 100 grms. of pyridine at 10° dissolve 60·6 grms. of the chloride and the soln. furnishes crystals of an addition compound, $YCl_3.3C_5H_5N$. G. A. Barbieri and F. Calzolari obtained crystals of an addition compound, $YCl_3.2C_6H_{12}N_4.11H_2O$, with hexamethylenetetramine. P. T. Cleve, and L. F. Nilson prepared chloroaurates, chloroplatinites, and chloroplatinates. O. Popp prepared enneahydrated **mercuric yttrium chloride,** $YCl_3.3HgCl_2.9H_2O$, from a soln. of the component salts. The deliquescent salt is easily soluble in water and alkalies.

According to P. T. Cleve, enneahydrated **yttrium bromide,** $YBr_3.9H_2O$, crystallizes from an aq. soln. of the salt in deliquescent crystals easily soluble in water. A. Duboin made the anhydrous bromide, YBr_3, by heating yttria in a mixture of bromine vapour and carbon dioxide; the crystals are said to be very deliquescent, and very fusible. P. T. Cleve similarly made deliquescent crystals of **yttrium iodide,** which are readily soluble in water and in alcohol.

P. T. Cleve made **yttrium sulphide,** Y_2S_3, by heating the anhydrous chloride in a stream of hydrogen sulphide; and O. Popp, by melting the oxide with sulphur and sodium carbonate; or by heating the oxide in a stream of carbon disulphide. The yellow powder of the sulphide is decomposed by water. A. Duboin made **sodium yttrium sulphide,** $Na_2S.Y_2S_3$, or $NaYS_2$, in greenish leaflets, by passing hydrogen sulphide over a heated mixture of yttrium oxide and sodium sulphide.

C. G. Mosander found that **yttrium sulphate** crystallizes from its aq. soln. in small, compact, colourless prisms ; the salt retains its water of crystallization at 80°. The crystals are octohydrated, $Y_2(SO_4)_3.8H_2O$; and, according to C. F. Rammelsberg, and E. H. Kraus, they form monoclinic prisms isomorphous with the corresponding salts of erbium, gadolinium, samarium, praseodymium, and neodymium ; the axial ratios are $a:b:c=3\cdot0284:1:2\cdot0092$, and $\beta=118° 25'$. H. Töpsöe gave 2·530 for the sp. gr., and E. H. Kraus, 2·558. According to the last-named, the double refraction is positive, and the indices of refraction for Na-light are $\alpha=1\cdot5433$, $\beta=1\cdot5490$, and $\gamma=1\cdot5755$. When the octohydrate is heated, it furnishes the anhydrous sulphate, $Y_2(SO_4)_3$, which, according to L. F. Nilson and co-workers, has a sp. gr. 2·52, and sp. ht. 0·1319. E. Löwenstein measured the vap. press. of the hydrated sulphates and found evidence of the octohydrate only. E. Wedekind and P. Hausknecht found the mol. magnetism of yttrium sulphate to be $-5\cdot7\times10^{-6}$. Both the anhydrous salt and the octohydrate are very soluble in cold water. J. Thomsen gave for the heat of soln. $Y_2(SO_4)_3+8\cdot04H_2O$, 10·68 Cals. F. Wirth found the solubility of the octohydrate is 5·02 grms. of the anhydrous sulphate in 100 grms. of soln. at 25° ; or 100 parts of cold water dissolve 9·3 grms. of the octohydrate, and 4·6 grms. at 100°. According to O. Brill, **yttrium dioxysulphate,** $Y_2O_2(SO_4)$, is formed when the anhydrous sulphate is heated to 700°. P. T. Cleve found that $Y_4O_5(SO_4).10H_2O$ is formed by a partial precipitation of a soln. of the sulphate by dil. ammonia ; but whether this is a chemical individual has not been demonstrated. B. Brauner and A. Picek made **yttrium hydrosulphate,** $Y(HSO_4)_3$, by crystallization from a soln. of the anhydrous sulphate in conc. sulphuric acid. P. T. Cleve prepared a white, amorphous, pulverulent **sodium yttrium sulphate,** $Na_2SO_4.Y_2(SO_4)_3.2H_2O$, easily soluble in water. According to C. James and H. C. Holden, equilibrium in the ternary system, $Na_2SO_4-Y_2(SO_4)_3-H_2O$, at 25°, is attained very slowly—to be exact, 14 months. The relative solubilities, expressed in grams of anhydrous salts per 100 grms. of water, are :

Na_2SO_4 . .	1·29	3·85	8·53	7·57	10·14	14·89	21·05	28·13
$Y_2(SO_4)_3$ . .	5·61	6·38	8·43	5·86	3·42	1·90	3 04	1·61
Solid phase . .	$Y_2(SO_4)_3.8H_2O$			$Y_2(SO_4)_3.Na_2SO_4.2H_2O$				

Hence, Fig. 25, the addition of sodium sulphate increases the solubility of yttrium sulphate up to a maximum ; the solubility then diminishes rapidly and at the same time the solid phase changes from octohydrated yttrium sulphate to the double salt. P. T. Cleve obtained crystals of **potassium yttrium sulphate,** $Y_2(SO_4)_3.4K_2SO_4$, by crystallization from a soln. of one mol of yttrium sulphate and three mols of potassium sulphate ; the mother liquid furnished P. T. Cleve and O. Höglund with needle-like crystals of $Y_2(SO_4)_3.3K_2SO_4$. 100 c.c. of a cold sat. soln. of potassium sulphate dissolve 4·865 grms. of Y_2O_3 as sulphate. P. T. Cleve also prepared small tabular crystals of **ammonium yttrium sulphate,** $2(NH_4)_2SO_4.Y_2(SO_4)_3.9H_2O$; it loses four mols of water when confined over sulphuric acid. R. J. Meyer and U. Müller made crystals of **yttrium hydrazine sulphate,** $Y_2(SO_4)_3.(N_2H_5)_2SO_4.3H_2O$, by evaporating a soln. of the mixed sulphates. The salt is very soluble in water.

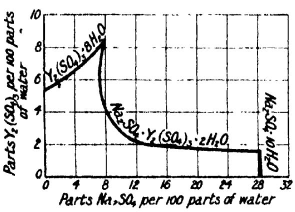

FIG. 25.—The Ternary System, $Y_2(SO_4)_3-Na_2SO_4-H_2O$, at 25°.

P. T. Cleve passed carbon dioxide into a soln. of yttrium hydroxide in one of sodium carbonate, and obtained white pulverulent **yttrium carbonate,** $Y_2(CO_3)_3.3H_2O$; he obtained the same salt by adding an alkali carbonate to a soln. of an yttrium salt ; the precipitate gradually crystallizes. O. Popp found that in this process the precipitate retains much sodium carbonate. P. T. Cleve and O. Höglund say that yttrium carbonate is insoluble in water, and very sparingly soluble in carbonic acid; it loses a mol of water at 100°, and all is lost at 130°. W. H. Evans reported that yttrium carbonate acts unfavourably on the growth of plants. P. H. M. P. Brinton and C. James found that the percentage hydrolysis of yttrium carbonate—the ratio of the amount of carbon dioxide expelled by boiling to the total carbon dioxide originally present in the system—is after boiling with water for different periods of time:

Hours boiling	0·5	1·0	1·5	2·0	2·5	3·0
Hydrolysis	44·9	48·5	51·0	52·8	54·0	55·1

According to P. T. Cleve, yttrium carbonate is soluble in an excess of sodium carbonate, and, when the soln. is allowed to crystallize, needle-like crystals of **sodium yttrium carbonate,** $Na_2CO_3.Y_2(CO_3)_3.4H_2O$, are formed; the same salt is formed as a voluminous precipitate when sodium carbonate is digested with an aq. soln. of yttrium chloride. The precipitate slowly crystallizes. A soln. of yttrium carbonate in one of ammonium carbonate likewise furnishes **ammonium yttrium carbonate,** $(NH_4)_2CO_3.Y_2(CO_3)_3.2H_2O$; it is also obtained by adding a soln. of yttrium nitrate to an excess of a soln. of ammonium carbonate.

C. G. Mosander found that the crystallization of a soln. of **yttrium nitrate** furnishes a mass of laminated crystals. P. T. Cleve and O. Höglund evaporated the soln. over sulphuric acid, and obtained the hexahydrate, $Y(NO_3)_3.6H_2O$, in crystals which, according to F. Zambonini, belong to the triclinic system. According to V. von Lang and L. Haitinger, the crystals are strongly doubly refracting, triclinic pinacoids, isomorphous with the gadolinium salt; and isodimorphous with bismuth nitrate. P. T. Cleve and O. Höglund found the crystals are deliquescent in moist air; and they lose three mols. of water at 100° or over conc. sulphuric acid, forming the trihydrate, $Y(NO_3)_3.3H_2O$. E. Löwenstein measured the vap. press. of yttrium nitrate crystals and found evidence of the hexa-, penta-, and tri-hydrates. The trihydrate, according to E. Demarçay, crystallizes from conc. nitric acid. P. T. Cleve and O. Höglund found the hexahydrate to be readily soluble in water, alcohol, and ether. S. M. Tanatar and I. Voljansky also reported a dihydrate, $Y(NO_3)_3.2H_2O$. F. Zambonini obtained a series of mixed crystals of calcium nitrate, $Ca(NO_3)_2.4H_2O$, and up to 2·19 per cent. of yttrium nitrate, $Y(NO_3)_3.6H_2O$; and also between strontium nitrate, $Sr(NO_3)_2.4H_2O$, and up to 0·86 per cent. of yttrium nitrate. According to J. F. Bahr and R. Bunsen, a basic nitrate is formed when yttrium nitrate is heated until red nitrous fumes appear; and the residue passes into yttria at a still higher temp. When the basic nitrate is boiled with the smallest possible amount of water and allowed to cool, the hydrated salt $Y(NO_3)_3.Y(OH)_3.3H_2O$ appears. According to C. James and L. A. Pratt, the only basic nitrate stable at 25° in aq. soln. is **yttrium oxynitrate,** $Y(NO_3)_3.YO(NO_3).10H_2O$, or $3Y_2O_3.4N_2O_5.20H_2O$. C. James and L. A. Pratt studied the ternary system, $Y(NO_3)_3-Y(OH)_3-H_2O$, and, expressing the conc. of the compounds in grams per 100 c.c. of water at 25°, they found:

$Y(NO_3)_3$	3·13	13·87	33·02	44·35	89·06	137·10	141·6
Y_2O_3	0·014	0·034	0·160	0·114	0·074	0 083	0
Sp. gr.	1·0260	1·1106	1·2517	1·3268	1·5587	1·7440	1·744
Solid phase	$Y(OH)_3$		$3Y_2O_3.4N_2O_5.2H_2O$				$Y(NO_3)_3$

The results are plotted in Fig. 26. This salt is stable in air, and in the presence of a soln. of yttrium nitrate containing one-fourth of its weight or more of anhydrous nitrate. It is not affected by absolute alcohol, but is decomposed by water.

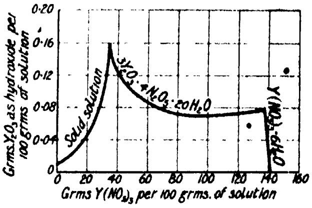

FIG. 26.—The Ternary System, $Y_2O_3-N_2O_5-H_2O$, at 25°.

The mineral xenotime (*q.v.*) is **yttrium orthophosphate,** YPO_4; and weinschenkite (*q.v.*) is another, (Y, Er, . . .)$PO_4.2H_2O$. According to P. T. Cleve, when an ammoniacal soln. of ammonium orthophosphate, or phosphoric acid, is *added to a soln. of yttrium nitrate, the dihydrate,* $YPO_4.2H_2O$*, is precipitated. F. V. Radominsky obtained crystals of the amorphous phosphate, artificial xenotime, by melting the precipitated phosphate with ten times its weight of yttrium chloride, and washing with water and acetic acid. F. Zambonini made crystals of yttrium apatite by fusing and slowly cooling a mixture of calcium orthophosphate and chloride, and yttrium orthophosphate. The crystals contained up to 6 per cent.* YPO_4. P. T. Cleve found that if disodium hydrophosphate is added to a soln. of an yttrium salt, amorphous **yttrium hydrophosphate,** $Y_2(HPO_4)_3$, is precipitated. According to W. Wartha, xenotime is sparingly soluble in conc. hydrochloric acid, but if it has been previously heated with a little conc. acid, dissolution readily occurs. K. R. Johnson obtained microscopic six-sided plates of **yttrium pyrophosphate,** $2Y_2O_3.3P_2O_5$, or $Y_4(P_2O_7)_3$, by melting orthophosphoric acid with yttrium sulphate. The salt fuses with difficulty, its sp. gr. is 3·059, and it is insoluble in acids. P. T. Cleve made **yttrium hydropyrophosphate,** $Y_2(H_2P_2O_7)_3.7H_2O$, in crystal aggregates, from a soln. of yttria in pyrophosphoric acid. The salt loses six mols of water over conc. sulphuric acid; and it does not fuse at a red heat. K. A. Wallroth heated yttria with microcosmic salt, and obtained **sodium yttrium pyrophosphate,** $NaYP_2O_7$. By melting the amorphous phosphate with sodium or potassium ortho- or pyro-phosphate, A. Duboin obtained crystals of salts with the composition $K_2O.Y_2O_3.2P_2O_5$; $3K_2O.Y_2O_3.2P_2O_5$; $3K_2O.5Y_2O_3.6P_2O_5$; and $3Na_2O.Y_2O_3.2P_2O_5$. P. T. Cleve evaporated to dryness a soln. of yttrium nitrate with an excess of orthophosphoric acid; and extracted the calcined mass with water. The resulting white crystalline **yttrium metaphosphate,** $Y(PO_3)_3$, was insoluble in water and acids.

§ 21. The Terbium Family of Rare Earths

The terbium family of rare earths is arbitrarily taken to include the three elements, europium, Eu; gadolinium, Gd; and terbium, Tb. The general characters resemble those of the cerium family. The members of this family decrease in basicity in the order: . . ., Sa, Eu, Gd, Tb, Dy, . . ., so that the cerium family merges into the terbium family, and the latter into the yttrium family. There are no sharp lines of demarcation between these three families. The elements are all tervalent and yield colourless oxides of the type R_2O_3, although terbium alone furnishes what is considered to be a higher oxide, Tb_4O_7. The terbium elements yield salts of the type RX_3, where X represents a univalent acidic radicle; europium alone gives rise to salts of the type EuX_2, corresponding with the unknown oxide, EuO, where europium is bivalent. Samarium is the only other rare earth element which acts as a dyad, and it forms halides of the type SaX_2. Soln. of the salts of terbium and europium exhibit a weak absorption spectra in the visible region; where soln. of terbium salts give an absorption spectrum only in the ultra-violet region. The salts of terbium are generally less soluble than those of gadolinium. The solubility of the double potassium or sodium sulphates is rather greater than is the case with the cerium family, and less than with the yttrium family.

The history and occurrence have already been discussed. The terbia earths are found in small amounts in the majority of the ceria and yttria minerals. They are usually extracted from gadolinite, xenotime, and samarskite, because these minerals are readily obtained, and contain a larger proportion of the terbia earths than other minerals. Probably europium is the most sparsely distributed and gadolinium the most plentiful of these elements, but in any case the actual proportion of these elements in any given mineral is very small. G. Urbain and H. Lacombe [1] say that monazite does not contain more than 0·002 per cent. of europia. The occurrence of these elements in the sun has been previously considered.

The isolation of the terbium earths.—As previously indicated, the terbium earths can be separated from the cerium and yttrium earths by fractional crystallization of the double alkali sulphates, but the separation is not clean since a large proportion crystallizes with the cerium earths, and remains in soln. with the yttrium earths. The fractional crystallization of the ethylsulphates with alcohol or water as solvent enables the terbia earths to be isolated fairly quickly, the cerium ethylsulphates crystallize first, and the yttrium sulphates last. The fractional crystallization of the formates from aq. formic acid also enables a separation to be made, although there is a loss since some of the terbia earths accompany the yttria earths and are not separable by the formate process. The general scheme for the isolation of the rare earths, previously discussed, provides for the isolation of the members of this family of earths.

The isolation of europia.—E. Demarçay [2] noted that in the fractional crystallization of a mixture of rare earths rich in samaria and gadolinia from conc. nitric acid, there appeared a new nitrate with a solubility greater than that of gadolinium and less than that of samarium. The element was found to have a characteristic spectrum; and he named it provisionally Σ. A year later he named it europium, and found that the crystallization of the double magnesium nitrate gave a more rapid separation. Before E. Demarçay's work, L. de Boisbaudran had noted some spectral lines in some samarium preparations which were attributed to elements Z_ϵ and Z_ζ, and which were afterwards found by E. Demarçay to coincide with those given by europium; similarly, in 1885, W. Crookes noted a red band, $\lambda=6090$, in the phosphorescent spectrum of a preparation obtained by fractionating yttria earth. The band was sometimes nebulous, sometimes clear and sharp, and almost as narrow as a spark line. W. Crookes called it the *anomalous line*, and he considered it to be produced only when samaria and yttria are simultaneously present; soon afterwards, W. Crookes attributed the line to a new element which he called

S_δ. This element was afterwards shown by E. Demarçay to have the same spectrum as europium. G. Urbain and H. Lacombe found that bismuth magnesium nitrate furnishes crystals which were isomorphous with the corresponding salts of samarium and europium, and were intermediate in solubility; and with the bismuth salt as *l'élément séparateur*, it was found possible to separate europium from samarium and gadolinium. C. James and J. E. Robinson obtained europium from monazite residues by the following process:

The crude oxides were dissolved in conc. nitric acid, taking care that the soln. did not become alkaline. An eq. amount of nitric acid was similarly treated with magnesium oxide. The two soln. were mixed, and evaporated until half the solute crystallized out on cooling. The mother liquid was poured off and evaporated further for crystallization. The double nitrates which separated were recrystallized three times, and then set aside. When the mother liquors began to crystallize badly, they were treated with oxalic acid, and the washed oxalates were ignited. The resulting mixture of oxides of lanthanum, cerium, praseodymium, neodymium, samarium, gadolinium, yttrium, etc., were again converted into double magnesium nitrates and recrystallized from 30 per cent. nitric acid. The cerium, lanthanum, praseodymium, and neodymium rapidly collected in the least soluble portion; the intermediate fraction contained the pale yellow samarium salts; and the most soluble portion contained gadolinium, erbium, and yttrium salts. As soon as crystals of yttrium nitrate appeared in the most soluble fractions, bismuth magnesium nitrate was introduced and all traces of samarium and europium were soon separated. The samarium was removed, by fractionation, from the cerium, lanthanum, praseodymium, and neodymium fraction. The samarium-gadolinium fractions were then recrystallized. The blue europium absorption band appeared in the fractions of the gadolinium next to the samarium; and the blue europium band gradually became stronger in the fractions between samarium and gadolinium. Later, the two green europium bands appeared. The fractions showing no europium absorption spectrum were removed. The fractions containing bismuth magnesium nitrate were mixed according to their absorption spectra, diluted, and treated with hydrogen sulphide. The filtrates containing europium were treated with oxalic acid; and the europium oxalate collected and washed. The oxalate from each filtrate was ignited, dissolved in nitric acid, and the soln. examined spectroscopically. The soln. of europium nearest to the samarium fraction were still contaminated with that element. The europium material was again converted to the double magnesium nitrate, and fractionally crystallized with bismuth magnesium nitrate until free from samarium. The bismuth was then removed with hydrogen sulphide, and the europium oxalate precipitated as before.

The isolation of gadolinia.—J. C. G. de Marignac[3] announced the discovery of a new earth in samarskite which he designated Y_a. The impure earth was obtained by fractional precipitation with potassium sulphate. L. de Boisbaudran applied the term gadolinium to the new element which he obtained by the fractional decomposition of the nitrates, and also by fractional precipitation with ammonia. A. Bettendorff separated gadolinium from orthite. C. Benedicks obtained gadolinia by the fractional crystallization of the simple nitrates from nitric acid, and also by fractional precipitation with ammonia. E. Demarçay fractionally crystallized the double magnesium nitrates; and R. Marc fractionally crystallized the double potassium sulphates. G. Urbain and H. Lacombe used bismuth magnesium nitrate in conjunction with E. Demarçay's process, and later purified the material by recrystallization of the double nickel nitrates from conc. nitric acid. According to L. Jordan and B. S. Hopkins, the dimethyl phosphate fractionation very rapidly and completely concentrated the europium and samarium and removed them from the gadolinium. The greater part of the terbium was separated in the insoluble fractions of the series. The method did not remove the last traces of terbium which still coloured the gadolinium oxide a light yellow-brown. Gadolinium oxide of considerable purity was obtained from the middle fractions of this series. Gadolinium material giving an oxide coloured orange-brown by terbium was fractionated as the bromate in the presence of neodymium. The method was more tedious than the dimethyl phosphate method, but almost completely removed even the last traces of terbium from the gadolinium and furnished a light cream, almost colourless, oxide. This oxide still contained a small quantity of neodymium and samarium. The first method studied would seem to be an effective method for removing these earths. C. C. Kiess and co-workers, and R. J. Meyer and U. Müller have also discussed this subject.

The isolation of terbia.—In 1842, C. G. Mosander[4] first obtained what he called erbium from some yttria earths, but several chemists—*vide* the history of the rare earths—failed to obtain C. G. Mosander's orange-yellow erbia, and in consequence the term came to be applied to an earth which gave a rose-red oxide. In 1887, M. Delafontaine succeeded in getting C. G. Mosander's erbia from samarskite, and since the term was now generally applied to another earth, M. Delafontaine and C. G. Mosander's erbia was called terbia. J. C. G. de Marignac, and P. T. Cleve confirmed the existence of orange-yellow terbia. L. de Boisbaudran concluded that there were four terbia earths, which he designated Z_α, Z_β, Z_γ, and Z_δ. K. A. Hofmann and G. Krüss found that what was regarded as terbia could not be resolved by the fractionation of the double sulphates or formates, but could be resolved in aniline hydrochloride. R. Marc, E. Portratz, and W. Feit made some observations on this subject. G. Urbain found that a soln. of terbium oxide which he prepared gave the absorption spectrum of Z_δ, the inverse spectrum of Z_β, the spark spectrum of E. Demarcay's element Γ, and the phosphorescent spectrum of one of W. Crookes' ionium, incognitum, and his G_β. C. A. von Welsbach fractioned the double oxalates of the yttria earths, and claimed to have split terbium into three elements, but neither G. Urbain nor C. James and D. W. Bissel could confirm this.

The methods originally used for separating terbia gave preparations with only a few per cent. of that earth. These methods included the fractional decomposition of the nitrates; fractional precipitation by potassium sulphate; fractional precipitation of the oxalates from a nitric acid soln.; and the fractional precipitation of the formates. L. de Boisbaudran recommended fractional precipitation by ammonia, but G. Urbain said the process is very tedious, and recommended the fractional crystallization of the double nitrates of these earths and nickel; the fractional crystallization of the simple nitrates in the presence of bismuth nitrate; and the fractional crystallization of the ethylsulphates. C. James and D. W. Bissel used the bromate process:

> The fraction, mainly containing the gadolinium, terbium, dysprosium, and holmium oxides, was warmed with bromic acid; and the resulting bromates fractionally crystallized. The order of decreasing solubility is: La, Ce, Pr, Nd, Sa, and Eu; and the solubility then increases in the order Eu, Gd, Tb, Dy, Ho, Y, Er, Tm, Yb, Lu, and Sc. The whole of the terbium and most of the holmium and dysprosium soon collected in the most soluble portions. As the work proceeded, some europium collected in the least soluble portion as shown by the blue absorption band of the soln. The gadolinium collected in the least soluble portion and gave a white oxide. Gadolinium bromate was removed as soon as it gave a white oxide; and the more soluble fractions as soon as they gave a buff-coloured oxide. The fractions which gave the darkest coloured oxides gave the absorption band of terbium alone; the more soluble portions of the fractions giving the terbium band also gave absorption bands of dysprosium; and the less soluble portions, the absorption bands of neodymium. As large amounts of gadolinium bromate were, however, rapidly removed from one end, and fair quantities of the bromates of erbium, yttrium, holmium, and dysprosium from the other, the bulk of material undergoing fractionation quickly decreased. The whole of the erbium was removed in the most soluble portion after a few crystallizations. This was followed by yttrium and holmium with some dysprosium. Finally, the holmium bands became very faint, and later dysprosium, with a little terbium, formed the most soluble fractions of the series. The crystallization of the chlorides from hydrochloric acid was used in the endeavour to separate small amounts of terbium from dysprosium. The chlorides formed very nice crystals, and the mother liquor could easily be drained off. The rate of fractionation seemed to be about the same as in the case of the nitrates. The oxide from the least soluble portion was darker than that from the most soluble. This showed that terbium chloride like terbium nitrate passed into the least soluble fractions.

The metals of the terbium family have not been isolated. The **spark spectrum** of dysprosium has been investigated by E. Demarçay,[5] C. Benedicks, J. M. Eder and E. Valenta, W. Crookes, G. Urbain, F. Exner and E. Haschek, etc.; and the **arc spectrum** by F. Exner and E. Haschek, G. Eberhard, J. Lunt, and J. M. Eder and E. Valenta. The most prominent lines in the arc spectra have the wave-lengths:

3688·57, 3725·10, 3819·80, 3907·28, 3930·66, 3972·16, 4129·90, 4205·20, 4435·75, 4522·76, 4594·27, 4627·47, 4662·10, 6645·44. The spark spectrum of gadolinium[6] has been measured by C. Benedicks, E. Demarçay, L. de Boisbaudran, F. Exner and E. Haschek, G. Urbain, W. Crookes, J. M. Eder, E. Baur and R. Marc, etc. The arc spectrum of gadolinium is very rich in lines which have been measured by F. Exner and E. Haschek, C. C. Kiess, G. Eberhard, and J. M. Eder and E. Valenta. The more prominent lines in the arc-spectrum characteristic of gadolinium have the wave-lengths: 3082·15, 3100·66, 3422·62, 3545·94, 3549·52, 3585·12, 3646·36, 3671·39, 3719·63, 3743·68, 3768·60, 3796·62, 3814·18, 3852·65, 3916·70, 4037·49, 4050·05, 4063·62, 4070·51, 4073·99, 4085·73, 4098·80, 4130·59, 4184·48, 4251·90, 4262·24, 4325·83, 4327·29, 4342·35, 6114·26. W. M. Hicks, and E. Paulson have sought for regularities in the spectral lines of gadolinium. The spark spectrum of terbium[7] has been measured by E. Demarçay, G. Urbain, etc.; and the arc spectrum by G. Eberhard, J. M. Eder and E. Valenta, F. Exner and E. Haschek, etc. The more prominent lines in the arc spectrum of terbium have the wave-lengths: 3324·53, 3509·34, 3531·86, 3561·90, 3568·69, 3600·60, 3628·53, 3650·60, 3659·02, 3704·10, 3711·91, 3848·90, 3874·33, 3899·34, 3925·60, 3939·75, 3977·01, 3982·07, 4005·70, 4012·99, 4278·70, 4752·69.

The **reversion spectrum** of europium was studied by E. Demarçay,[8] G. Urbain, and L. de Boisbaudran. There is a red phosphorescence, and a dil. acid soln. gives two bands, one between $\lambda=6160$ and $\lambda=6110$ with a maximum at $\lambda=6125$, and the other between $\lambda=5970$ and $\lambda=5920$ with a maximum at $\lambda=5890$. L. de Boisbaudran, and G. Urbain also found that terbium gives a green phosphorescence, and the chloride soln. shows four bands with maxima respectively at $\lambda=6205$, 5858, 5432, and 4870.

G. Urbain[9] found that purified europia gives no **cathodic phosphorescent spectrum,** but if a trace of calcium sulphide or oxide be present, or if traces of other earths are present, the luminescent spectrum is very intense; it has been studied by W. Crookes, G. Urbain, and E. Demarçay. Gadolinia when pure gives no cathodic luminescent spectrum, but if slightly impure it gives a green phosphorescence whose spectrum has been studied by G. Urbain, and W. Crookes. Terbia also gives no luminescent spectrum if purified, but if a trace of alumina is present, it gives a white fluorescence. The green fluorescence of terbium chloride in the cathode rays was studied by G. Urbain. The high frequency or **X-ray spectra** of europium, gadolinium, and terbium were studied by H. G. J. Moseley, E. Friman, D. Coster and co-workers, and E. Hjalmar.

Neutral soln. of europium chloride are rose-coloured, and the **absorption spectrum** has been studied by G. Urbain,[10] W. Prandtl, L. F. Yntema, and E. Demarçay. The bands in the visible part of the spectrum are narrow and faint. There are maxima for $\lambda = 5913$, 5882, 5790, 5337, 5251, 5234, 4656, 4645, 4000, 3950, 3853, 3836, 3800, 3760, 3746, 3663, 3615, 3207, 3192, 3178, 3168, and 2983; with a soln. of europium nitrate, Fig. 27, a band 5913 replaces 5913 and 5882 of the chloride spectrum; 5337 gives place to 5337; 5250 replaces 5251 and 5234; and 4660 replaces 4656 and 4645. Soln. of gadolinium salts are colourless if the acid radicle is colourless. The absorption bands of an aq. soln. of gadolinium chloride were studied by G. Urbain, J. L. Soret, and H. C. Jones and W. W. Strong; they are all in the ultra-violet with maxima at 3794, 3697, 3596, 3515, 3108, 3059, 3056, and 3052. H. C. Jones and W. W. Strong measured

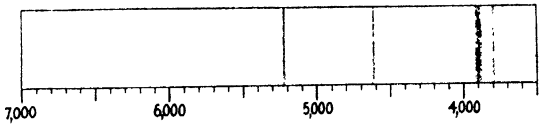

FIG. 27.—Absorption Spectrum of Europium Nitrate Solution.

the absorption spectrum of a soln. of gadolinium chloride in aq. alcohol, and found it very different from that in aq. soln. Soln. of terbium salts are colourless if the acid radicle is colourless. L. de Boisbaudran, and G. Urbain showed that with the exception of the feeble blue band 4880, Fig. 28, the nine absorption bands of terbium salt soln. are in the ultra-violet with maxima at 4880, 3787, 3694, 3592, 3519, 3420, 3390, 3266, 3176, 3029. J. Carrera gave for the absorption coeff. for the K-series of X-ray spectra, Eu, 59·81; Gd, 60·84; and Tb, 61·93. The K-series were examined by M. Siegbahn and E. Jönsson, and W. Duane and T. Shimizu; and for the L-series, D. Coster, E. Hjalmar, and M. Seigbahn gave for europium $\alpha_2\alpha'=2{\cdot}12733$; $\alpha_1\alpha=2{\cdot}11633$; $\beta_1\beta=1{\cdot}91631$; $\beta_2\gamma=1{\cdot}807$; $\gamma_1\delta=1{\cdot}659$; $\gamma_2\theta=1{\cdot}598$; $\beta_4\upsilon=1{\cdot}921$; and $\beta_3\phi=1{\cdot}886$; for gadolinium, $\alpha_2\alpha'=2{\cdot}05264$; $\alpha_1\alpha=2{\cdot}04193$; $\beta_1\beta=1{\cdot}84246$; $\beta_2\gamma=1{\cdot}741$; $\gamma_1\delta=1{\cdot}58863$; $\beta_4\upsilon=1{\cdot}848$; and $\beta_3\phi=1{\cdot}809$; and for terbium, $\alpha_2\alpha=1{\cdot}98231$; $\alpha_1\alpha=1{\cdot}97149$; $\beta_1\beta=1{\cdot}77268$; $\beta_2\gamma=1{\cdot}67925$; $\gamma_1\delta=1{\cdot}529$; $\eta=1{\cdot}935$; $\beta_5\zeta=1{\cdot}656$; $\gamma_2\theta=1{\cdot}474$; $\beta_4\upsilon=1{\cdot}781$; $\beta_3\phi=1{\cdot}74256$; $\gamma_3\chi=1{\cdot}468$; and $\gamma_4\psi=1{\cdot}437$. A. Dauvillier measured the L-series for europium and gadolinium. A. Dauvillier, and B. Cabrera have discussed the **magnetic properties** of these elements.

The atomic weights of the terbium metals.—The general reactions of salts of the terbium earths resemble those of the yttrium salts (*q.v.*). E. Demarçay[11] first obtained europia and gadolinia of a high degree of purity, but owing to the weak absorption spectra which they exhibited, he suggested that these earths might be heterogeneous. This question was further tested by G. Urbain, who fractionated the earths in a number of ways, and tested the extreme and intermediate fractions for new elements by the spark and absorption spectra, and by at. wt. methods, but found no evidence of the resolution of these earths into simpler components. He also found that europia isolated by the bismuth nitrate method from monazite is identical with the earth isolated by the same process from gadolinite, xenotime, and pitchblende, and with europia obtained by the double magnesium nitrate process. Gadolinia was treated by G. Urbain in an analogous manner, and he failed to get any evidence of heterogeneity. The earth derived from gadolinite was identical with that obtained from xenotime or pitchblende. In the case of terbia, G. Urbain obtained no signs of complexity when the products obtained by different processes were compared. G. Eberhard also compared the arc spectra of these preparations, and concluded that there are no signs of the resolution of europia, gadolinia, or terbia into their components, and there are no signs of any intermediate elements in the terbium family. C. A. von Welsbach, however, claimed to have resolved terbia, by his double ammonium oxalate methods of fractionation, into Tb_1, Tb_2, and Tb_3; but C. James and D. W. Bissel were able to confirm G. Urbain's conclusions, and not those of C. A. von Welsbach. The conclusion that europium, gadolinium, and terbium are well-defined elements is also in harmony with J. M. Eder's work on the arc spectra, and with H. G. J. Moseley's work on the relation between the at. numbers and the frequencies of the lines in the X-ray spectra. The **atomic numbers** are Eu, 63; Gd, 64; and Tm, 65.

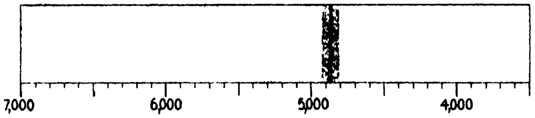

FIG. 28.—Absorption Spectrum of Terbium Nitrate Solution.

J. M. Eder has examined the arc spectra of C. A. von Welsbach's preparations of terbium, and he could find no evidence of a new element between gadolinium and terbium. The spectral lines of F. Exner and E. Haschek, and attributed by them to a hypothetical element, *E*, are produced by the blending of the terbium lines with those of gadolinium of nearly the same wave-length. J. M. Eder, however, affirms that the lines of the mixed fractions

lying between terbium and dysprosium correspond with the existence of a new element, which is named **welsium** in honour of C. A. von Welsbach. The differences in the measurements of the spectral lines by J. M. Eder and by G. Eberhard are attributed to impurities in the latter's samples.

From a comparison of the characteristics of this family of elements with those of the cerium family, it is assumed that the elements are tervalent. E. Demarçay[12] found the at. wt. of europium to be 151 from the ratio $Eu_2O_3 : Eu_2(SO_4)_3$. G. Urbain and H. Lacombe obtained 152·00 from the ratio $Eu_2(SO_4)_3.8H_2O : Eu_2(SO_4)_3$; 151·93 from the ratio $Eu_2(SO_4)_3 : Eu_2O_3$; and 151·94 from the ratio $Eu_2(SO_4)_3.8H_2O : Eu_2O_3$. G. Jantsch also calculated 152·05 from the results obtained by calcining the hydrosulphate; and W. Feit and C. Przibylla, 152·66, from the ratio $Eu_2O_3 : 3H_2SO_4$. The International Table for at. wt. for 1921 gives 152 as the best representative value. J. C. G. de Marignac[13] gave 156·75 for the at. wt. of gadolinium; and L. de Boisbaudran, 156·12. From the ratio $Gd_2O_3 : Gd_2(SO_4)_3$, A. Bettendorff calculated 156·72; C. Benedicks, 156·51; B. Brauner, 154·78; and R. Marc, 156·46. From the ratio $Gd_2(SO_4)_3.8H_2O : Gd_2O_3$, G. Urbain calculated 157·24. From the ratio $Gd_2O_3 : H_2SO_4$, W. Feit and C. Przibylla obtained 157·39. The International Table for 1921 gives 157·3 for the best representative value of the at. wt. of gadolinium.

The early data for the at. wt. of terbium by M. Delafontaine,[14] J. L. Smith, and J. C. G. de Marignac are based on determinations with very impure materials. From the ratio $Tb_2O_3 : Tb_2(SO_4)_3$, L. de Boisbaudran gave 161·4 to 163·1, and later, 159·0 to 159·95; K. A. Hofmann and G. Krüss, 148·9 to 162·2; R. Marc, 151·9 to 161·2; W. Feit, 158·6; and E. A. Potratz, 154. G. Urbain obtained 159·2 from the ratio $Tb_2(SO_4)_3.8H_2O : 8H_2O$. The International Table for 1921 gives 159·2 as the best representative value for the at. wt. of terbium.

§ 22. The Compounds of the Terbium Earth Metals

According to E. Demarçay,[1] and G. Urbain and H. Lacombe, the oxides of these earths are obtained by the ignition of the hydroxide, nitrate, sulphate, oxalate, or other salts of the volatile oxyacids. *Europia*, or **europium sesquioxide**, Eu_2O_3, is a pale pink powder. When derived from the sulphate, a very high temp. is needed—say 1600°—in order to expel the last traces of the sulphur oxides ; and the colour is then rather more intense than when prepared at a lower temp. According to W. Prandtl, europia is white with a reddish-yellow tinge, and when obtained by heating the oxalate at 900°, it has the sp. gr. 7·42 at 15°/4°, and that obtained by heating the nitrate, 6·55 at 15°/4°. White, hygroscopic *gadolinia*, or **gadolinium sesquioxide,** Gd_2O_3, can be prepared by similar processes; and, according to G. Eberhard, if the gadolinia contains a trace of terbia it will be tinged yellow. According to W. Prandtl, white gadolinia has a sp. gr. 7·407 at 15°/4°. E. H. Williams found the magnetic susceptibility of gadolinium oxide at 20° to be $129·7\times10^{-6}$; at 0°, $138·2\times10^{-6}$; at $-40°$, $160·7\times10^{-6}$; at $-80°$, $194·2\times10^{-6}$; at $-100°$, $217·0\times10^{-6}$; at $-120°$, $244·6\times10^{-6}$; and at $-140°$, $279·0\times10^{-6}$. E. Wedekind and P. Hausknecht found the mol. magnetism to be 9850×10^{-6}. When terbium oxalate is ignited it furnishes a dark brown **terbium peroxide,** and if the sulphate is employed, at a high temp., the product is almost black. The oxygen content is rather greater than is required for the formula Tb_4O_7, and it may be a mixture of that substance with the dioxide, TbO_2. The peroxide is converted into terbium salts when treated with hot conc. acids; it loses oxygen when heated; and when heated in hydrogen, it furnishes *terbia*, or **terbium sesquioxide,** Tb_2O_3, as a white solid.

C. Benedicks found that gadolinia absorbs carbon dioxide from the air, and it dissolves slowly in acids, the rate of dissolution increasing as the action proceeds. The three oxides dissolve in acids, forming the corresponding salts. According to C. Benedicks, when gadolinia is heated in hydrogen, it acquires a dark colour, but no reduction can be detected. The sp. gr. of gadolinia is 7·407. According to D. W. Bissel and C. James, when a mixture of air and coal-gas is directed upon terbium peroxide, or upon gadolinium oxide mixed with terbium peroxide, heated almost to redness, the mass immediately becomes incandescent, and the gas often takes fire. E. L. Nichols and H. L. Howes studied the luminescent spectrum of incandescent gadolinia. All three oxides are magnetic; and G. Urbain and co-workers found the magnetic susceptibility of erbia to be $33·5\times10^{-6}$; that of gadolinia, 161×10^{-6}; and that of terbia, 237×10^{-6}. Gelatinous **europium hydroxide,** $Eu(OH)_3$, is obtained as in the case of the hydroxides of the cerium earths; **gadolinium hydroxide,** $Gd(OH)_3$; and **terbium hydroxide,** $Tb(OH)_3$, are obtained similarly. They rapidly absorb carbon dioxide when exposed to the atm.

The halides.—J. Popovici prepared **gadolinium fluoride,** GdF_3, as a gelatinous precipitate by the action of hydrofluoric acid on an aq. soln. of gadolinium sulphate; the precipitate becomes granular when warmed. F. Bourion prepared **europium chloride,** $EuCl_3$, in yellow needles by heating the oxide, sulphate, or oxalate in a stream of sulphur chloride vapour or sulphur chloride vapour and chlorine. G. Urbain and F. Bourion found that if the oxide be employed in this process, the product is a mixture of europium di- and tri-chlorides. F. Bourion similarly prepared **gadolinium chloride,** $GdCl_3$, and **terbium chloride,** $TbCl_3$. The chlorides can be obtained in soln. by dissolving the oxides, hydroxides, or carbonates in conc. hydrochloric acid. When the soln. are evaporated over conc. sulphuric acid; or the hot soln. are cooled; or hydrogen chloride is passed into the cold aq. soln., crystals of the hexahydrates are obtained. The hydrated chlorides cannot be dehydrated by simply heating in air, since the salts are decomposed; but when heated in hydrogen chloride, at 180° to 200°, the anhydrous chloride is formed. Anhydrous gadolinium chloride is a white hygroscopic mass of monoclinic prisms which have a sp. gr. 4·52 at 0°; and a m.p. of 628°; it forms prismatic crystals of a hexahydrate, $GdCl_3.6H_2O$, of sp. gr. 2·424. Anhydrous terbium chloride gives colourless crystals which melt to a colourless liquid. The crystals at 0° have a sp. gr. 4·35, and a m.p. of 588°. They dissolve in water without hydrolysis. The hexahydrate, $TbCl_3.6H_2O$, forms colourless prismatic crystals. Hexahydrated terbium chloride is deliquescent and very soluble in water with a tendency to form supersaturated soln. If anhydrous europium trichloride be heated to 400°–450°, in a stream of hydrogen, colourless amorphous **europium dichloride,** $EuCl_2$, is formed. This salt is more stable than samarous chloride; it dissolves in cold water, forming a neutral soln., which oxidizes when boiled: $12EuCl_2+3O_2+6H_2O=8EuCl_3$

$+4Eu(OH)_3$. The salt is sometimes called *europous chloride;* just as the corresponding samarium chloride is called samarous chloride. The notation is not good because cerous chloride is derived from the tervalent metal, and ceric chloride from the quadrivalent metal. Hence, the -ous salts of the rare earths are derived from both bivalent and tervalent metals. F. Bourion prepared **gadolinium oxychloride**, GdOCl, by passing a slow current of air or steam over the molten anhydrous chloride; similarly, when europium chloride is heated in air to 600°, **europium oxychloride**, EuOCl, is formed. Both oxychlorides are white powders insoluble in water but readily soluble in acids. G. Urbain made **terbium oxychloride**, TbOCl, in a similar manner. C. A. Matignon and F. Bourion prepared **gadolinium bromide**, $GdBr_3$, by heating the anhydrous chloride in a stream of dry hydrogen bromide, taking care not to fuse the material; similarly also with **terbium bromide**, $TbBr_3$. According to C. Benedicks, the crystallization of the aq. soln. of gadolinium bromide furnishes the hexahydrate, $GdBr_3.6H_2O$, in rhombic plates of sp. gr. 2·84.

The sulphides and sulphates.—H. Erdmann and F. Wirth made **gadolinium sulphide**, Gd_2S_3, as a hygroscopic yellow solid of sp. gr. 3·8. It is slowly decomposed by water and by acids. G. Urbain and H. Lacombe obtained pale pink crystals of octohydrated **europium sulphate**, $Eu_2(SO_4)_3.8H_2O$, from a soln. of the oxide in sulphuric acid. S. H. Katz and C. James found that the salt is slightly hydrolyzed in soln.; and the octohydrate becomes anhydrous at 375°. G. Jantsch found that it is completely decomposed at 1600°. C. Benedicks obtained octohydrated **gadolinium sulphate**, $Gd_2(SO_4)_3.8H_2O$, in a similar manner. The monoclinic crystals of the octohydrate have the axial ratios $a:b:c=3·0086:1:2·0068$, and $\beta=118° 2'$. The sp. gr. of the salt is 3·01 at 14·6°. At ordinary temp., the aq. soln. deposits monoclinic crystals of the octohydrate which are isomorphous with the corresponding salts of the cerium and yttrium metals. When heated, the octohydrate becomes anhydrous, when the sp. gr. is 4·139 at 14·6°. The solubility expressed in grams of $Gd_2(SO_4)_3$ per 100 grms. of water, was found to be:

	0°	10°	14°	25°	34·4°
$Gd_2(SO_4)_3$	3·98	3·3	2·8	2·4	2·26

where the solid phase is the octohydrate, but there is an irregularity in the curve at about 10° which C. Benedicks attributed to the formation of another hydrate. F. Wirth gave for the percentage solubility of gadolinium sulphate in sulphuric acid of normality *N*—*i.e.* grams of $Gd_2(SO_4)_3$ per 100 grms. of sat. soln.—when the solid phase is the octohydrate, at 25°:

Normality H_2SO_4	0	0·1	0·505	1·1	2·16	6·175	12·6
$Gd_2(SO_4)_3$	2·981	3·291	3·931	3·807	2·974	0·8777	0·0867

D. W. Bissel and C. James gave 2·15 for the solubility at 25° in 100 parts of water. According to S. H. Katz and C. James, gadolinium sulphates are slightly hydrolyzed in aq. soln., and, comparing the results with those obtained with the other rare earths, the tendency of the sulphates to hydrolyze in aq. soln. increases with the at. wt. of the basic element. L. Wöhler and M. Grünzweig found the partial press. of the sulphur trioxide at 900° to be 7 mm., and the heat of dissociation, 56·9 Cals. L. C. Jackson and H. K. Onnes found the octohydrate is strongly paramagnetic; and G. Breit and H. K. Onnes, and H. R. Woltjer measured the magnetic susceptibility at very low temp., *viz.*, —258°. A basic salt, **gadolinium oxysulphate**, $Gd_2O_2SO_4$, was made by heating the anhydrous sulphate to 800°–850°.

D. W. Bissel and C. James found the solubilities of soln. of gadolinium sulphate in soln. of sodium sulphate of different conc., expressed in grams of anhydrous salt per 100 grms. of water at 25°, to be:

Na_2SO_4	0	0·42	0·44	0·66	1·26	1·94	3·01	5·71	27·40
$Gd_2(SO_4)_3$	2·15	2·08	2·04	0·88	0·17	0·10	0·07	0·06	0·05

The results are plotted in Fig. 29. The solid phase is **sodium gadolinium sulphate**, $Na_2SO_4.Gd_2(SO_4)_3.2H_2O$. This salt is readily obtained by crystallization from a soln. containing three mols of alkali sulphate for one of gadolinium sulphate; similarly also C. Benedicks made **potassium gadolinium sulphate**, $K_2SO_4.Gd_2(SO_4)_3.2H_2O$, which furnishes well-formed crystals which are sparingly soluble in water. The sp. gr. of the double salt is 3·503; and 100 c.c. of a sat. soln. of potassium sulphate can dissolve 0·87 to 0·77 grm. of Gd_2O_3—A. Bettendorff said 0·77 grm. of Gd_2O_3. R. J. Meyer and U. Müller obtained colourless, sparingly soluble crystals of **gadolinium hydrazine sulphate**, $Gd_2(SO_4)_3.(N_2H_5)_2SO_4.3H_2O$, by boiling a soln. of the mixed sulphates for some time.

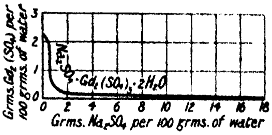

FIG. 29.—Solubility of Gadolinium Sulphate in Solutions of Sodium Sulphate.

The carbonates.—P. H. M. P. Brinton and C. James made **europium carbonate** by adding europium sulphate to an eq. amount of a soln. of sodium carbonate; **terbium carbonate** was made in the same way. According to C. Benedicks, if carbon dioxide be passed through cold water in which gadolinium hydroxide is suspended, no crystalline carbonate is formed, but microscopic, needle-like crystals appear if the liquid is warm. The crystals, dried at 100°, correspond with **gadolinium hydroxycarbonate**, $Gd(OH)CO_3.H_2O$. If the carbon dioxide be passed through the liquid for a very long time, say 12 days, the acicular crystals of the basic carbonate disappear, and larger crystals appear. When dried at 100°, the composition corresponds with **gadolinium carbonate**, $Gd_2(CO_3)_3.13H_2O$, where there is a little doubt about the exact proportion of water. According to P. H. M. P. Brinton and C. James, the hydrolysis—represented by the ratio of the amount of carbon dioxide evolved, when the carbonates are boiled with water o the original quantity of carbon dioxide present in the system—is:

Time boiling .	0·5	1·0	1·5	2·0	2·5	3·0	3·5	4·0
$Eu_2(CO_3)_3$.	33·4	37·4	39·9	41·9	43·6	45·1	46·3	47·0
$Gd_2(CO_3)_3$.	34·8	38·9	41·3	43·1	44·4	45·6	46·7	47·6
$Tb_2(CO_3)_3$.	37·6	42·5	45·7	48·1	—	—	—	—

On comparing these results with those for the cerium metals the order of basicity s . . . Pr, Nd, Sa, Eu, Gd, Tb, . . .

The nitrates.—These salts are prepared as in the case of the nitrates of the cerium metals. E. Demarçay, V. von Lang and L. Haitinger, and C. Benedicks found that hexahydrated **gadolinium nitrate**, $Gd(NO_3)_3.6H_2O$, separates from aq. soln. in triclinic crystals of sp. gr. 2·332, and which melt at 91°. V. von Lang and L. Haitinger gave for the axial ratios of the triclinic crystals $a : b : c = 1 : 1·795 : 1·367$, and $\alpha = 90° 6'$, $\beta = 109° 55'$, and $\gamma = 109° 48'$. C. Benedicks gave $Gd(NO_3)_3.6\frac{1}{2}H_2O$ for the composition of the preceding salt, and he obtained the pentahydrate, $Gd(NO_3)_3.5H_2O$, from conc. nitric acid soln. in prismatic crystals of sp. gr. 2·406, and m.p. 92°. This salt is less soluble in conc. nitric acid than any of the other rare earth nitrates which have been tried. C. Benedicks obtained long, hair-like, deliquescent crystals of **ammonium gadolinium nitrate**, $Gd(NO_3)_3.NH_4NO_3.nH_2O$, from soln. which contained the component salts in the molar proportion, $Gd(NO_3)_3 : NH_4NO_3 = 1 : 2$. E. Demarçay prepared **magnesium gadolinium nitrate**, $3Mg(NO_3)_2.2Gd(NO_3)_3.24H_2O$. A. Ries found the trigonal crystals have the axial ratio $a : c = 1 : 1·5786$. G. Jantsch found the sp. gr. 2·163 at 0°/4°; the mol. vol. 723·0; the m.p., 77·5°; and the molar solubility 0·2252 grm. per litre of nitric acid of sp. gr. 1·325 at 16°/4°. G. Jantsch prepared **zinc gadolinium nitrate**, $3Zn(NO_3)_2.2Gd(NO_3)_3.24H_2O$, with sp. gr. 2·351 at 0°/4°; mol. vol., 717·5; m.p., 56·5°; and molar solubility, 0·2801 grm. per litre of nitric acid of sp. gr. 1·325 at 16°/4°. G. Urbain and co-workers prepared hexahydrated **terbium nitrate**, $Tb(NO_3)_3.6H_2O$, in monoclinic needles from nitric acid soln. The salt melts at 89·3°.

§ 23. The Erbium Family of Rare Earths

For convenience, the four rare earth elements—dysprosium, Dy; holmium, Ho; erbium, Er; and thulium, Tm—are considered as a family or sub-group of the yttrium elements. The history of these earths has already been discussed. The earth terbia, discovered by C. G. Mosander[1] in 1842, as previously indicated, was later designated erbia. All the members of this family have been separated from C. G. Mosander's terbia. They are characterized by their absorption spectra, and by furnishing highly coloured salts. They form basic oxides of the type M_2O_3; of these dysprosia is the strongest base, then follow in order holmia, erbia, and thulia. The chemistry of these earths is very incomplete; erbium has been investigated more than the others.

Erbia is one of the least abundant of the yttrium earths; some estimate it to be next to yttria in abundance; the erbia earths occur in virtually all the rare earth minerals, but usually to a very small extent. According to N. Engström and P. T. Cleve, orthite from Hitterö has 0·52 per cent. of erbia earths, and that from Ytterby, 2·00 per cent.; and, according to L. G. Eakins, gadolinite from Colorado has 12·74–15·80 per cent. of erbia earths. The most convenient sources of these earths are xenotime, fergusonite, gadolinite, euxenite, polycrase, and blomstrandine.

The isolation of the erbium earths.—The individual earths of this family are derived from the mother liquids remaining after the separation of the cerium earths by the alkali sulphate process. The mixture of yttrium earths so obtained can be fractioned by precipitation by bases; by the fractional decomposition of the nitrates; by the oxalate, chromate, acetylacetonate, or ethylsulphate processes previously described. C. James[2] recommended the bromate process; and G. Urbain the ethyl sulphate process. In either case, three main fractions are obtained: (i) the least soluble fraction with terbium, dysprosium, holmium, and yttrium: (ii) an intermediate fraction with yttrium, dysprosium, holmium, and erbium; and (iii) the most soluble fraction with erbium, thulium, ytterbium, lutecium, and celtium—*vide* general method of resolving a mixture of the rare earths into its components.

The isolation of dysprosia.—Dysprosia was first isolated by L. de Boisbaudran from J. L. Soret's X-earth which P. T. Cleve considered to be holmium. Dysprosia was supposed by G. Krüss and L. F. Nilson, W. Crookes, and S. Forsling to be a mixture of elements. In 1885, W. Crookes, in studying the cathodic phosphorescent spectra, was attracted by a citron band with wave-length $\lambda=5740$. He assumed that the brightness of the citron band would increase as the proportion of the element responsible for it increased in his preparations. He traced the element to the yttrium group, and finally identified it with yttrium; but G. Urbain showed that this is a wrong inference, for the band is generated by dysprosium. In order to isolate dysprosia the terbium is eliminated in the less soluble fractions during fractional crystallization with the ethyl sulphates. The holmium is eliminated by fractional crystallization of the nitrates from conc. nitric acid. The purification of dysprosium nitrate by the last operation is facilitated if bismuth nitrate be introduced as *l'élément séparateur*. The subject has also been discussed by C. C. Kiess and co-workers; and by H. C. Kremers and co-workers.

The isolation of holmia.—The fractional crystallization of the ethyl sulphates enables holmia to be separated from erbia, thulia, etc., and to be partially separated from dysprosia; the remaining dysprosia can be removed by the crystallization of the nitrates as indicated in connection with dysprosia. Yttria, however, was shown by G. Urbain to remain with the dysprosia, and he suggested removing yttria by the fractional decomposition of the nitrates, or by fractional precipitation with ammonia. P. H. M. P. Brinton and C. James highly recommend the basic nitrate method in the two forms herein outlined for the separation of erbium, holmium, dysprosium, and the less basic earths from yttrium; and the crystallization of the chlorides from 1 : 1 hydrochloric acid for the separation of holmium and dysprosium from yttrium. L. F. Yntema and B. S. Hopkins preferred the sodium nitrite method to the phthalate process. H. C. Kremers and C. W. Balke tried fractional precipitation with lactic acid, and ammonium carbonate; and the fused nitrate process. The earlier samples of holmia contained much dysprosia, and the later, less impure specimens have been called *neo-holmia*. O. Holmberg employed the following process, and obtained holmia containing traces of erbia and dysprosia:

Twenty-nine kgrms. of finely powdered euxenite were decomposed in small portions at a time with hot conc. sulphuric acid, and the excess of acid finally expelled. After cooling, the resulting mass was powdered and gradually added to cold water, whereby the ytterbium earths, oxides of cerium, iron, uranium, and some of the acidic oxides were dissolved. The soln. was completely precipitated with ammonia, the washed precipitate dissolved in conc. nitric acid, and the soln. heated to boiling; the filtrate from the precipitate so formed was precipitated with oxalic acid, and the oxalate collected and ignited. The resulting oxide amounted to 5·5 kgrms., and contained the holmium present in the original euxenite. The oxide was transformed into oxalate and separated into two fractions by repeated treatment with a hot sat. soln. of ammonium oxalate, the oxalates of scandium, thorium, and of the ytterbium earths with the highest at. wt. being much more soluble than the oxalates of yttrium, terbium, etc. The less soluble oxalates gave 4773 grms. of oxides, and were treated for holmium by converting them into the *m*-nitrobenzenesulphonates and submitting them to a long series of fractional crystallizations. The five least soluble fractions consisted of a mixture of yttrium, erbium, holmium, dysprosium, terbium, gadolinium, europium, and samarium; they were converted into the nitrates and fractionally crystallized in the presence of bismuth nitrate, whereby gadolinium is eliminated. The fourteen chief fractions consisted mainly of holmium, dysprosium, terbium, and yttrium, but europium, samarium, and erbium were also present. The holmium in these fractions was further conc. by the ammonium oxalate method; the nitrate soln. of the three most soluble fractions showed a strong holmium spectrum, but also a weak erbium and dysprosium spectrum. The oxide was yellow in colour, showing the presence of terbium, and the at. wt. 144 showed that it contained a considerable content of yttrium. It was converted into the nitrate and again submitted to 160 fractionations, and the fractions richest in holmium submitted to spectral examination; they were found to be practically free from erbium, but contained a trace of terbium, a small quantity of dysprosium, and some yttrium (about 19 per cent.), the at. wt. determination giving the value 150. Two partial precipitations with aniline raised the at. wt. from 150 to 156.

The isolation of erbia.—Erbia of a high degree of purity has probably not been obtained; the erbia of the earlier chemists undoubtedly contained much ytterbium, holmium, dysprosium, and thulium. The later, less impure, preparations have been called *néo-erbia*. The fractions from the preceding operations containing yttrium, erbium, thulium, ytterbium, lutecium, and celtium are fractionally crystallized either by the bromate process, or by the nitrate process: (i) the least soluble fractions contain neodymia, samaria, and gadolinia; (ii) the next fractions contain terbia, dysprosia, yttria, and holmia; (iii) the next contain dysprosia, holmia, yttria, and scandia; (iv) the next, yttria, erbia, and thulia; and (v) the last contain thulia, ytterbia, erbia, lutecia, and celtia. The erbium bromate is less soluble than thulium bromate, so that the erbia and thulia can be separated by the bromate process, but the yttria is not eliminated from the erbia. C. James said that this can be effected by the fractional decomposition of the nitrates, or by fractional precipitation with ammonia. P. H. M. P. Brinton and C. James strongly recommend the basic nitrate process for the separation of erbium, holmium, and dysprosium from yttrium. The subject was also discussed by L. Hermann, and C. C. Kiess and co-workers.

The isolation of thulia.—C. James has described processes for the extraction of thulia from ytterspar (Norwegian xenotime), euxenite, and a Norwegian columbate resembling sipylite. The liquors containing the yttria earths were converted into bromates, and fractionally crystallized. The thulium collected in the fractions between erbium and ytterbium. The fractions in which the thulium bands were intense were finally submitted to a long series of recrystallizations, as they consisted mainly of ytterbium and lutecium, with some erbium and traces of scandium. The thulium was gradually conc. in the fractions next to the least soluble erbium, and when free from erbium, the soln. possessed a bluish-green colour. The presence of a little erbium turns the colour yellowish-green, a little more renders it colourless, and further addition changes it to pink. The various colours so obtained were made use of in collecting the fractions. It was found that the thulium fractions did not change in colour, always retaining a greenish tint when in soln. Other methods of fractionation were tried, but none could be compared with the bromate method. Spectroscopic examination of the purest thulium fraction obtained showed it to contain a trace of ytterbium and a very faint trace of calcium.

The metals of the four erbia earths have not been examined. S. Meyer[3] described the metal erbium as a dark grey metallic powder of sp. gr. 4·77 at 15°. Dysprosium salts are yellow or greenish-yellow; holmium salts are yellow or orange; erbium salts are rose-red; and thulium salts are green. The **flame spectrum** of erbia has been examined by J. F. Bahr,[4] R. Bunsen, L. de Boisbaudran, R. Thalén, W. Crookes, K. A. Hofmann and co-workers, W. B. Anderson, and K. Schaum and H. Wüstenfeld; while that of thulia has been examined by R. Thalén. The lines in the discontinuous flame spectrum of erbia are approximately in the position of the absorption bands—*vide infra*. The **spark spectrum** of dysprosium has been studied by G. Urbain,[5] by L. de Boisbaudran, etc. The five lines in the visible spectrum are 5835, 5750, 5700, 5269, and 5259. There is a large number of lines in the ultra-violet. The **arc spectrum** has been studied by G. Eberhard, J. M. Eder and E. Valenta, C. C. Kiess, G. Urbain, F. Exner and E. Haschek, etc. The more prominent lines have wave-lengths 3385·16, 3531·86, 3645·54, 3898·69, 3944·83, 4000·59, 4078·11, 4187·00, 4211·82.

The **spark spectrum** of holmium has been studied by L. de Boisbaudran,[6] G. Eberhard, and F. Exner and E. Haschek; and the **arc spectrum** by G. Eberhard, J. M. Eder and E. Valenta, and F. Exner and E. Haschek. The older observations were made on a mixture of at least two elements; the element prepared of a higher degree of purity is called for distinguishing purposes *neo-holmium*. F. Exner and E. Haschek record about 2300 lines in the arc spectrum, and 1900 in the spark spectrum. The more important lines in the arc spectrum are 3399·12, 3425·49, 3429·27, 3456·15, 3474·40, 3484·98, 3515·73, 3598·92, 3748·32, 3757·41, 3889·10, 3891·17, 4045·58, and 4254·59.

The **spark spectrum** of erbium has been measured by F. Exner and E. Haschek,[7] R. Thalén, G. Eberhard, etc. The most prominent and persistent lines are 3230·72, 3264·91, 3312·56, 3372·92, 3499·28, 3692·85, 3896·40, 3906·47, and 3938·79. The **arc spectrum** of erbium has been measured by F. Exner and E. Haschek, J. M. Eder and E. Valenta, G. Eberhard, etc. The most intense lines are 3230·73, 3264·91, 3312·56, 3372·92, 3499·28, 3692·85, 3896·10, 3906·47, 3938·79, 3973·26, 3973·78, 4008·12, 4020·69, 4059·98, 4087·80, 4143·11, 4419·78, 4563·45, 4631·10, 4675·77, 4759·83, 5827·01, and 6221·22.

The **spark spectrum** of thulium has been investigated by F. Exner and E. Haschek,[8] and the **arc spectrum** by F. Exner and E. Haschek, J. M. Eder and E. Valenta, C. A. von Welsbach, etc. The most intense lines in the arc spectrum are 3131·40, 3134·00, 3362·78, 3425·27, 3462·37, 3441·71, 3453·82, 3608·92, 3700·41, 3701·54, 3718·07, 3734·29, 3744·22, 3761·49, 3762·09, 3795·90, 3848·13, 4094·33, 4105·99, 4187·79, and 4481·44. E. Paulson has described some regularities in the spectrum of thulium.

L. de Boisbaudran,[9] and G. Urbain have studied the **reversion spectrum** of dysprosia; it shows a yellow phosphorescence; and the chloride exhibits two bands with maxima at $\lambda=5730$ and 4765. The **cathodic phosphorescent spectrum** of dysprosium has been investigated by G. Urbain;[10] it is yellow or greenish-yellow. The **X-ray spectra** of dysprosia, holmia, and erbia have been studied by H. G. J. Moseley,[11] and E. Friman, and W. Duane measured the absorption frequencies of the X-rays for dysprosium. J. Carrera gave for the absorption coeff. for the K-series of X-ray spectra, Dy, 62·93; Ho, 64·09; Er, 64·99; and Tu, 66'11. The K-series of dysprosium were measured by W. Duane and T. Shimizu, and M. Siegbahn and E. Jönsson; and that of holmium by M. Siegbahn and E. Jönsson. The L-series were examined by D. Coster and co-workers, E. Hjalmar, and M. Siegbahn, who gave for dysprosium, $\alpha_2\alpha'=1{\cdot}91564$; $\alpha_1\alpha=1{\cdot}90460$; $\beta_1\beta=1{\cdot}70658$; $\beta_2\gamma=1{\cdot}61975$; $\gamma_1\delta=1{\cdot}467$; $\gamma_2\theta=1{\cdot}419$; $\beta_4\nu=1{\cdot}718$; $\beta_3\phi=1{\cdot}680$; $\gamma_3\chi=1{\cdot}468$; and $\gamma_4\psi=1{\cdot}437$; for holmium, $\alpha_2\alpha'=1{\cdot}85206$; $\alpha_1\alpha=1{\cdot}84098$; $\beta_1\beta=1{\cdot}64352$; $\beta_2\gamma=1{\cdot}56365$; $\gamma_1\delta=1{\cdot}412$; $\gamma_2\theta=1{\cdot}366$; $\beta_4\nu=1{\cdot}653$; $\beta_3\phi=1{\cdot}61677$; and $\gamma_3\chi=1{\cdot}415$; for erbium, $\alpha_2\alpha'=1{\cdot}79140$; $\alpha_1\alpha=1{\cdot}78040$; $\beta_1\beta=1{\cdot}58344$; $\beta_2\gamma=1{\cdot}5142$; $\gamma_1\delta=1{\cdot}363$; $\eta=1{\cdot}725$; $\gamma_2\theta=1{\cdot}320$; $\beta_4\nu=1{\cdot}596$; $\beta_3\phi=1{\cdot}556$; and $\gamma_3\chi=1{\cdot}313$. For the M-series, E. Hjalmar, and G. Wentzel gave for dysprosium, $\alpha=9{\cdot}509$, $\beta=9{\cdot}313$; for holmium, $\alpha=9{\cdot}123$, $\beta=8{\cdot}930$; and for erbium, $\alpha=8{\cdot}770$, $\beta=8{\cdot}561$. J. O. Perrine found erbium oxide showed no ultra-violet fluorescence.

The **absorption spectra** of dysprosium salts exhibit four bands in the visible region, measured by L. de Boisbaudran,[12] and seven in the ultra-violet, measured by G. Urbain. H. C. Jones and W. W. Strong, and L. F. Yntema, have also studied the absorption bands of dysprosium salt soln. The heads of the absorption bands with didymium chloride soln. are at 7530, 4750, 4515, 4275, 3970, 3865, 3795, 3650, 3510, 3380, and 3225. The absorption spectrum of holmium salts was originally characterized by two bands, $\lambda=6400$ and 5360. There are, however, 15 bands which have been measured by O. Holmberg, G. Urbain, L. F. Yntema, and S. Forsling. These bands are $\lambda=6577$–6551, 6538–6518, 6446–6418, 6414–6384, 5491, 5438–5427, 5411–5401, 5385–5349, 4910, 4860–4846, 4830, 4683–4672, 4554–4459, 4223–4216, 4179–4152 when a $2N$-soln. of a holmium salt is used. The absorption spectra of erbium salts have sharp red, green, and blue bands which have been measured by R. Bunsen, P. T. Cleve, J. L. Soret, S. Forsling, L. F. Yntema, K. A. Hofmann and co-workers, F. Exner, etc. The data are not concordant, presumably because of the presence of impurities in the specimens, and it is not at all certain if all the bands are really due to erbium. S. Forsling gives the following: 6665, 6530–6515, 6483, 5490, 5412, 5231, 5202–5188, 4908, 4871, 4845–4534, 4497, 4427, 4084, 4069, 4058, 4050, 3792, 3644, 3637, 3588, and 3561. K. A. Hofmann and O. Burger could not locate the bands 6483, 5490, and 4534. A. H. Pfund observed the bands $0{\cdot}649\mu$, $0{\cdot}687\mu$, $0{\cdot}797\mu$, and $0{\cdot}980\mu$ in the infra-red region. H. C. Jones and W. W. Strong investigated the effect of temp. on the bands; and F. Wick, the effect of press. R. du Bois found that at the temp. of liquid air, and under the influence of a magnetic field, new absorption bands appear. The absorption spectra of thulium salts were investigated by P. T. Cleve, R. Thalén, L. F. Yntema, etc. S. Forsling found characteristic bands at 7015, 6845–6825, 6593–6585, 4643, 3604, and 3604–3595. A. Dauvillier, G. Wistrand, and B. Cabrera have discussed the **magnetic properties** of these elements.

The atomic weights of the erbium metals.—The general reactions of the salts of the erbium family are similar to those of yttrium salts. G. Urbain[13] observed no signs of the complexity of dysprosia in fractionating the ethyl sulphate and the nitrate. Forty consecutive fractions of the purified earth were practically identical. S. Forsling denied the elementary nature of holmium; and G. Krüss and L. F. Nilson, and K. A. Hofmann stated that holmia is a mixture; but O. Holmberg, and A. Langlet have shown that holmium can be obtained showing but the merest traces of erbia and dysprosia. J. L. Soret, and P. T. Cleve showed that the old erbia was complex, and holmia and thulia were separated from it. C. A. von Welsbach, G. Krüss and L. F. Nilson, C. James, and W. Muthmann and L. Weiss stated that erbia is complex, but the later work of K. A. Hofmann, and C. James and co-workers shows that erbium is homogeneous and elementary. R. Marc denied the elementary nature of thulium; and C. A. von Welsbach stated that he has fractionated thulium into three elements which he named provisionally Tm_1, Tm_2, and Tm_3. *Au contraire,* C. James failed to effect any separation of thulium into dissimilar parts by 15,000 crystallizations of the bromate. According to H. G. J. Moseley's relation between the vibration frequencies of the X-ray spectral lines and the atomic numbers dysprosium, holmium and erbium are probably elemental, and if thulium be elemental, the four places between erbium and tantalium are filled by thulium, ytterbium, lutecium, and celtium. The **atomic numbers** are Dy, 66; Ho, 67; Er, 68; Tm, 69. F. W. Aston found that erbium has a series of **isotopes** from 164 to 176.

In 1905, G. Urbain[14] obtained values between 162·64 and 162·28 for the at. wt. of dysprosium; and in 1906, as a mean of six determinations, G. Urbain and M. Demenitroux obtained 162·29 to 162·75—mean 162·52—from the ratio $Dy_2(SO_4)_3.8H_2O : Dy_2O_3$; after a further purification of the same material, values between 162·36 and 162·63—mean 162·54—were obtained; another determination gave 162·49. G. D. Hinrichs recalculated G. Urbain's results and obtained 162·5. E. W. Engle and C. W. Balke obtained 164·228 for the ratio $Dy_2O_3 : 2DyCl_3$; and H. C. Kremers, B. S. Hopkins, and E. W. Engle showed that the ratio $Dy_2(SO_4)_3.8H_2O : Dy_2O_3$ is not constant because the octohydrate is not constant in composition when dried over conc. sulphuric acid. They obtained 163·83 from the ratio $2DyCl_3 : Dy_2O_3$; and 162·52 from the ratio $DyCl_3 : 3Ag$. The International Table for 1921 gives 162·5 as the best representative value for the at. wt. of dysprosium.

In 1879, P. T. Cleve[15] obtained 160–161 for the at. wt. of holmium, but the material contained traces of erbium and dysprosium. K. A. Hofmann and G. Krüss found for various holmium fractions at. wt. between 158·5 and 169·4. G. Urbain believes the at. wt. lies between 162·5 and 167. O. Holmberg obtained 156; and later still, 163·5. The International Table of at. wt. for 1921 gives 163·5 for the best representative value of the at. wt. of holmium.

In 1864, M. Delafontaine[16] obtained 118·7 for the at. wt. of erbium from the ratio $Er_2(SO_4)_3 : Er_2O_3$, but he was working with very impure material. J. F. Bahr and R. Bunsen, working with a more highly purified material, obtained 169·08 from the ratio $Er_2O_3 : Er_2(SO_4)_3$. From the same ratio P. T. Cleve and O. M. Höglund obtained 170·59; J. S. Humpidge and W. Burney, 171·62; P. T. Cleve, 166·25; K. A. Hofmann and G. Krüss, 165·4–172·4; B. Brauner, 167·14; W. Nernst and E. H. Riesenfeld, 161·0–163·3; K. A. Hofmann and O. Burger, 167·4; O. Brill, 166·76. The results are unsatisfactory because of the difficulties attending the separation of yttria, etc. The International Table for 1921 gives 167·7 as the best representative value for the at. wt. of erbium. The at. wt. of thulium has not been accurately determined. P. T. Cleve[17] gave 170·7 without describing the procedure. G. Urbain said that the at. wt. is below 168·5. The International Table for 1921 gives 168·5 as the best representative value for the at. wt. of thulium.

§ 24. Compounds of the Erbium Earth Metals

The oxides of these earths are obtained by igniting the oxalates or the salts of the volatile oxy-acids. According to G. Urbain,[1] **dysprosium oxide**, Dy_2O_3, or **dysprosia**, is white, and does not form a peroxide, nor absorb oxygen when heated in that gas, and it is not affected by heating in hydrogen. It dissolves in acids to produce green or yellow salts. E. W. Engle and C. W. Balke gave 7·81 for the sp. gr. of dysprosia at 27°/4°. O. Holmberg found that purified **holmia** or **holmium oxide**, Ho_2O_3, has a pale yellow colour, and dissolves in acids to produce yellow or orange salts. According to P. T. Cleve, erbium furnishes rose-red **erbia** or **erbium oxide**, Er_2O_3, which dissolves in acids to give intensely red salts. The colour of erbia remains unchanged after strong ignition. W. W. Coblentz examined the ultra-red emission spectrum and found maxima at 2μ, 2·85μ, 3·2μ, 4·1μ, 5μ, and 7·5μ. W. S. Mallory investigated the distribution of energy in the spectrum of erbium oxide. C. James prepared **thulia** or **thulium oxide**, Tm_2O_3, as a dense white powder with a greenish tinge; it emits a carmine-red glow when heated, and as the temp. is raised the glow becomes yellow, and then almost white. C. A. von Welsbach's thulium-II was also stated to give a white sesquioxide which when heated in the flame gave a purple light quickly succeeded by a brilliant glow. Thulia dissolves in acids to form green soln. The colours of erbium and thulium salts are almost complementary, so that traces of the one have a marked influence on the other. The salts of thulium-II were said to be pale yellowish-green by daylight and emerald-green by artificial light.

According to L. F. Nilson and O. Pettersson, erbia has a sp. gr. 8·64, and a sp. ht. of 0·065 between 0° and 100°. W. R. Mott gave 3000° for the b.p. of erbium oxide. W. W. Strong said that the salts of erbia are feebly radioactive when tested by the photographic method. W. S. Mallory, and E. L. Nichols and H. L. Howes found the emissivity of erbium oxide is greater at 1000° than that of an ideal black body; this is attributed to the luminescence of the oxide. E. L. Nichols and H. L. Howes studied the luminescent spectrum of the incandescent oxide. E. H. Williams found the magnetic susceptibility of erbium oxide to be $188·6 \times 10^{-6}$ at 20°; $201·7 \times 10^{-6}$ at 0°; $234·8 \times 10^{-6}$ at −40°; $282·3 \times 10^{-6}$ at −80°; $314·8 \times 10^{-6}$ at −100°; $355·0 \times 10^{-6}$ at −120°; and $402·8 \times 10^{-6}$ at −140°. According to G. Urbain, dysprosia is the most strongly paramagnetic oxide known; its magnetic susceptibility is 290×10^{-6}, a number 12·8 times as large as that of ferric oxide. E. H. Williams gave for the magnetic susceptibility $233·3 \times 10^{-6}$ at 20°; $250·0 \times 10^{-6}$ at 0°; $291·3 \times 10^{-6}$ at −40°; $291·3 \times 10^{-6}$ at −80°; $384·2 \times 10^{-6}$ at 100°; $430·2 \times 10^{-6}$ at −120°; and $490·0 \times 10^{-6}$ at −140°. E. Wedekind and P. Hausknecht found the mol. magnetism to be $+40600 \times 10^{-6}$. Erbium oxide does not unite directly with water; **dysprosium hydroxide,** $Dy(OH)_3$, is obtained by treating soln. of the salts of dysprosium with ammonia; **holmium hydroxide,** $Ho(OH)_3$; **erbium hydroxide,** $Er(OH)_3$; and **thulium hydroxide,** $Tm(OH)_3$, are produced in a similar manner. The addition of hydrogen dioxide and ammonia to soln. of erbium salts furnishes hydrated **erbium peroxide.**

F. Bourion obtained anhydrous **dysprosium chloride,** $DyCl_3$, by passing a mixture of chlorine and sulphur chloride over the heated oxide. E. W. Engle and C. W. Balke prepared the highly purified chloride for their at. wt. determination. The yellow shining crystals are said to have a sp. gr. of 3·67, and melt at 680°. According to E. W. Engle and C. W. Balke, anhydrous dysprosium chloride dissolves slowly and completely in water developing much heat, and forming a soln. which is almost neutral to litmus, quite neutral to methyl orange, and faintly acid to phenolphthalein and methyl red. G. Urbain and G. Jantsch found that the aq. soln. furnishes bright yellow crystals of the hexahydrate, $DyCl_3.6H_2O$, which resemble the corresponding terbium salt but are less deliquescent. C. James obtained green crystals of heptahydrated **thulium chloride,** $TmCl_3.7H_2O$, by crystallization from a soln. of the oxide in hydrochloric acid. The salt is very soluble in water and in alcohol. F. Bourion showed that when anhydrous dysprosium chloride is heated in oxygen, it furnishes yellowish-green leaflets of **dysprosium oxychloride,** DyOCl, which is insoluble in water, but dissolves slowly in nitric or hydrochloric acid. K. A. Hofmann and K. Höschele made crystals of **erbium oxychloride,** ErOCl, from a soln. of the oxide in fused magnesium chloride. G. Wistrand found the magnetic susceptibility of **holmium chloride** is $172·0 \times 10^{-6}$, when the value for water is $-0·7260 \times 10^{-6}$. F. Bourion made anhydrous **dysprosium bromide,** $DyBr_3$, by heating the oxides in a stream of sulphur chloride vapour mixed with an excess of hydrogen bromide.

G. Urbain and M. Demenitroux found that a soln. of dysprosia in sulphuric acid furnishes pale yellow crystals of octohydrated **dysprosium sulphate,** $Dy_2(SO_4)_3.8H_2O$, which are stable in air at 110°, and are dehydrated at 360°. The anhydrous sulphate furnishes the oxide at a white heat. The sulphate dissolves in water giving a faintly acid soln. O. Holmberg made **holmium sulphate.** P. T. Cleve showed that a soln. of erbia in sulphuric acid furnishes red monoclinic crystals of octohydrated **erbium sulphate,** $Er_2(SO_4)_3.8H_2O$, when slowly conc. at 20°–25°. According to E. H. Kraus, the axial ratios are $a : b : c = 3·0120 : 1 : 2·0043$, and $\beta = 118° 27'$. There is a feeble double refraction. H. Töpsöe gave 3·217 for the sp. gr.; L. F. Nilson and O. Pettersson gave 3·18; and E. H. Kraus, 2·731. The crystals are said to be isomorphous with the corresponding salts of praseodymium, neodymium, and yttrium. According to F. Wirth, 100 grms. of aq. soln. at 25° contain 11·94 grms. of $Er_2(SO_4)_3$, when the solid phase is the octohydrate. F. Wirth gave for the percentage solubility in sulphuric acid—*i.e.* grams of $Er_2(SO_4)_3$ per 100 grms. of sat. soln.—with the octohydrate as the solid phase:

Normality of H_2SO_4	0	0·1	0·505	1·1	2·16	6·175	12·6
$Er_2(SO_4)_3$	11·94	12·02	10·164	8·549	6·473	1·521	0·1386

S. H. Katz and C. James said that the salt is slightly hydrolyzed in aq. soln. According to O. Brill, and K. A. Hofmann and co-workers, anhydrous erbium sulphate, $Er_2(SO_4)_3$, is formed when the octohydrate is heated to 400° for a long time; the sp. gr. is 3·68. E. Wedekind and P. Hausknecht found the mol. magnetism of erbium sulphate to be $+36700\times10^{-6}$. The salt commences to decompose at 630°, and white acicular crystals of **erbium dioxysulphate,** $Er_2O_3.SO_3$, or $Er_2O_2(SO_4)$, are formed at 845°; and this compound begins to decompose at 950°, and is completely converted into the oxide at 1055°. The double salts, **potassium erbium sulphate,** $K_2SO_4.Er_2(SO_4)_3.4H_2O$, and **ammonium erbium sulphate,** $(NH_4)_2SO_4.Er_2(SO_4)_3.4H_2O$, are formed by crystallization from an aq. soln. of the component salts. They are readily soluble in water. C. James prepared green crystals of octohydrated **thulium sulphate,** $Tm_2(SO_4)_3.8H_2O$, by adding an excess of alcohol to a soln. of the chloride in dil. sulphuric acid. The salt is dehydrated at a red heat.

According to G. Jantsch and A. Ohl, **dysprosium carbonate,** $Dy_2(CO_3)_3.4H_2O$, is formed as an insoluble powder when an aq. suspension of the hydroxide is sat. with carbon dioxide. At 15°, it loses $3H_2O$. When added to a conc. soln. of ammonium carbonate, it gradually changes into the white, crystalline, and sparingly soluble **dysprosium ammonium carbonate,** $NH_4Dy(CO_3)_3.H_2O$, which loses ammonia at 60°. C. James also prepared **thulium carbonate.** P. H. M. P. Brinton and C. James found the percentage hydrolysis of dysprosium and thulium carbonates, expressed as a ratio of carbon dioxide given off on boiling with water to the total carbon dioxide originally present.

Hrs. boiling	0·5	1·0	1·5	2·0	2·5	3·0
$Dy_2(CO_3)_3$	40·0	44·4	47·6	49·9	51·4	52·8
$Tm_2(CO_3)_3$	49·0	53·1	55·5	57·5	59·3	—

G. Urbain and G. Jantsch prepared yellow crystals of pentahydrated **dysprosium nitrate,** $Dy(NO_3)_3.5H_2O$, more resembling the bismuth salt than the terbium salt. This salt loses its water of crystallization in a dry atm. The pentahydrate melts at 88·6° in its water of crystallization. It dissolves in water giving a neutral soln. P. T. Cleve obtained red crystals of pentahydrated **erbium nitrate,** $Er(NO_3)_3.5H_2O$, by concentrating a soln. of the oxide in nitric acid. The crystals are stable in air at ordinary temp. G. A. Barbieri and F. Calzolari made a complex with hexamethylenetetramine, and T. H. Behrens, one with antipyrine. C. James prepared green deliquescent crystals of tetrahydrated **thulium nitrate,** $Tm(NO_3)_3.4H_2O$, by crystallization from nitric acid. The salt is very soluble in water. The amount of water of crystallization in the salt corresponds with that in paleo-ytterbium—παλαιός, ancient. G. Wistrand found the magnetic susceptibility of **holmium nitrate** is $132·6\times10^{-6}$ when the value for water is $-0·7260\times10^{-6}$.

According to G. Jantsch and A. Ohl, **dysprosium phosphate,** $DyPO_4.5H_2O$, forms first as a gelatinous precipitate on mixing a soln. of the nitrate with ammoniacal sodium phosphate soln.; on keeping for three or four days it becomes crystalline, and then forms a white powder with a yellow tinge. A mol of the salt loses five mols of water above 200°. K. A. Wallroth made rose-red rhombic prisms of **sodium erbium pyrophosphate,** $NaErP_2O_7$, by fusing microcosmic salt with erbia. The salt is soluble in dil. acids.

§ 25. The Ytterbium Family of Earths

The ytterbium family of earths includes two little-known elements—ytterbium, Yb; and lutecium, Lu, which have been obtained from the ytterbium separated by J. C. G. de Marignac[1] from the erbium earths in 1878. J. Gadolin's yttria was resolved by C. G. Mosander in 1842 into yttria, terbia, and erbia; the erbia was resolved by J. C. G. de Marignac into rose-coloured erbia and colourless ytterbia. The properties of ytterbia were investigated by L. F. Nilson, A. Cleve, etc. Ytterbium was considered to be an element until 1905, when C. A. von Welsbach stated that the spectroscopic evidence showed that it is probably complex. In 1907, G. Urbain, and in 1908, C. A. von Welsbach, described how ytterbium could be resolved into two elemental forms. The latter suggested the name *aldebaranium* and *cassiopëium* for the components of the old ytterbium; but G. Urbain is considered to be the discoverer of these two elements, and his terms neo-ytterbium, or simply **ytterbium**, and **lutecium** are now generally adopted. The source of G. Urbain's paleo-ytterbium was xenotime. The lines λ=5104·6, 5067·4, and 5009·7 do not appear in the arc spectrum of lutecium, or neo-ytterbium, the components of ytterbia; but they appear in the spectrum of paleo-ytterbium. Hence, it is inferred that ytterbium must contain yet another element, different from the three known components.

The elements neo-ytterbium and lutecium occur in virtually all the minerals which contain yttrium; but the amounts are small. G. Urbain regards gadolinite, xenotime, polycrase, and blomstrandine as the most convenient sources of these earths. C. A. von Welsbach estimated that about 80 or 90 per cent. of the paleo-ytterbium consisted of neo-ytterbium.

The isolation of paleo-ytterbia.—The starting-point is the soluble double alkali sulphates of the yttria earths. Various methods of fractionation can be employed—*e.g.* precipitation by alkali hydroxide, ammonia, or aniline; the oxide process; decomposition of nitrates; fractional precipitation by oxalic or chromic acids; fractional crystallization of the acetylacetonates, ethylsulphates, or bromates; etc. These methods have been described. The ytterbium accumulates in the most soluble fractions, and remains after the separation of thulium and erbium (*q.v.*).

The separation of neo-ytterbia and lutecia.—G. Urbain fractionally crystallized the simple nitrates from nitric acid of sp. gr. 1·3, and found the separation of erbium, thulium, neo-ytterbium, and lutecium to be slow but otherwise satisfactory. He made 15,000 fractional crystallizations in order to separate the two elements. C. A. von Welsbach fractionated the double ammonium oxalates from a soln. of ammonium oxalate. He stated that the separation proceeds slowly for about 200 operations, when there is a marked increase in the rate of separation. He said that this is due to the presence of a third element between neo-ytterbium and lutecium, but he could obtain no spectroscopic indication of such an element. C. James fractioned the mixed bromates for ytterbium. At the end of a long series of fractional crystallizations of ytterbium nitrate derived from gadolinite using conc. nitric acid as solvent, G. Urbain obtained a non-crystallizable mother liquor which, with ammonia, furnished what he called *celtia*. The new earth was afterwards shown to be a mixture of known earths.

The **spark spectrum** of neo-ytterbium has been investigated by C. A. von Welsbach,[2] and F. Exner and E. Haschek. The arc lines have been measured by F. Exner and E. Haschek, J. M. Eder and E. Valenta, etc. J. Blumenfeld and G. Urbain found the more intense arc lines of purified neo-ytterbia are 2398·1, 2464·5, 2512·1, 2538·7, 2653·9, 2776·4, 2784·8, 2831·1, 2891·5, 2970·7, 3005·9, 3031·3, 3107·9, and 3298·4. They found about 500 lines in the region between 2300 and 3500. They also examined the ultra-violet spectra. The **cathodic phosphorescent spectrum** has been examined by G. Urbain. E. Friman measured the high frequency **X-ray spectrum** of ytterbium; and E. Hjalmar the M-series of the X-ray spectrum.

The **spark spectrum** of lutecium has been examined by C. A. von Welsbach, G. Urbain, and J. M. Eder and E. Valenta. The **arc spectrum** of lutecium has also been investigated by J. M. Eder and E. Valenta, and by F. Exner and E. Haschek, etc. The more intense lines are 2615·50, 2911·53, 3077·75, 3198·27, 3254·45, 3281·89, 3312·30, 3359·74, 3376·69, 3397·21, 3472·65, 3507·57, 3508·55, 3554·58, 3568·00, 3624·10, 3636·41, 3876·80, 4124·87, 4184·40, 4518·74, 5476·88, 5983·92, 5984·32, 6222·10, and 6463·40. The high frequency or **X-ray spectrum** of lutecium has been studied by E. Friman. The L-series of the **X-ray spectra** of ytterbium and lutecium were measured by D. Coster and co-workers, E. Hjalmar, and M. Siegbahn, who gave for ytterbium, $\alpha_2\alpha'=1·6789$; $\alpha_1\alpha=1·66779$; $\beta_1\beta=1·472$; $\beta_2\gamma=1·412$; $\gamma_1\delta=1·265$; $l_\epsilon=1·892$; $\eta=1·618$; $\gamma_2\theta=1·225$; $\beta_4\upsilon=1·488$; $\beta_3\phi=1·448$; and $\gamma_3\chi=1·221$; and for lutecium, $\alpha_2\alpha'=1·6236$; $\alpha_1\alpha=1·61151$; $\beta_1\beta=1·417$; $\beta_2\gamma=1·366$; $\gamma_1\delta=1·220$; $l_\epsilon=1·834$; $\gamma_2\theta=1·184$; $\beta_4\upsilon=1·434$; $\beta_3\phi=1·395$; and $\gamma_3\chi=1·180$. For the M-series, E. Hjalmar, and G. Wentzel gave for ytterbium, $\alpha=8·123$, $\beta=7·895$; and for lutecium, $\alpha=7818$, $\beta=7·587$. The **cathodic phosphorescent spectrum** has been examined by G. Urbain. M. de Broglie and J. Carrera gave for the absorption coeff. of the K-series of X-ray spectra, Yb, 67·23; and Lu, 68·34. A. Dauvillier, and B. Cabrera have discussed the **magnetic properties** of those elements.

J. Blumenfeld and G. Urbain sought a new element between thulium and ytterbium, and considered it very unlikely that such a one exists. The individuality of ytterbium, and lutecium fits in with H. G. J. Moseley's work on the X-ray spectra, and with the assumption that these elements have the **atomic numbers**, Yb, 70; and Lu, 71—*vide infra*. The **atomic weight** of paleo-ytterbium was found to be 172·5 by J. C. G. de Marignac;[3] L. F. Nilson gave 173·16; A. Cleve, 173·11; and B. Brauner, 173·08. In each case the at. wt. was computed from the ratio $Yb_2O_3 : Yb_2(SO_4)_3$. For neo-ytterbium, G. Urbain first obtained 170·1 and 173·4 for lutecium; later, from the analysis of the octohydrated sulphates, he obtained 170·66 for neo-ytterbium and 174·04 for lutecium. C. A. von Welsbach obtained 172·9 for neo-ytterbium and 174·25 for lutecium from the ratio $R_2(SO_4)_3 : R_2O_3$; and still later, he obtained neo-ytterbium 173·0 and lutecium 175·0. J. Blumenfeld and G. Urbain obtained 173·54 for the at. wt. of neo-ytterbium. The International Table of at. wt. gives 173·5 as the best representative value for the at. wt. of ytterbium, and 175·0 for that of lutecium.

A. Cleve found paleo-**ytterbium oxide,** or *ytterbia*, Yb_2O_3, to be colourless, but if it contains a trace of thulium, it assumes a brown or yellow tint. According to L. F. Nilson, the oxide has a sp. gr. 9·175, while L. F. Nilson and O. Pettersson found 0·0646 for the sp. ht. G. Urbain found neo-ytterbia was likewise white; and is more paramagnetic than lutecium. S. Meyer gave $18·3\times10^{-6}$ for the magnetic susceptibility; and J. Blumenfeld and G. Urbain, $33·6\times10^{-6}$. L. F. Nilson, and J. C. G. de Marignac said that paleo-ytterbia fuses with difficulty; and it dissolves slowly in dil. acids in the cold, and rapidly when heated. J. C. G. de Marignac described paleo-ytterbium as a gelatinous precipitate, **ytterbium hydroxide,** $Yb(OH)_3$, obtained by adding ammonia to a soln. of the salt. C. A. von Welsbach obtained colourless *lutecia*, or **lutecium oxide,** Lu_2O_3; G. Urbain said that it is four to five times less paramagnetic than neo-ytterbium. All these oxides and hydroxides react with acids to form colourless salts with no visible absorption spectrum.

According to A. Cleve, a soln. of paleo-ytterbia in hydrochloric acid furnishes crystals of hexahydrated **ytterbium chloride,** $YbCl_3.6H_2O$; and the same salt is obtained by saturating the aq. soln. with hydrogen chloride. The salt is readily soluble in water, and is deliquescent. W. W. Coblentz studied the ultra-red transmission spectrum. Ytterbium chloride furnishes a chloroplatinate and chloroaurate. When the chloride is heated in a stream of hydrogen chloride it furnishes **ytterbium oxychloride,** YbOCl, as a white deliquescent mass. G. Urbain found anhydrous **lutecium chloride,** $LuCl_3$, to be more volatile than anhydrous neo-ytterbium chloride, $YbCl_3$; but less so than scandium chloride. A. Cleve similarly made paleo-**ytterbium bromide,** $YbBr_3.8H_2O$, which is more deliquescent than the chloride. She also made the bromoplatinate.

L. F. Nilson, and A. Cleve found that a boiling soln. of paleo-ytterbia in sulphuric acid furnishes crystals of octohydrated **ytterbium sulphate,** $Yb_2(SO_4)_3.8H_2O$, and similar crystals are obtained by spontaneous evaporation at ordinary temp. The sp. gr. of the crystals at 20° is 3·3; and L. F. Nilson gave 3·286. L. F. Nilson and O. Pettersson gave for the sp. ht. 0·1788. When heated, the octohydrate furnishes crystals of the anhydrous sulphate, $Yb_2(SO_4)_3$, which has a sp. gr. 3·62 according to A. Cleve; L. F. Nilson gave 3·793, and for the sp. ht. 0·1039. The solubility, like that of other rare earth sulphates, decreases with rise of temp. Expressing the results in grams of $Yb_2(SO_4)_3$ in 100 grms. of water, A. Cleve found:

	15·5°	35°	55°	60°	70°	80°	90°	100°
$Yb_2(SO_4)_3$.	34·6	19·6	11·5	10·4	7·22	6·93	5·83	4·67

At 18°, she gave for the eq. electrical conductivity, λ, for soln. with a mol of the salt in v litres of water at 18°:

v	3·33	6·67	33·33	333·3	666·7	3333	6667
λ	20·7	24·7	35·3	61·6	74	98	105

It is therefore inferred that the salt is much hydrolyzed in dil. aq. soln. Neo-ytterbium sulphate was found by G. Urbain, and C. A. von Welsbach to furnish a similar octohydrate; likewise also with **lutecium sulphate,** $Lu_2(SO_4)_3.8H_2O$.

According to A. Cleve, when ammonium carbonate is added to a soln. of paleo-ytterbium nitrate, a gelatinous precipitate of normal **ytterbium carbonate,** $Yb_2(CO_3)_3.4H_2O$, is obtained; if an alkali carbonate is employed, the precipitate retains alkali very tenaciously. The basic **ytterbium hydroxycarbonate,** $Yb(OH)CO_3.H_2O$, is formed by passing carbon dioxide into water holding the hydroxide in suspension. P. H. M. P. Brinton and C. James found that the percentage hydrolysis—*i.e.* the ratio of the amount of carbon dioxide evolved to the total carbon dioxide originally present—after boiling with water, is:

Hrs. boiling	0·5	1·0	1·5	2·0	2·5	3·0	3·5	4·9
Hydrolysis .	52·6	57·3	60·4	62·4	64·4	66·1	67·3	68·5

On comparison with analogous results from the other rare earth carbonates, it follows that ytterbium carbonate is more rapidly hydrolyzed than any of the other carbonates so far examined.

By evaporating over sulphuric acid a soln. of paleo-ytterbia in nitric acid, L. F. Nilson, and A. Cleve obtained deliquescent plates of trihydrated **ytterbium nitrate,** $Yb(NO_3)_3.3H_2O$; while deliquescent prisms of the tetrahydrate, $Yb(NO_3)_3.4H_2O$, crystallize from a conc. soln. in nitric acid. The sp. gr. is 2·682. The water content of the crystals is smaller than is usually the case with the rare earth nitrates. A. Cleve made **ytterbium orthophosphate,** $YbPO_4.4\frac{1}{2}H_2O$, as a gelatinous precipitate by adding disodium hydrophosphate to a soln. of paleo-ytterbium nitrate When the anhydrous sulphate is fused with metaphosphoric acid, and boiled with water, **ytterbium metaphosphate,** $Yb(PO_3)_3$, is formed as a crystalline powder. On evaporation of the soln., a salt, $Yb_2O_3.2P_2O_5.5H_2O$, separates out. K. A. Wallroth made paleo-**ytterbium sodium pyrophosphate,** $NaYbP_2O_7$, in microscopic prisms by fusing ytterbia with molten microcosmic salt.

G. Urbain reported *celtia* or *celtium oxide*, Ct_2O_3, to be a white earth with a magnetic susceptibility about one-quarter the value of that of lutecia derived from xenotime. G. Urbain said that *celtium hydroxide*, $Ct(OH)_3$, is a weaker base than *lutecium hydroxide*, $Lu(OH)_3$, but is stronger than scandium hydroxide, $Sc(OH)_3$. In other respects the properties of celtium compounds were said to be intermediate between those of lutecium and scandium compounds. After the discovery of hafnium, G. Urbain and fellow-workers revised the previous work on celtium and stated that celtium is probably the same element as hafnium, and is not a rare earth at all—*vide* hafnium. The only enduring fact is that A. Dauvillier found in these preparations, before the discovery of hafnium, the X-ray spectrum of a new element to which the old name was assigned. There are therefore two celtiums. G. Urbain's evidence in favour of *celtium-I* proved to be worthless; and the evidence for *celtium-II* was based on A. Dauvillier's discovery of two feeble lines with wave-length $\alpha_1 = 1561{\cdot}8$, and $\beta_2 = 1319{\cdot}4$, in the L-series of the X-ray spectrum of celtium. G. Urbain considered that these lines are in agreement with the at. number 72; and establish the right of celtium-II to a place in the periodic system. D. Coster and G. Hevesy claim that the element hafnium isolated by them fits the lacuna in the periodic table for an element with an at. number 72, better than G. Urbain's celtium-I. The element occupying the gap in the periodic table corresponding with at. number 72 should be a homologue of titanium and zirconium, and be quadrivalent, and not a tervalent rare earth. The main reasons offered by D. Coster and G. Hevesy for assuming that celtium-II is not the same as hafnium, at. number 72, are: (i) There is no difficulty in purifying hafnia from the rare earths, but celtia is exceedingly difficult to isolate. (ii) Preparations of hafnium do not show the optical spectrum ascribed by G. Urbain to celtium. (iii) The X-ray spectrum of a preparation of an element sufficiently conc. to measure its magnetic properties should show very intense X-ray lines, not the weak ones found by A. Dauvillier. These lines, moreover, do not coincide within the error of measurement with the lines found by D. Coster and G. Hevesy; and (iv) Hafnium occurs more abundantly than celtium—*vide* hafnium (**6.** 43, 2).

CHAPTER XXXIX

CARBON

§ 1. The History of Carbon

What have been the sources of that fascination which precious stones have from time immemorial exercised over the minds of men ? It is because they have acquired by tradition a prestige which fashion perpetuates ; a prestige rooted on strange attributes and mystic powers wherewith the fancies of five thousand years have endowed such stones ; a fashion that has been ever pandered to by a harpy host of money-making parasites, and has been fostered by that human weakness which, while endeavouring to associate what is pretty with what is costly in the materials chosen for personal ornament, is apt to attach more importance to their price than to their real beauty, in proportion as cupidity is a passion more common than refinement and taste.—ANON. (1866).

THE diamond has long been prized as a precious stone on account of its beauty, rarity, and permanence. As a gem-stone, it is altogether unique, for it is distinguished from all other precious stones by peculiar qualities. The diamond has been known to the Hindus from the remotest antiquity. The scholars tell us that the Hindu *Vedas*, 1100 to 1200 B.C., and the two epic poems *Ramayana* and *Mahabharata* frequently refer to the marvellous light of the diamond. Many properties of the diamond are described in the *Puranas*, and still more particulars in the *Brhatsanhita* of the sixth century. Some Hindu proverbs relate to the hardness of the diamond—" Diamond cuts diamond ; " " The heart of a magnate is harder than the diamond ; " etc. No precise data concerning the diamond have been gleaned from Hindu sources. Consonant with their mystic temperament, and glowing imagination, the Hindus consecrated the diamond to their chief gods, and attributed to it sovereign virtues. Even in the seventeenth century, A. B. de Boot[1] gravely discussed whether the power of the diamond to discriminate between right and wrong, or between legal and illegal conjugal affection, be a natural quality of the stone, or belongs to a spirit dwelling in the gem.

According to *Exodus* (**28.** 18), the diamond was the sixth in order in the second row of the twelve precious stones on which the names of the children of Israel were engraved. These stones were jewels of the breast-plate of judgment worn by the High Priest. The diamond is also mentioned by the prophets Jeremiah and Ezekiel. Many scholars, however, are not satisfied with these translations, and say that the words rendered diamond really signify a stone hard to break, or a stone used in breaking others. It is therefore considered to be very doubtful if the diamond was really known in the time of Moses.

The *ἀδάμας*, the indomitable, of the Greeks, mentioned in the fourth century B.C., in the *Περὶ τῶν Λίθων Βιβλίον* of Theophrastus, is often translated diamond. The term is supposed to be derived from *α*, privative, and *δαμάω*, to subdue, in reference, said Pliny, " to its unspeakable hardness, to its unconquerable fire-resisting qualities, and to the fact that it is incapable of being heated." The Persian term *almas* refers to the diamond. The scholars tell us it is probable that both the Greek and Persian terms are derived from the Hebrew word *achlamah*, or *chalam*, implying in one of its senses to be hard, and compact. The term *adamas* was at first used by the Greeks for some very hard metal, sometimes apparently for steel itself ; and subsequently the term came to be used for some precious stone of great hardness. Homer mentions the *adamas* in his description of the toilet of Juno

If Homer's *adamas* referred to the true diamond, E. Boutan said that it is very difficult to explain how a knowledge of this very precious stone was lost among a people whose sense of beauty was so well developed; for, at the time of Plato, it is doubtful if the Greeks had any knowledge of its properties, or even of its existence. In his *Historiæ naturalis* (**37.** 15), about 77 A.D., Pliny has a strange jumble of truth and fable in his description of the *adamas*, and this in spite of his introductory claim:

> We shall refute the infamous lies that have been promulgated by the magicians about precious stones; for it is more particularly about these stones that most of their fabulous stories have been circulated. Under the guise of ascertaining remedial virtues, they have stepped beyond all bounds, and entered the region of the phantasy.

It could be argued from his narration that the diamond, as we know it, was outside his ken. He applied the term *adamas* to several minerals—*e.g.* quartz, specular iron ore, corundum, emery, and other hard substances which cannot now be identified—and even hard metal. It is, however, possible that the Arabian and Indian varieties of *adamas* which he describes were truly diamonds. The description of the all-resplendent and brilliant *adamas* in Dionysius' *Periegesis* (**5.** 318, 1119), written some time after Pliny's work, agrees better with crystals of quartz than with the true diamond. M. Manilius, in his astrological poem *Astronomica* (**4.** 926), made the earliest unequivocal mention of the true diamond—*adamas, pretiosior auro*—near the first century of our era.

According to Pliny, the engravers of his time used fine particles of *adamas* for cutting the hardest substances known; several other writers likewise mention this custom—*e.g.* P. J. Mariette, C. J. Solinus, St. Isidorus, Albertus Magnus, etc. According to J. Beckmann, however, there is no evidence to show that the ancients used diamond-dust for cutting the diamond into facets, etc., to render it brilliant; nor is there any definite evidence that diamond pencils were used for engraving on diamonds. P. J. Mariette believed that they were not, C. A. Klotz believed that they were, but L. Natter was doubtful. According to J. Beckmann, and A. Brongniart, the method of polishing diamonds was developed in 1456 by Ludwig von Berquem. According to C. W. King, the cutting of diamonds must have been practised much earlier in India, because the faceting of the famous *Koh-i-noor*, or mountain of light, dates back into uncertain time. It was formerly owned by the Rajah of Lahore, and is now included amongst the English crown jewels.

The *Cullinan* is the largest known diamond. It was found near Pretoria (South Africa), January, 1905, and weighed 3025¾ carats or over 1⅓ lbs. It measured 4 × 2½ × 2 ins. After cutting, it weighed about 800 carats, and was valued at about £100,000. It was presented to the King of England by Cape Colony in 1909. The *Regent* or *Pitt* diamond shown in the Louvre with the French crown jewels, is the purest and finest stone known. It weighs 136½ carats, and is valued at £480,000. The *Orloff* diamond was the largest diamond of the Russian crown jewels; it has the appearance of an irregular rosette, and weighed 194¾ carats. The *Florentine* of the State treasury at Vienna weighs 133⅕ carats; it is pale yellow and is cut like a double rosette or briolette. The *Sancy* diamond weighs 53¾ carats and is the property of an Indian prince. The Brazilian diamond *Star of the South*, weighing 125 carats, is also the property of an Indian prince. The *Grand Mogul* is also an Indian diamond weighing $279\frac{9}{16}$ carats. The *Star of South Africa* weighs 46½ carats and was sold for £25,000. The *Victoria* diamond of South Africa weighed 457½ carats uncut, and 180 carats when cut. The *Excelsior* diamond, also from South Africa, weighed 971¾ carats uncut. There are numerous other historic and celebrated diamonds. Stones over an ounce in weight are comparatively rare.

Diamonds occur in their natural state as more or less rounded, rough-looking pebbles, not unlike pieces of gum arabic in appearance. The natural diamond must be cut and polished to bring out its lustre and sparkle. The diamond-cutting industry has developed largely in Amsterdam and Antwerp. The shape of the so-called *crystal* as it leaves the diamond-cutter has no relation to the natural crystalline shape. About half the mass of the diamond is lost in the cutting. The object of the lapidarist is to get the maximum reflection of light from the interior of the stone. The *rose* and *brilliant*, for instance, are standard shapes; the latter has a rather large flat face which is really the base of a pyramid with many sides (facets). The high reflecting and refracting power of the diamond are the particular qualities which make it supreme above other gems. In virtue of these qualities, the light falling on, say, the front face of a brilliant passes into the diamond, and is reflected from the interior surface of the facets. The reflected light is refracted into a wonderful play of "lightning flashes, and sparkling scintillations" as it passes into the air.

Diamonds are sold by the **carat.** The term carat is derived from the carob bean, formerly used as a small weight by the diamond merchants of India. The carat represents the Roman *siliqua* or Greek *κεράτιον*. It was $\frac{1}{24}$th of the golden solidus of Constantine which was $\frac{1}{6}$th oz. The carat used for diamonds and other precious stones was originally $\frac{1}{144}$th oz., or $3\frac{1}{3}$ grains; but now, one carat corresponds with 0·207 gram of $3\frac{1}{5}$ grains troy. Expressing the weights in milligrams, the carat at London is 205·409 mgrms.; Paris, 205·500; Amsterdam, 205·700; Berlin, 205·440; Vienna, 206·130; Madras, 207·353; Batavia, 205·000; Florence, 197·200; etc. There are so many different countries with different values of the carat, that those interested are adopting the *International carat* of 200 mgrms., or 3·08647 grains troy. The carat is also used as a proportional measure, $\frac{1}{24}$th, in stating the fineness of gold (*q.v.*).

In the fourth century, St. Epiphany wrote a brochure on the diamond and other precious stones; in the seventh century, St. Isodorus reproduced much of what Pliny and St. Epiphany had previously stated; in the eleventh century, G. Marbodus wrote a small work on the subject, and M. C. Psellus described the medicinal virtues of the precious stones; in the twelfth century, Abd Al-Malik ibn Muhammad ibn Ismail treated the subject systematically, and collected data on the properties of the gem-stones; and in the sixteenth century appeared G. Agricola's work which was compiled largely from that of Pliny. In the sixteenth century there also appeared the works of J. de Mandevil, and of Garcia da Orta. The nature of the diamond did not attract special attention until the seventeenth century. About this time appeared the treatise of A. B. de Boot. In studying the action of heat on the diamond, it will be shown how it was demonstrated that the diamond is a form of carbon; or, as J. Dalton expressed it, carbon and the diamond are the same element in different states of aggregation.

Many monographs have been published on the diamond and precious stones: *e.g.*, in addition to some mentioned in the references, there are, among others, E. Boutan, *Le diamant*, Paris, 1886; Ibn Abi Bakr Abd Al-Rahman. *De proprietatibus ac virtutibus medicis animalium, plantarum, ac gemmarum*, Paris, 1647; A. Bacci, *De gemmis ac lapidibus pretiosis*, Roma, 1577; J. W. Baumer, *Historia naturalis lapidum pretiosorum*, Francofurti, 1771; R. Belleau, *Les amours et nouveaux échanges des pierres précieuses*, Paris, 1576; C. P. Brard, *Traité des pierres précieuses*, Paris, 1808; U. F. B. Brückmann, *Abhandlung von Edelstein*, Braunschweig, 1757; L. Dutens, *Des pierres précieuses et des pierres fines*, Paris, 1776; H. Dieulefait, *Diamonds and Precious Stones*, London, 1874 ; J. E. Middlebrook, *Illustrations of the Diamond Industry*, Kimberley, 1892 ; L. de Launay, *Les diamants du Cap*, Paris, 1897 ; C. F. Williams, *The Diamond Mines of South Africa*, New York, 1902 ; J. R. Blum, *Taschenbuch der Edelsteinkunde*, Stuttgart, 1832 ; C. Barbot, *Traité complète des pierres précieuses*, Paris, 1858 ; W. Crookes, *Diamonds*, London, 1909.

As indicated in connection with the history of tin, lead, molybdenum, and galena, Aristotle,[2] Dioscorides, Pliny, and Gahlen used the terms *molybdæna* and *galena* in no very precise way for the sulphide and for oxidized ores and other products. Pliny used the term *plumbago* for a mineral product—a kind of litharge also denoted by the words *molybdæna* and *galena* ; as well as for the name of a plant, and for a lead-like colour. In some sixteenth-century translations of Dioscorides —H. Barbarus, J. Ruellinus, and M. Virgilius—the term *plumbago* is used as the Latin equivalent of μολύβδαινα. In the sixteenth century, G. Agricola, C. Entzelt of Saalfeld, and J. Mathesius regarded *plumbago*, *galena*, and *molybdæna* as identical with *Glantz* or the modern *galena*. The *galena sterilis* of G. Agricola was probably graphite ; and his *galena inanis*, zinc blende. According to J. W. Evans, one of the earliest references to graphite and its use for pencils occurs in C. Gesner's *De rerum fossilium, lapidium, et gemmarium* (Zürich, 104, 1565), where a drawing occurs showing the black-lead fixed into a handle. He added, on the authority of G. Agricola, J. H. G. von Justi, and J. Beckmann,

> The flaky graphite of Bavaria has been worked from prehistoric times for mixing with clay to form pottery, and the Passau or Ips crucibles, in which this material was employed, were widely used, but it does not seem to have been employed for writing so early as that from the Borrowdale mine, near Keswick, in Cumberland, which was for some three centuries the principal source of supply of the mineral for this purpose. Metallic lead and silver were used in both ancient and mediæval times for drawing lines. Subsequently in the early renascence an alloy of two parts of lead and one of tin, known as *lo stile del piombo* or *lapis piombino*, was employed for drawing These terms were probably transferred to graphite when it came into use.

A. Cæsalpinus, and F. Imperato, in 1599, also made observations on the use of graphite for crucibles. J. Mathesius referred to *einem newem und Selbwachssenen Metall* used for writing which J. W. Evans said must have been graphite, and H. Platte, W. Camden, and others refer to graphite under the name *black-lead*, although as a translation of Pliny's *plumbum nigrum* the term was used by B. Anglicus, J. Marplet, and others in the sense of metallic lead. At the end of the sixteenth century, F. Imperator referred to the use of *grafio piombino* for writing, and the Italian *grafio* is derived from the Latin *graphium*, a style for writing, and the Greek γραφεῖον, a style for writing. In 1627, J. C. Boulanger referred to *plumbea graphis*, and *galena pictoris*, which J. W. Evans considers to be represented by the French *crayon de mine*, and *plomb de mer*, terms used for graphite. C. Merrett, and W. Charleton used the term *nigrica fabilis* for graphite ; and in 1671, J. Webster wrote concerning graphite :

> It cannot be amiss to say someting of that which we commonly call *Black-Lead*, because it discoloureth the hands far more than common Lead, and is that whereof pencils are made for Painters and Scriveners, and many other such like uses. In the North we call it *Kellow*, and some call it *Wadt*. . . . All that we can say here concerning galena, plumbago, lapis plumbarius, and molybdæna is that there is much said to no little purpose, and that in some respects they may be taken for all one.

In his posthumous *Minerali* (Hamburg, 1689), J. Junge applied the term *pseudo-galena* to *galena inanis* or *galena sterilis*, and for a time this usage was followed by J. G. Wallerius, G. Hoffmann and J. B. Boehmer, A. G. Monnet and others. J. Junge also referred to *plumbago scriptoria* and *plumbago anglica*, meaning graphite. In the English translation of P. Pomet's *Histoire général des drogues* (Paris, 1694), *mine de plomb noire* or *mine de plomb* is rendered *black-lead ;*

and *plombagine* and *plomb de mer* are rendered respectively *plumbago* and *sea-lead.* All these terms refer to graphite. R. Plot suggested calling graphite *ochra nigra* or *black ochre.* During the seventeenth and eighteenth centuries, *lapis plumbarius, plumbago, galena,* and sometimes *molybdæna* were employed for graphite, and the mineral called molybdenite. It was soon found that graphite (and molybdenite) do not contain lead. In a paper on graphite entitled: *Examen chymicum plumbi scriptorii vulgo plumbaginis,* J. H. Pott, in 1740, gave a long list of synonyms which had been used by different peoples for graphite. He showed that this substance does not contain sulphur or zinc; and that it is decomposed by fused potassium nitrate. He probably worked with a graphite containing some pyrites, for he concluded that it is a *terra talcosa, igni et menstruis indomita, pauco martiali et pauciore acido vitriolico.* J. W. Baumer first showed that the minerals referred to by *molybdæna* and its numerous synonyms contained two different substances, one of which, containing some iron, was combustible. The confusion between graphite and molybdenite, then called plumbago or molybdæna, was cleared when C. W. Scheele demonstrated that when plumbago is heated with saltpetre, it is transformed into carbon dioxide. Hence, he concluded: "plumbago is a kind of mineral charcoal the constituent parts of which are aerial acid (carbon dioxide) and a considerable quantity of phlogiston." He further demonstrated that molybdæna is a compound of sulphur with a peculiar acid of a metallic nature. There does not appear any definite reason, other than chance, why C. W. Scheele applied the term *molybdæna* to molybdenite, and *blyerts* or *plumbago* to graphite, because previously the term molybdæna had been more frequently applied to graphite. C. W. Scheele's application of the terms decided subsequent usage. In order to prevent further confusion, A. G. Werner, and D. L. G. Karsten proposed the term **graphite** for plumbago as distinct from molybdæna.

Although C. W. Scheele showed that the small amount of iron oxide which occurs associated with graphite "can hardly be taken into account, for it seems to be mixed with it only mechanically," yet several later observers assumed that the iron is an essential part of graphite. R. J. Haüy called it *carbure de fer* because of the analysis of C. A. Vandermonde, G. Monge, and C. L. Berthollet—carbon, 90·9 per cent.; iron, 9·1 per cent. L. B. Guyton de Morveau regarded the graphite he obtained from cast-iron as an iron carbide; but C. J. B. Karsten showed that the iron in this product is mechanically mixed with the graphite; and this view was also demonstrated by N. G. Sefström. L. Vanuxem also showed that the iron exists in the mineral graphite as oxide and that it is an accidental impurity, and not an essential constituent; and B. Pelletier demonstrated that plumbago is *une substance particulière . . . les substances dans lesquelles l'air fixe ne paroit pas entrer, donnent après leur décomposition des indices de cet être.* The name *Graphit* is used in Germany where the term *Reisblei* still survives; in France, the terms *mine de plomb, plombagine,* and *graphite* are used; in England, *black-lead, plumbago,* and *graphite;* in Italy, *graffite,* and *piombaggine;* and in Spain, according to E. Halse, *grafite, plombagina, lápiz, lápiz plomo, alquifol, carbon, chacal, mine de plomo,* and *piedra mineral de plomo.* Soot must have been used from the earliest times as a colouring agent, and in the making of a kind of ink. A further contribution to the history of the diamond, graphite, etc., is indicated in connection with the action of heat on these substances.

The deposits of graphite at Borrowdale (Cumberland) were worked about 1550. According to C. A. Mitchell, W. W. F. Petrie discovered a lump of impure graphite with 39·4 per cent. of carbon, at Ghorub, and this must have dated back to a period between 1500 and 1200 B.C. There is, however, no evidence of the use of graphite as a pigment in ancient Egypt. C. T. Schönemann said that lines in black lead (Reisblei) are found on some eleventh- or twelfth-century works in the Wolfenbüttel and Göttingen libraries, but C. A. Mitchell considers that graphite was here mistaken for ordinary lead. He also examined the markings in the British Museum and Bodleian Libraries, but found none earlier than 1640.

§ 2. The Occurrence of Carbon

Carbon occurs in nature in many forms. It occurs crystallized as the diamond and as graphite. It is the dominant element in organic matter. It is the principal element in coal. Natural gas, petroleum, and bitumen are essentially hydrocarbons. Carbon dioxide is a normal constituent of the atm.; and carbonic acid and carbonates occur in most natural waters. The carbonates of calcium, magnesium, and iron form great masses of rock. Carbon is also present in a few naturally occurring silicates.

Reviewing the known analyses of terrestrial matters, F. W. Clarke[1] placed carbon 12th in the series showing the relative abundance of the different elements. It is less abundant than chlorine, titanium, and hydrogen, and more abundant than phosphorus, sulphur, and barium. The averages in the following excerpta include the atm.:

	O	Si . . .	Ti	Cl	C	P	S	Ba . . .
Lithosphere . .	47·33	27·74	0·46	0·06	0·19	0·12	0·12	0·08
Hydrosphere . .	85·79	—	—	2·07	0·002	—	0·09	—
Average . .	50·02	25·80	0·43	0·20	0·18	0·11	0·11	0·08

F. W. Clarke and H. S. Washington place carbon 13th in the list, with 0·13 per cent. For the lithosphere, the carbonates occur 11th in the series:

	Igneous rocks.	Shales.	Sandstones.	Limestones.	Weighted Average.
SiO_2	59·83	58·10	78·33	5·19	59·77
H_2O . .	1·90	5·00	1·63	0·77	2·02
TiO_2	0·79	0·65	0·25	0·06	0·77
ZrO_2	0·023	—	—	—	0·02
CO_2	0·49	2·63	5·03	41·54	0·70
P_2O_5	0·29	0·17	0·08	0·04	0·28

The occurrence of carbon in the sun has been investigated spectroscopically by J. N. Lockyer,[2] J. Dewar, J. Trowbridge and C. C. Hutchins, H. A. Rowland, etc. The fainter red stars like Schjellerup are characterized by shaded bands which are attributed to carbon; the bands are darkest on the red side of the spectrum, and fade away towards the blue. W. Huggins, and B. Hasselberg also stated that the spectra of various comets all show the hydrocarbon spectrum. A. Fowler has examined the spectrum of Morehouse's comet.

Diamonds are sparsely distributed in different parts of the world; they sometimes occur like alluvial gold in the beds of rivers and streams, and the river stones are usually the most highly prized, and valuable. The diamonds which are not alluvial, are found in a heterogeneous mixture of fragments of various rocks and minerals[3] cemented together with a bluish-green indurated clay known as *blue earth*, or *blue clay*. The diamonds are found imbedded in the blue earth. The mines in India[4] are the oldest; and they yielded the finest and most prized diamonds. Diamonds occur in Nisam near the river Kistna; in Sambalpur near the rivers Godavari and Mahanadi; and in Bundelkhand, near Panna. There are mines in the west and south-east of Borneo. The region of Minas Geraes (Diamantina, near Abaété, Bagagem, Grao Mogul, Bahia, etc.) in Brazil has long been famed for its diamond mines. Diamonds have been reported in British Guiana, Columbia, and Mexico; and in the United States—California, Oregon, Idaho, Montana, Arizona, Indiana, Kentucky, Tennessee, Georgia, North and South Carolina, Virginia, Wisconsin, and Michigan. Diamonds were discovered in the Urals about 1829; and in Australia about 1852. The diamond fields of South Africa—Jagersfontein, Koffyfontein, Kimberley, etc.—have been the most prolific source of diamonds in recent years.

The blue earth is mined, and exposed to the weather on the veld. The earth may with advantage be frequently harrowed and occasionally watered. In about a year, the blue earth becomes friable and disintegrates. The stuff is then conveyed to the crushing machinery and washers, where the clay is separated into earth and gravel. The diamantiferous gravel is then conveyed to sifters, where it is graded. Each grade drops on to pulsator tables, where it is sorted into materials of different sp. gr. The higher portion is washed by water to the end of the trough and conveyed to the heap of tailings: the heavier portions fall through a grating and are conveyed to percussion or shaking tables smeared with grease. The diamonds adhere to the grease, and the other constituents flow as tailings over the end of the percussion tables. The tailings may be dribbled on to a second shaking table; and the reject from this may be examined and any diamonds picked out. The grease is scraped from the tables, and is placed in a pot which is immersed in a cauldron of boiling water. The grease is recovered to be used again, and the diamonds are then examined on

sorting table, where the true diamonds are separated from *pyrites, barytes,* etc., by hand-picking.

J. Thoulet discussed the occurrence of diamonds on the bed of the sea in the Gulf of Gascogne. Diamonds have been found in meteorites by E. Mallard,[5] H. Moissan, G. F. Kunz and O. W. Huntington, F. von Sandberger, A. Daubrée, C. Friedel, etc. G. A. König and A. E. Foote described the Canyon Diablo meteorite (Arizona, U.S.A.), which contained both black and transparent diamonds; W. Will and J. Pinnow, the meteoritic stone of Carcote (Chile); and M. Jeroféeff and P. Latschinoff, that of Novo-Urei (Russia).

Graphite is very widely distributed over the surface of the globe,[6] but most graphites are so impure by intimate admixture with other minerals—quartz and mica—and the cost of transport is so great, that only a few deposits are of commercial importance. The bulk of the world's supply of graphite is obtained chiefly from Ceylon, Austria, Bavaria, Siberia, the United States, and Canada. There are, however, workable deposits in many other places. It occurs (i) in veins running through cracks in gneiss, limestones, pegmatite, and eruptive rocks—*e.g.* the deposits at Ceylon, Borrowdale (Cumberland), and Batugal (Siberia); (ii) bedded masses—*e.g.* in Ontario (Canada), Passau (Bavaria), Madagascar, Schwarzbach-Kruman (Bavaria), and Styrian Alps; and (iii) it is also found disseminated through many rocks in scattered scales or plates. Graphitic granite, gneiss, mica schist, quartzite, pegmatite, and felspar are well known in various localities. The Laurentian limestones of Canada are graphitic.

Graphite has been reported from extra-terrestrial sources. Thus, it has been found in some of the most famous meteorites—*e.g.* Lenarto (Hungary) in 1815; Benedego (Bahia) in 1816; Bohumilitz (Bohemia) in 1829; Sevier (Crosly Creek) in 1840; Congford (Tennessee) in 1845; Chartago (Tennessee) in 1846; Seelasgen (Brandenburg) in 1847; Chesterville (South Carolina) in 1847; Kaba (Hungary) in 1857; etc. The subject has been discussed by C. Reichenbach,[7] M. Berthelot, A. Daubrée, H. Moissan, J. L. Smith, W. Tassin, R. Brauns, S. Meunier, L. Troost, W. Flight, G. Ansdell and J. Dewar, etc. Some of the largest and best-developed crystals of graphite have been obtained from meteorites.

The chief monographs on graphite are; E. Wienschenk, *Der Graphite, seine wichtigsten Vorkommnisse und seine technische Verwendung*, Leipzig, 1904; *Zur Kenntniss der Graphit-lagerstätten*, München, 1900; F. Muck, *Die Steinkohlen Chemie*, Bonn, 1881; E. Donath, *Der Graphit*, Leipzig, 1904; F. Cirkel, *Graphite, its Properties, Occurrence, Refining, and Uses*, Ottawa, 1907; H. Weger, *Der Graphit*, Berlin, 1872; A. Hasnig, *Der Graphit*, Wien, 1910; H. S. Spence, *Graphite*, Ottawa, 1920.

§ 3. The Different Forms of Carbon—Allotropy

> What are allotropic states? Curious states which chemists frequently dispose of by calling them allotropic, a term frequently used when they are puzzled to know what has happened.—W. S. JEVONS.
>
> It matters much with what others, and in what positions, the same atoms are held together. . . . When the configuration of the atoms is changed, the properties of the body which is formed from them must also change.—LUCRETIUS (B.C. 60).

Near the beginning of the nineteenth century, chemists—*e.g.* H. Davy[1]—recognized that carbon occurs in three different forms which they called diamond, graphite, and amorphous carbon. H. C. Sorby proposed four classes: diamond—octahedral crystals, sp. gr. 3·52; graphite—hexagonal crystals, sp. gr. 2·18; hard coke—cubic crystals, sp. gr. 1·89; and anthracite—quadratic crystals, sp. gr. 1·76. H. F. Weber said that the sp. hts. give no evidence of the existence of three intrinsically different forms of carbon, and he considers that there are only two forms of carbon, one transparent and the other opaque. This fits P. Debye and P. Scherrer's observations on the X-ray spectra of graphite and amorphous carbon, since both have the same internal crystalline structure—*vide infra*. The physical properties of graphite are usually intermediate between those of the diamond and of amorphous carbon—*vide* Table I. The electrical conductivity is exceptional because, according to G. Wiedemann and R. Franz's rule (**3.** 21, 5), the ratio of the thermal and electrical conductivities of the metals is approximately constant; the thermal conductivity of graphite is normal, while the electrical conductivity is abnormal. The explanation is not known.

A. Breithaupt found a mineral in the clay shales of Singbhom, near Calcutta; its sp. gr. was 1·9; and he considered it to be a special variety of carbon. A. von Inostranzeff found a black lustrous variety of what he called *schungite*, near Schunga (Russia). The sp. gr. of dried schungite is 1·981. A. Sauer found a variety of carbon in the gneiss, mica schists, and quartzite formations near Wiesenthal (Saxony). He called it *graphitoid*. E. Weinschenk considered it to be graphite. W. Luzi regarded graphitoid as a variety of carbon with over 95 per cent. carbon, and falling between anthracite and graphite. P. and L. Schützenberger stated that the carbon obtained from cyanogen is different from other forms of this element. According to C. de Douhet, the so-called *anthracitic diamond* of Brazil contains 97 per cent. of carbon. It occurs in spherical masses, and its sp. gr. is 1·66. As G. B. Trener pointed out, it is not clear if many of these substances are graphite, amorphous carbon, or a mixture of the two.

Table I.—A Comparison of Some Properties of Different Forms of Carbon.

Physical property.	Diamond.	Graphite.	Amorphous carbon.
Specific gravity	3·5	2·10–2·52	1·30–2·00
Heat of combustion (Cals.)	94·31	94·81	97·65
Ignition temp. in oxygen	800°–875°	650°–700°	300°–500°
Coeff. vol. expansion	0·00000375	0·0000104	0·0000162
Thermal conductivity	0·33	0·0117	0·000405
Specific heat	0·1128	0·1604	0·1653
Electrical conductivity	$2{\cdot}1\times10^{-15}$	$0{\cdot}082\times10^{4}$	0·25

In his *Recherches sur les états du carbone* (Paris, 1870), M. Berthelot showed that graphite could not be characterized as *une espèce défine*. Before that time all varieties of carbon leaving a grey mark on paper were called graphite. There appears to be continuous series ranging from those varieties of carbon with a sp. gr. just below that of the diamond, to that of amorphous carbon, 1·6. Well-defined graphite, and amorphous carbon were supposed to differ in the degree of polymerization, and L. Staudenmaier showed that free carbon atoms have a marked tendency to associate into complexes to a higher and higher degree as the temp. rises, furnishing a series of modifications of carbon. M. Berthelot applied B. C. Brodie's nitric acid reaction as a criterion for distinguishing graphites from other forms of carbon. He arbitrarily defined a graphite to be *any variety of carbon which furnishes graphitic acid on oxidation* with a hot mixture of potassium chlorate and nitric acid—*vide infra*, action of nitric acid on graphite. Neither diamond nor charcoal yield graphitic acid, and B. C. Brodie believed that graphite may accordingly be regarded as a peculiar radicle to which he gave the name *graphon*. H. Moissan accepted this definition of a graphite, and, in his *Recherches sur les différentes variétés du carbone* (Paris, 1896), showed that the complete oxidation of some graphites by M. Berthelot's method requires six to eight successive treatments, but when the process is applied in the following manner, with nitric acid prepared by distillation from recently fused nitre with a large excess of boiling sulphuric acid, the application is simplified :

> Dry graphite is added to conc. nitric acid, and then small amounts of dry chlorate; the oxidation is far more rapid and, in the case of natural graphites, the result is apparent at the end of the first treatment. Far more chlorate than graphite must be used, weight for weight. The oxidation must last some twelve hours and finish at 60°. Care must be taken at the outset not to bring the mixture of chlorate, nitric acid, and carbon up to 60°, or rather violent explosions may take place. The admixture of the smallest amount of organic matter must also be avoided. At the end of these oxidations, the graphitic oxide, obtained in more or less well-defined crystals, has always the same greasy appearance and the same light yellow colour.

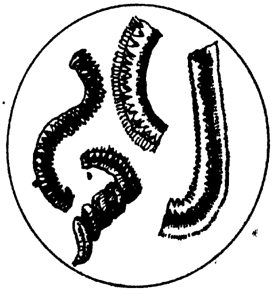

Fig. 1.—Vermiculites from Swelling Graphites.

P. Schafhäutl, R. F. Marchand, and B. C. Brodie further showed that some natural graphites after having been heated in the presence of sulphuric acid, or a mixture of that acid with potassium chlorate or nitric acid, increase largely in volume when subsequently heated on a platinum foil; and W. Luzi further showed that it is sufficient to moisten the graphite with a small amount of nitric acid to cause it to swell when heated, and to produce vermiform or dendritic projections—illustrated Fig. 1—

with a circumference from a quarter to half an inch, and a length extending up to several inches, and bent or twisted in regular curves. The vermiculites consist of a number of oblong cells densely grouped together, and exhibiting on the outer surface long parallel folds and wrinkles. These forms always rise to the surface when placed in alcohol or water, and behave thus even when thoroughly soaked with liquid. The vermiculites can be readily pressed into different forms, and compressed between the fingers. The internal structure exhibits planes of highly metallic lustre which, according to E. Donath, are supposed to represent crystallization. W. Luzi, O. Lüdecke, H. Moissan, and F. Sestini then proposed to divide the graphites into two classes: (i) Those which swell after treatment with nitric acid were called **graphites.**

To this group belong graphites from Ceylon, Ticonderoga, Amity (New York State), Grenville, and Buckingham, Province of Quebec; Borrowdale, England; Monte Rosa, Calabria; Bamle Skütteriid, Norway; Marbach, Lower Austria; Pfaffenreuth, near Passau, Bavaria; and Spain.

(ii) Those which do not swell under these conditions were called **graphitites.**

To this group belong graphites from Alstadt (Moravia); Krumau, Schwarzbach, Mugrau (Bohemia); Passau (Bavaria); Saxonian graphite; Irkutsk, Tunguska (Siberia); Storgard, (Finland); Karsock and Omesnack (Greenland); Colfax County (New Mexico); South Australia; Takaschimiza (Japan); and Lerigliani, Monte Pisano, Italy. Also all artificial graphites made by electric processes.

H. Moissan found that all the graphites obtained solely by the help of a very high temp. on any variety of carbon—diamond or lampblack—or by the condensation of carbon vap., showed no tendency to swell under the action of conc. nitric acid. On the contrary, all graphites prepared at a high temp. by dissolving carbon in a metal—zirconium, vanadium, molybdenum, tungsten, uranium, chromium, iron, and aluminium—swelled readily. Graphite from low temp. iron did not swell, but that from iron which had been heated to a high temp. swelled abundantly.

E. Weinschenk attributed the different behaviour of various kinds of graphites in nitric acid to a difference in their structure. The graphites which expand so much in volume by the nitric acid treatment usually consist of very thin, minute scales or plates, which, on account of their capillary structure, suck up the acid, and swell up through the gases produced during the action of heat on the acid. Graphite and graphitite, said he, differ only in their state of division, but are otherwise strictly identical. L. Jaczewsky has opposed this statement.

According to E. Weinschenk, the term *amorphous graphite* is a misnomer because it refers to varieties characterized by a compact dense structure, but which otherwise, like the larger lamellar aggregates, really consist of minute crystals. Graphite may be in so fine a state of subdivision that it is difficult to recognize its crystalline structure, " in all cases, the limit between crystalline and amorphous carbon is so sharp and distinct that a transition from one to the other is out of the question." L. Forquignon stated that the carbon of malleable cast iron is wholly combined with the iron. The metal is softened at a temp. below the m.p., and there is a segregation of graphite throughout the whole mass. This graphite furnishes graphitic acid, but it is "absolutely amorphous even when magnified × 400." This test for crystallinity is inadequate; since internal structure not external form is the only test that can now be recognized when dealing with pulverulent substances.

Some diamonds are dark grey and even black. They exhibit a more or less imperfect crystalline structure, and are known as **black diamonds,** *bort,* or **boart,** or **carbonado.** Boart is an imperfectly crystallized, translucent, dark-coloured diamond which has various colours, but no clear portions, and is therefore useless as a gem; boart is used in the drilling of rocks, and in cutting and polishing other stones. Carbonado is the Brazilian term for a still less perfectly crystallized black diamond. It is as hard as boart, and has similar uses. Boart and carbonado are usually regarded as forms intermediate between diamonds and graphite. They occur in the diamond fields, and were synthesized by H. Moissan[2] who, in his *Recherches sur les différentes variétés de carbone*, showed that if silver be substituted for iron, only black diamonds are produced.

Amorphous carbon is often taken to include coke, gas carbon, anthracite, soot, lampblack, animal charcoal, wood charcoal, and the forms of carbon which separate during the decomposition of many chemical compounds—*vide infra.* M. Berthelot obtained a product which he called *benzene carbon*, by heating benzene, naphthalene, etc., with a quantity of hydriodic acid insufficient for complete saturation. C. F. Cross and E. J. Bevan obtained what they called *pseudo-carbon*, by the dry distillation of cellulose, or by heating it with a dehydrating agent. It is probable that bituminous coals are hydrocarbons.

The work of J. L. Proust discussed in the first volume (**1.** 2, 10) led to the idea that substances containing the same elements united in the same proportions must of necessity have the same chemical properties. In the early part of the nineteenth century this conception was regarded as axiomatic; but facts began to accumulate which rendered a revision necessary. Referring to M. Faraday's discovery[3] of two hydrocarbons with the same elements united in the same proportion but with very different properties, J. J. Berzelius said in 1827:

> Definite knowledge concerning this phenomenon is of such significance in the theory of the composition of animal and vegetable substances, and has such an important bearing in organic chemistry, that it must not be accepted as demonstrated until its truth has been subjected to the most severe proof.

The discovery that racemic and tartaric acids; cyanic and fulminic acids; and α- and β-stannic oxides have the same percentage composition, but different properties, led J. J. Berzelius (1832) to adopt the implication; and suggest that the simple atoms of which substances are composed may unite with each other in different ways. He added:

> E. Mitscherlich's remarkable discovery that substances composed of different elements, but containing these in the same atomic ratio and arranged in the same manner, crystallize in the same form or are isomorphous, as we now say, has thus received its complement; and this complement consists in the discovery that bodies exist composed of an equal number of atoms of the same elements, arranged, however, in an unlike manner, and possessing therefore different chemical properties and crystalline forms, *i.e.* that they are heteromorphous. If further investigation should confirm this view, an important step would have been taken in the advancement of our theoretical knowledge concerning the composition of substances. But since it is requisite that we should be able to express our conceptions by definite and appropriately chosen terms, I have proposed to call substances of the same composition and of different properties "isomeric," from the Greek ἰσομερής (composed of equal parts).

Related phenomena were quickly discovered, and it became necessary to define more accurately the meaning of the term isomerism. Freely translating J. J. Berzelius' further remarks (1833):

> The cases where bodies like the two stannic oxides have the same absolute and relative number of the same elements, and the same mol. wt., must not be confounded with others in which the relative number of atoms is the same, but not the absolute number. Thus the relative number of carbon and hydrogen atoms in ethylene, C_2H_4, and in the hydrocarbon oil, C_4H_8, is identically the same (*i.e.* the number of atoms of hydrogen is twice that of carbon), but one atom of the gaseous substance contains only two atoms of carbon and four of hydrogen, $=C_2H_4$, whilst one atom of the hydrocarbon oil contains four atoms of carbon and eight atoms of hydrogen, $=C_4H_8$. For the designation of this type of similarity in composition combined with dissimilarity in properties, I would suggest the term *polymeric* (from πολύς, many). But there are yet other relations in which substances appear isomeric in the true sense of the word without actually being so. Such a case arises when substances consist of two compound atoms of the first order, which are related to one another in different ways and which in consequence can form dissimilar combinations, *e.g.* stannous sulphate, $SnSO_4$, and stannic oxysulphite, contain the same absolute and relative number of atoms of the same elements and have the same at. wt., but (in case the latter salt should exist) they could not be considered as one and the same

substance. Substances of this kind, with time or change of temp., suffer a transposition of their components without anything being added or taken away, and a combination of different constitution is formed. . . . In order precisely to differentiate such cases from isomerism, we may use for them the designation of *metameric* substances (from μετά), in the same sense as in metamorphosis.

The terms isomeric, polymeric, and metameric here coined were not always used consistently, and they are not now used in quite the same way as that suggested by J. J. Berzelius ; not all are agreed even to-day. Thus, A. Kekulé, H. von Fehling, E. Frémy, A. Ladenburg, L. Meyer, and W. Nernst give for substances with the same percentage composition :

ISOMERISM	Mol. wt. same	METAMERISM.
	Mol. wt. different	POLYMERISM.

H. E. Roscoe and C. Schorlemmer, A. Bernthsen, and V. von Richter give for substances with the same percentage composition :

Mol. wt. different		POLYMERISM.
Mol. wt. same	Radicles different	METAMERISM.
	Radicles same	ISOMERISM.

J. J. Berzelius, and H. E. Armstrong used a similar classification but restricted the use of isomerism in the narrower sense given in this table. J. J. Berzelius objected to the practice of describing the different forms of an element as examples of isomerism. He said :

I feel compelled to call attention to the fact that the word *isomerism*, which is applied to different substances composed of an equal number of atoms of the same elements, is not compatible with the view as to the cause of the different properties exhibited by the various modifications of sulphur, carbon, silicon, etc. . . . Whilst the term still lends itself to the expression of the relation between ethyl formate and methyl acetate, it is no longer suitable in the case of simple substances which assume different properties, and it might be desirable to substitute for it a better chosen term, *e.g.* allotropy, or allotropic modifications from ἄλλος, another, τρόπος, habit. In accordance with these views, there can be more than one cause for that which we call isomerism, namely : (i) Allotropy, in which case the difference between the two sulphides of iron (pyrite and marcasite) is due to the fact that they contain different modifications of sulphur. (ii) Differences in the relative position of the atoms in the compound, of which the two kinds (ethyl formate and methyl acetate) are so striking a proof. (iii) Allotropy due to substances containing different forms of an element arranged in different positions.

J. J. Berzelius thus believed that the isomerism of compounds was often produced by the elements retaining their allotropic states in combination and that the cause of the isomerism in such compounds is to be sought in a change in the nature of the atoms themselves. After chemists had learned to appreciate Avogadro's hypothesis, and to recognize that the mols. of elements like those of compounds, may be composed of several atoms, J. J. Berzelius' distinction between isomerism and allotropy lost its significance, and the term allotropy may be applied quite generally to both elements and compounds. **That property in virtue of which one substance, without changing its state, may exist in two or more forms with different properties is called allotropy.** One allotropic form is an alias, so to speak, of the other. The less common form is sometimes called an " allotrope " or an "allotropic modification " of the other. Are the allotropic forms of an element to be regarded as one and the same substance ? No ! because each form has a set of distinctive and characteristic properties which distinguish it from all other substances. Two important and consistent theories have been derived to explain allotropy.

1. *Position theory.*—When a determination can be made of the mol. wt. of two allotropic modifications, there is frequently a difference, for the one modification may contain more atoms per mol. than the other. This is the case, for instance, with oxygen and ozone. In consequence, it is often stated that allotropy is due to a difference in the mol. wt. of the element. In other cases, it is assumed that

even when the mol. wt. are the same, as is probably the case with some of the different forms of sulphur, the atoms of the mol. are arranged differently. The idea is sometimes expressed in this way: Just as the bricks of the same kind in the hands of a builder be fashioned into various structures, so Nature, from the same kind of atoms, builds up mol. structures with widely different properties. Lucretius illustrated a similar idea when he stated that the same letters differently arranged may produce words with an entirely different meaning. M. Berthelot thus regarded the different forms of carbon not as substances containing different carbon atoms, but rather as complexes with different proportions of carbon atoms per mol.—polymerized states of carbon. M. Copisarow discussed the allotropy of carbon on the assumption that allotropy is a function of valency and that the different allotropic forms are produced by differences in the mode of intramolecular linking.

2. *Energy theory.*—There is a change in the internal energy of an element when one allotropic modification is transformed into another. For example, ozone is formed from ordinary oxygen by an endothermal reaction. The heat absorbed in the production of one mol. of ozone is 34·1 Cals. Hence, $3O_2=2O_3-68\cdot2$ Cals.; or $3O_2+68\cdot2$ Cals.$=2O_3$. Accordingly, ozone is supposed to have more available energy than ordinary oxygen. Similar remarks might be applied to the different forms of carbon and of phosphorus. In the case of sulphur, α-$S+O_2=SO_2+71\cdot08$ Cals.; β-$S+O_2=SO_2+71\cdot72$ Cals. This means that the conversion of 32 parts by weight of rhombic sulphur into the monoclinic form is attended by the absorption of 0·64 Cal. There is a difference in the energy content of the two forms of sulphur as was the case with oxygen. W. von Siemens also regarded the allotropes of carbon as combinations of a hypothetical metal *carbonium* with *latente Wärme*. Hence the definition: **the allotropic modifications of an element are composed of one element associated with different proportions of available or potential energy, and consequently they exhibit different physical and chemical properties.** A definition of this kind describes the facts and no more. That is, of course, the function of a good definition. But there is a plausible finality about it not altogether pleasing. Energetics may tell us when reactions can occur, but they do not tell us if they will occur, or how they occur. Energy definitions in general are strictly non-committal and less likely to stimulate the imagination than, perhaps, the more hypothetical views. This indicates one great objection to the energy method of dealing with chemical reactions. The atomic, mol., and kinetic methods are far more likely to prompt new and fruitful investigations. However, if we accept J. C. Maxwell's view,

> The potential energy of a mol. depends essentially on the relative positions of the parts of the system in which it exists, and that potential energy cannot be transformed in any way without some change in the relative position of these parts,

it follows that the energy theory of allotropy is quite in harmony with the position theory, and that the one supplements the other, for changes in the internal energy are dependent on changes in the configuration of the system.

The transition of ordinary α-S to β-S is reversible. There is a definite transition temp. below or above which only one of the forms is stable, and the other form unstable. This is a case of **enantiotropic allotropy**—from the Greek ἐναντίος (enantios), opposite; τρόπος (tropos), habit. The transformation of λ-S to μ-S is also reversible, but there is not a definite transition temp., for the amount of each form present when the system is in equilibrium is determined by the temp. The phenomenon is called **dynamic allotropy,** to distinguish it from that which precedes. In yet a third type of allotropy, the change is irreversible, one form is in a metastable condition at all temp. This is called **monotropic allotropy,** to distinguish it from the two phenomena which precede—example, diamond and graphite.

§ 4. The Action of Heat on the Diamond and Graphite

In 1694–5, G. Averani and C. A. Targioni,[1] of the Accademia del Cimento, showed that when heated in the focus of a large burning glass, diamonds disappeared. It was concluded that the diamond evaporated, or volatilized under the influence of heat. After comparing the high refractive indices of camphor, olive oil, amber, etc., "which are fat, sulphureous, unctuous bodies," with the high refractive index of the diamond, Isaac Newton, in 1704, inferred that "a diamond is probably an unctuous substance coagulated." Later observations showed that this hazardous guess happened to be near the mark, but, as G. Delafosse has pointed out, had the same argument been applied to anatase, or to greenockite, the analogy would have broken down. It is interesting to note that Isaac Newton's guess was anticipated a century before by A. B. de Boot. R. Boyle (1672) heated diamonds in a crucible, but with no definite results. J. Kunckel said that the diamond is not altered by fire. The subject was discussed by J. F. Henckel in 1725. T. Bergman (1777) proved by means of the blowpipe that the diamond does not contain silica, and he assumed it to be a special earth, *terra nobilis*. "Urged by intense heat, the diamond contracts a kind of soot on its surface." Five years afterwards he verified the observation that the diamond is combustible. In 1766 J. d'Arcet repeated the experiments of G. Averani and C. A. Targioni; he heated diamonds in a crucible and found that they were *complètement volatilisés.* After heating a diamond in a luted crucible in a pottery oven, he found the interior of the crucible contained a kind of *fumée noire,* without sensible loss of weight. P. J. Macquer observed that *une espèce d'auréole ou de flamme* played about the diamond during its destruction by fire. A. L. Lavoisier inquired if the apparent destruction is truly a volatilization or a combustion. He proved that the volatilization of the diamond is *en réalité un phénomène de combustion,* and that the diamond burns only in contact with air. It resists the action of the most violent heat if air be rigorously excluded. In answer to the question: *Qu'est-ce que le diamant?* A. L. Lavoisier replied:

> It is still impossible to answer this question in a satisfactory manner, and perhaps it will never be possible to do so. Nevertheless, in summarizing our knowledge on this subject we can regard as proved: (i) The diamond is a combustible substance which burns at a temp. near the m.p. of silver; (iii) Like most combustible bodies it gives a surface film of a black substance resembling carbon; (iii) When the conditions are unfavourable for combustion it is converted into carbon; (iv) When heated to a very high temp. exceeding that of the porcelain oven, it is partly converted into a *vapour incoercible* and into a gas which gives a precipitate with lime-water, and which resembles very closely *le gaz dégagé des effervescences, des fermentations, et des réductions métalliques.*

A. L. Lavoisier thus demonstrated the close analogy between the diamond and carbon, but he did not prove that these two substances have the same chemical composition. In 1797, S. Tennant burnt the diamond by fusing it with nitre, and collected the carbon dioxide which was formed. He demonstrated that equal weights of carbon and diamond furnish the same quantity of carbon dioxide, and concluded that the diamond is composed exclusively of carbon. G. S. Mackenzie, and W. Allen and W. H. Pepys concluded that different varieties of charcoal and graphite furnish the same amount of carbon dioxide as the diamond; and added that "the diamond differs from charcoal solely in the firmness of its aggregation which is generally known to be an obstacle to every chemical change." L. B. Guyton de Morveau (1799) came to the same conclusion from an experiment in which the diamond was heated with iron whereby the latter was converted into steel, just as occurs when iron is similarly treated with carbon. The general conclusion, as summarized by R. J. Haüy, is that *le diamant a passé dans la classe des substances inflammables, comme étant uniquement composé de charbon.*

In 1808, J. B. Biot and F. J. Arago ascribed the high refractive index of the diamond to the presence of at least 25 per cent. of hydrogen. L. B. Guyton de Morveau also regarded the diamond as pure carbonaceous matter containing possibly some water of crystallization, but the experiments of H. Davy on the combustion of the diamond showed that no substance other than carbon dioxide is produced by the combustion of the diamond in oxygen; there is no evidence of the formation of moisture, and the assumption that the diamond contains hydrogen or water must be abandoned. J. B. A. Dumas and J. S. Stas have shown that the diamond cannot contain more than $\frac{1}{120}$th per cent. of hydrogen. H. Davy suggested that possibly the diamond contains oxygen, and A. Caire-Morant also said in 1826 that *on n'est pas bien assuré encore s'il est pur ou combiné avec l'oxygène.* The various determinations of the at. wt. of carbon (*q.v.*) on the form of the diamond show that this assumption is also untenable.

In 1890, A. Krause raised the question whether the diamond is chemically the same as carbon since all the preceding work may be interpreted that twin elements—like cobalt and nickel—are in question. Diamond splinters were burnt in a current of oxygen, the products of combustion absorbed by ammonia, and the ammoniacal soln. decomposed with pure sodium hydroxide. A comparison of the crystals obtained on evaporation with those of pure sodium carbonate, showed that they had the same percentage of water of crystallization, and that they were identical in crystalline form, optical properties, m.p., electrical conductivity, and solubility in water. He concluded that the diamond must be chemically identical with carbon, since not only is the at. wt. the same, but on oxidation they both yield exactly the same product.

According to J. B. A. Dumas and J. S. Stas,[2] only the clear and colourless diamonds leave no ash when burnt; with other samples they obtained 0·05 to 0·20 per cent. of straw-yellow to reddish-yellow ash; O. L. Erdmann and R. F. Marchand obtained 0·08 to 0·15 per cent. of reddish ash from the clearest diamonds; and L. E. Rivot, 0·24 to 2·03 per cent. of yellowish ash. A. Petzholdt found the ash contained microcrystalline plates. Some of the crystals, said C. Friedel, are active towards polarized light. A. Petzholdt said that the ash contains silica and iron oxide; L. E. Rivot, ferruginous clay; and H. Moissan, iron oxide as the principal constituent of the ash, along with silica and lime. According to G. Halphen, a diamond possessing a brownish tinge became rose-red when heated, and the colour vanished after heating 8–10 days. W. Flight and N. S. Maskelyne found that a dirty-yellow diamond was decolorized by heating it in hydrogen or chlorine gas; and a diamond which lost its rose-red colour on exposure to light, acquired the original tint when heated. C. Friedel found a green Brazilian diamond acquired a brown colour when heated to about 230° in the absence of air. H. Moissan also noted the colour of some diamonds becomes less marked after they have been heated in hydrogen.

A. F. de Fourcroy, L. B. Guyton de Morveau, P. J. Macquer, etc., have mentioned the blackening of the diamond when heated. B. Silliman noted that when the diamond is heated in the flame of the oxy-hydrogen blowpipe, and partially burnt, the edges appear rounded as if there has been superficial fusion, but it was not established whether fusion really did occur. W. Allen and W. H. Pepys, J. Murray, and C. M. Marx made a similar observation and noted that a blackening occurs. A. Morren found that when diamonds are heated in the coal-gas flame, they acquire a surface film of graphitic carbon. G. Rose noted that when some diamonds are heated, they shatter with a loud noise; but neither he nor E. H. von Baumhauer ever observed the slightest sign of blackening when the diamond is burnt in air. G. Rose attributed the blackening to the formation of graphite. E. D. Clarke's results with the oxy-hydrogen blowpipe were rather indefinite. V. A. Jacquelain, however, stated that no fusion occurs in the oxy-hydrogen or oxy-carbon monoxide flame. According to M. de K. Thompson and co-workers, diamonds darken at 1000°, due to numerous cracks causing absorption of light from total reflection. These cracks are probably produced by small black spots, which mark the beginnings of the change to graphite. At 1650°, diamonds change slowly to a substance which gives B. C. Brodie's reaction for graphite. By increasing the temp. to 1750°, the rate of transformation is increased 26 times.

G. Friedel and G. Ribaud studied the effect of heat on the diamond. When observed between nicol prisms, crystals from all sources show black lines which appear to be due to deformations of a substance originally isotropic. The uneven cooling of the original magma in which the crystals were formed, and external mechanical action, are not sufficient to account for the magnitude of the double refraction observed; and it is considered necessary to assume that a polymorphic transformation, accompanied by a change of volume, has taken place at a temp. when the plasticity was sufficient to allow the crystal to retain permanent deformations. The conversion of diamonds into graphite takes place near this point. Above 1500°, the surface of a diamond began to blacken, but only a thin skin was affected. This skin is translucid, and consists of diamond containing a small proportion of graphite; it is hard and brilliant; it is not affected by chemical reagents which oxidize graphite; but in a Bunsen burner it is burnt away leaving colourless diamond. A few minutes' heating at 1800° causes a more rapid production of graphite along the edges of the crystal. Up to between 1850° and 1865° the bands, between nicol prisms, show no alteration when re-observed after cooling; but towards 1875° or 1880°, they show some deformation in places indicating a certain plasticity at this temp. When 1885° ± 5° is exceeded the crystal breaks into fragments, bounded by octahedral planes of cleavage, and the bands due to double refraction undergo a complete change. It is possible to observe this only if the temp. is exceeded for a few seconds, otherwise the whole of the diamond is very rapidly converted into graphite. G. Friedel and G. Ribaud suggest that above this temp. a new form of crystal is produced, which is converted into graphite more rapidly than ordinary diamond.

H. Moissan found that if heated to 2000° in a crucible packed with powdered carbon, the diamond becomes covered with a black film which is not graphite. In the electric arc, at a somewhat high temp., the diamond becomes incandescent, swells up without melting, and becomes covered with black masses, consisting entirely of hexagonal lamellæ of graphite, which is easily converted into graphitic oxide. If the diamond is placed in a small carbon crucible in the electric arc furnace, the crystals first break up into small fragments along the planes of cleavage, and then at a higher temp. swell up and are completely converted into graphite, which yields yellow graphitic oxide. It follows that at the temp. of even a moderately intense electric arc, the stable form of carbon is graphite. L. von Schrötter observed that when a diamond resting on a platinum plate is heated to a high temp., some carbide is formed. By heating the diamond in the electric arc between carbon poles, the mineral softens and changes into a mass resembling coke; and C. Despretz likewise found the diamond is converted into graphite and melts to small spheres; but H. Moissan said that the diamond swells and is graphitized without melting. J. P. Gassiot also made some inconclusive experiments on this subject. W. Crookes found that during the bombardment of diamonds in the cathode rays, not only is there a brilliant phosphorescence, but the diamond becomes discoloured and in time becomes black on the surface. Some blacken in a few minutes, others require an hour or more. C. Doelter found that diamonds were browned or blackened superficially in some cases at 1300°, in others at 1500°, and in still other cases at 2000° and 2500° in an inert atm. H. Vogel and G. Tammann observed the superficial blackening at 1500°–1700°. The black film is removed by polishing powder; it is not ordinary amorphous carbon, but probably graphite. C. A. Parsons and A. A. C. Swinton found that when heated in the focus of a cathode-ray discharge, at a temp. of 1890°, the diamond is converted into black carbon.

C. Mène has analyzed a number of samples of graphite, and his results are shown in Table II. Other analyses have been made by W. Luzi, E. Weinschenk, H. V. Regnault, etc.

L. Elsner thought that graphite is volatilized in the porcelain oven because the containing vessel is blackened above the graphite, but H. V. Regnault showed that the blackening is probably due to the volatilization of a hydrocarbon in the graphite. M. Berthelot attributed the sublimation of some graphite from a mixture of boriferous graphite heated white hot in a stream of chlorine, to the formation of a volatile compound of the three elements. C. F. Rammelsberg thought that a loss which he observed on heating some purified graphite might be due to volatilization. R. Hare, and B. Silliman passed an electric current through a graphite or a charcoal rod, and observed that the surface became covered with fused carbon, which has the character of graphite; but L. Vanuxen claimed that the fused globules are nothing but the fused ash of charcoal or graphite and consist mainly of iron oxide and silica. R. Hare defended his statement that the carbon was actually fused, but L. Vanuxen's claim was probably right. According to F. Braun, if the discharge from a Leyden jar be passed through carbon between two glass plates, the carbon gives a continuous spectrum, and microscopic spheres of fused carbon can be detected. There has been some discussion as to whether or not the carbon is really fused.

H. Davy, and N. T. de Saussure observed that amorphous carbon is one of the most difficult substances to melt or vaporize. When heated to a high temp. it becomes hard enough to scratch glass. C. Despretz, and A. Bettendorff found that when heated intensely in vacuo by an electric current, amorphous carbon is converted into graphite. A. Schuller heated a carbon rod in vacuo and noted that a grey film appears on the glass walls; this is attributed to organic matter as an impurity in the carbon because the film does not get any thicker with subsequent heating. He could detect no evidence of fusion, but there were signs of the volatilization of the carbon. M. Berthelot noted the volatilization of carbon from the filaments of an electric incandescent lamp run with the smallest possible heating of the graphite filament. The temp. is probably 1200°–1500°. The sublimate is solely amorphous carbon. The formation of a sublimate in incandescent lamps under these conditions indicates that carbon exerts an appreciable vap. press. at temp. about 2000° below its b.p. 3600°. This unusually large interval is regarded as further evidence of the highly complex character of the mols. of solid carbon. R. Hare, and B. Silliman thought that they had established the volatilization of heated carbon:

> When two mahogany-charcoal electrodes connected with an electric machine are brought into contact, they become incandescent, and if the points are separated a short distance, they glow vividly, forming a bright luminous arc, and send up a white smoke having a peculiar odour. The negative pole decreases in width, and a quantity of additional matter is deposited on the point; this grows a length of about half an inch and is then replaced by a new growth. On the contrary, the charcoal of the positive pole soon loses its point, and a cup-like cavity is formed in it, whilst at the same time it suffers but little diminution on the sides. To whichever part of the positive charcoal the point of the negative piece is directed, there the excavation is produced. If the two pieces of charcoal come in contact, they stick together. If the positive charcoal be replaced by a piece of metal, the negative piece receives no increase, but is gradually shortened during the combustion. In nitrogen gas, the two pieces of charcoal exhibit as brilliant a light, and the same growth of the negative point, as in air. Hence it appears that carbon, in the state of vap., is transferred from the positive to the negative pole. If the eyes are protected by a pair of green spectacles, small particles of carbon may even be seen passing along the luminous arc from the copper pole to the zinc pole. The matter which accumulates on the negative point sometimes forms a cylinder, sometimes a round knob with a stem. When examined by a magnifying-glass, it exhibits a fused, warty or botryoidal, smooth, metallic-shining, greyish-black surface, and a non-fibrous structure; sinks rapidly in oil of vitriol; does not conduct electricity (hence its presence makes the charcoal less brightly incandescent—but on the removal of the fused portion, the brightness is restored); burns very slowly at a red heat, without visible flame, producing carbonic acid, and leaving, sometimes a yellowish-grey ash, sometimes none at all. It is not attacked by sulphuric acid, and very little by hot nitric acid. No sign of fusion ever appears on the positive charcoal.

Similar results were obtained by J. Griscom, and even with an ordinary battery by W. West. C. A. Parsons, and R. Threlfall have discussed the effect of high temp. and high press. on carbon—*vide infra*, synthesis of diamonds. According to H. Moissan, when a carbon tube of about 1 cm. diameter is heated in an electric arc furnace, a light black cloud forms in the interior, in consequence of the condensation of carbon vap. If a dish containing crystallized silicon is placed in the tube, the silicon melts and then boils, and its vap., coming into contact with the vap. of the carbon, forms slender needles of carbon silicide. No evidence of the fusion of carbon was obtained, although the temp. was sufficiently high rapidly to volatilize calcium and magnesium oxides. In all cases, the carbon subjected to these high temp. is converted into graphite. The black deposit formed on the internal surface of incandescent lamps consists of amorphous graphite mixed with crystals of carbon silicide and some other crystals that seem to be silica. The carbon vap., whether condensed in a carbon tube, or on the exterior of a copper tube kept cool by internal circulation of water, or on the electrodes themselves, condenses always in the form of graphite, and the deposits show no traces of fusion. When the filament of an incandescent lamp breaks, the fractured ends show no traces of fusion, but are covered with small crystals of graphite. It follows that carbon, like arsenic, volatilizes under ordinary press. without previously fusing. It is probable, however, that under a sufficiently high press. fusion would take place.

The effect of press. on a solid which evaporates under atm. press. without melting is illustrated by placing solid acetylene in a test-tube closed by the finger. It will liquefy under its own press., and on opening the tube, the liquid at once solidifies. The experiment can be repeated many times with a small quantity of liquid.

§ 5. The Synthesis and Genesis of Diamonds

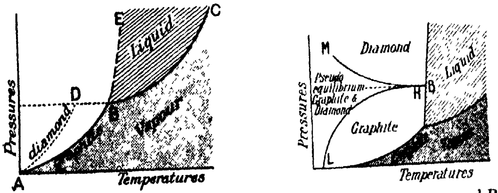
La reproduction du diamant est un problème pour les chimistes modernes le pendant de la pierre philosophale pour les alchimistes.—H. LE CHATELIER (1908).

Many attempts have been made to synthesize diamonds, *i.e.* to enhance the commercial value of carbon by transforming it from its ordinary opaque black condition to limpid crystals of diamond. In 1828, C. Cagniard de la Tour[1] reported that he had succeeded in making artificial diamonds, but L. J. Thénard showed that the product was charcoal mixed intimately with a hard crystalline slag containing alumina, ferric oxide, silica, and manganese oxide. In 1828, J. N. Gannal announced that by keeping a soln. of phosphorus in carbon disulphide under a layer of water for three months, he readily obtained crystals of carbon, some of which attained the size of *un grain de millet.* Both G. Gore, and H. Moissan failed to confirm this report. The latter obtained nothing but small grains of silica, completely soluble in hydrofluoric acid, even after five years; nor were any better results obtained with antimony in place of phosphorus. H. Moissan said that if purified carbon disulphide be used, no deposit appears during five years, but if moisture be present, small glistening drops of water appear on the glass as soon as the temp. is lowered, and these may have been mistaken for crystals.

C. Despretz caused an electric arc to play between a carbon electrode and a bunch of platinum wires, and obtained a crystalline dust which scratched rubies. H. Moissan said that the crystals may have been carbon silicide or boride, but the action of the electric arc on carbon has never yielded crystallized carbon other than graphite. M. Berthelot examined C. Despretz's electrodes and found graphite but no diamonds. J. Mactear claimed to have synthesized diamonds by an undescribed process, the crystals were examined by W. Crookes, and shown by N. S. Maskelyne to be a crystalline silicate. The synthesis of diamonds has been discussed by E. B. de Chancourtois, D. Rossi, A. Favre, E. J. Maumené, etc. A. Ludwig experimented in an atm. of hydrogen at 1500 to 3000 atm. press. Carbon rods, with their ends in contact with each other, were heated by an electric current; after a few seconds, the current-strength sank to nothing, soon increasing again to its former value. This went on for some minutes. The author assumes that the carbon points fuse to the transparent modification of carbon, which, like other transparent substances, is a non-conductor of electricity. Owing to the interruption of the current, the temp. falls and the transparent carbon changes into graphite, whereupon the process is repeated. In order to obtain the transparent fused carbon in the solid form, it appears necessary to cool it so quickly that the transformation into graphite cannot take place. Attempts to obtain rapid cooling by means of hydrogen gas and by dropping the fused carbon into water were unsuccessful owing to the difficulty of obtaining a sufficiently rapid flow of gas in the first case and to the occurrence of Leidenfrost's phenomenon in the second. In 1828, B. Silliman claimed to have demonstrated the fusion and volatilization of carbon by an electric current; O. Lummer, M. la Rosa, and F. Braun claimed to have obtained evidence of the fusion of sugar carbon in the electric arc. O. P. Watts and C. E. Mendenhall found that with a rising temp., deformation takes place with graphite rods between 1800° and 2150°, and it is concluded that the deformation is due to a gradually increasing plasticity of the carbon and not to the commencement of fusion. The alleged changes of structure are attributed to volatilization and subsequent condensation. S. Münch, and E. Ryschkewitsch agree that graphite becomes plastic before melting, and with a sufficiently high amperage the latter said that small graphite rods can be welded. J. G. Pammer found that the bending of carbon rods at high temp. is due to the presence of impurities. F. Sauerwald believed that E. Ryschkewitsch's fused globules of graphite were really beads of impurities distilled from the hot to the cooler parts of the graphite. A. Thiel and A. Ritter concluded that the presence of apparently solidified drops of graphite in the crater of the carbon electrode allowed to cool after forming the arc, is not a result of the fusion of the graphite.

According to A. König, graphite is the stable modification of carbon at temp. exceeding 1000°, and it is uncertain whether at lower temp. there is a transformation point for graphite or diamond, or whether the diamond is unstable at all temp. The sp. vol. of the diamond is smaller than that of graphite, so that the transition point will be raised by an increased press.—approximately 1° per 35·07 atm.—but the formation of the diamond at low temp. and high press. is very improbable because of the slowness of the reaction. The diamond can be produced at a high temp. only by accelerating the formation of the labile form before the stable form. The possible modes of formation are by crystallization from a molten flux; by condensation of the vap.; and by separation from soln. R. Threlfall, however, suggested that under suitable conditions, the formation of the diamond is not so much a transformation of carbon from one form to another, but is rather the result of a decomposition of a carbide in the presence of substances which accelerate the crystallization. The temp. must be sufficiently low to ensure that the velocity of the transformation from diamond to graphite is small. E. de Boismenu claimed to have made diamonds up to 2 mm. in diameter by the electrolysis of molten calcium carbide. The diamonds formed about the anode. A kilogram of calcium carbide is said to have furnished 1·75 carats of true diamonds. The claim yet remains unconfirmed.

Molten solids, on cooling, generally crystallize. Carbon, however, at atm. press. volatilizes at about 3600°, without passing through the intermediate liquid state. Its b.p. appears to be below its m.p. Carbon dioxide, acetylene, silicon tetrafluoride, and arsenic also volatilize without liquefaction at atm. press., but arsenic is easily liquefied if it be heated under press. It is therefore inferred that if sufficient press. could be applied, carbon would melt to a liquid and crystallize on cooling. C. A. Parsons attempted to melt carbon at press. up to 15,000 atm., and obtained soft graphite. As indicated above, the diamond at ordinary temp. is supposed to be the unstable form of carbon, and graphite the stable form. If one form can pass into the other at ordinary temp., the speed of the transformation must be exceedingly slow. The views of H. W. B. Roozeboom, and A. Smits on the equilibrium diagram of the allotropic forms of carbon are summarized in Fig. 2, and of G. Tammann in Fig. 3. It is estimated that if the press. were great enough, graphite would



FIGS. 2-3.—Equilibrium Conditions of Carbon at Different Temperatures and Pressures.

melt at about 3000°, and the liquid would have a vap. press. curve represented diagrammatically by *BC*, Fig. 2; and the vap. press. of solid graphite would be represented by *AB*. The vap. press. of the diamond would be represented by the curve *AD*. The m.p. of the diamond under great press. is represented by the point *D*; and *B* represents the m.p. of graphite. The curve *BE* shows how the m.p. of graphite changes with press. If molten graphite be undercooled, the soln. would become more and more viscous with a falling temp., and finally appear as amorphous carbon. G. Tammann modified the hypothetical diagram as indicated in Fig. 3. He postulates a region *MBL*, where the diamond is in a state of pseudo-equilibrium. The curve *MB* represents the temp. and press. where graphite changes into the diamond, and *LB* the conditions for the reverse change. When carbon is in soln., in iron, silver, or molten silicates, he assumes that the diamond and graphite are in equilibrium. Hence, diamonds may be produced with fast cooling, while with slow cooling graphite alone separates. The question whether the diamond and graphite can form solid soln. is an open one. Other observations have been made by O. Lummer, K. Fajans, E. Grüneisen, H. Kohn, J. A. M. van Liempt, J. J. van Laar, etc.

J. B. Hannay started from the fact that when the hydrocarbons are heated to a high temp. in the presence of the alkali metals, a hard, lustrous form of carbon is produced. He did not observe any signs of the formation of the diamond by working at high temp. and press. with the hydrocarbons—*e.g.* distilled paraffin—and lithium. He then heated bone oil in a sealed iron tube, and claimed that in some cases black or transparent crystals having the properties of the diamond were found in the carbonaceous mixture of iron and lithium at the bottom of the tube. He added:

> From the fact that the diamond was obtained only in the presence of nitrogenous matter, and that the product contained a little nitrogen, I am led to conclude that the diamond is produced in this reaction by the decomposition of some nitrogenous compound, and not by that of a hydrocarbon.

J. B. Hannay constantly mentioned the presence of silica; and H. Moissan added that if the diamond was really obtained, it was formed under press. owing to the solubility of carbon in a fairly fusible alloy of iron and lithium, and not from the nitrogenous compounds contained in the bone oil. H. Moissan did not succeed when following J. B. Hannay's directions. C. Combes took a view different from that of H. Moissan. The special feature of H. Moissan's experiment is the crystallization of the carbon from its soln. in molten iron under the great press. generated by the contraction of the cooled and solidified outer shell.

* *The maximum hydrostatic pressure in the interior of a sphere of liquid metal surrounded by a shell of solid metal.* According to R. Threlfall, neglecting the rigidity and modulus of incompressibility of the metal, it follows from L. J. G. Violle's formula that if P denotes the hydrostatic press. per unit area; τ, the tensile stress of the metal; r_1 the radius of the liquid portion; and r_2 the radius of the sphere; then the relation between the maximum hydrostatic press. which can be produced before the metal ruptures is given by $P=\{2\tau(r_2^3-r_1^3)\}/(r_2^3-2r_1^3)$. When τ is known, the press. corresponding with different values of r_1 and r_2 can be computed. If the breaking strength of iron under a tensile stress be 10 tons per sq. in., the hydrostatic press. might rise to 20 tons per sq. in., although R. Threlfall considers 8 or 9 tons per sq. in. would be nearer the mark.

According to G. Rousseau, crystals of the diamond, accompanied by graphite, are formed at ordinary press. when acetylene, generated from calcium carbide, is decomposed at 3000° by an electric current. C. A. Parsons heated a carbon rod electrically while immersed in liquids—benzene, paraffin, treacle, and carbon tetrachloride and disulphide—at press. up to 2200 atm., and found deposits of amorphous carbon were obtained in all cases. Similar results were obtained at 4400 atm. press. The distillation of carbon in an atm. of carbon monoxide or dioxide also gave amorphous carbon. O. Ruff observed that no increase in size occurs when diamonds were heated at 790° for 14 days in acetylene, coal gas, methane, or carbon monoxide, On the other hand, a carbon arc in liquid air gives a minute residue of crystals fluorescing like diamonds. A carbon arc through which a spray of water passes continuously gives a minute residue, the fluorescence of which is very faint. Organic vap. mixed with carbon monoxide yield amorphous carbon and graphite, and mixtures of molten organic solids with catalytic agents give entirely negative results. W. von Bolton, however, claimed to have recrystallized diamond dust by heating it in mercury vapour derived from sodium amalgam.

In 1880, R. S. Marsden, heated up to the m.p. of steel, silver, or an alloy of silver and platinum in a crucible lined with sugar charcoal, when the silver dissolved a small quantity of carbon, and gave it up again on cooling. When the metal was removed by nitric acid, the residue consisted of amorphous carbon, graphite, and some small black or transparent crystals with properties like the diamond. H. Moissan said that he obtained more or less well crystallized black diamonds by this process, especially when the crucible is heated in a wind furnace with retort carbon. K. Chrustchoff also obtained diamonds from a soln. of carbon in molten silver. He added that molten silver can dissolve about 6 per cent. of carbon. C. V. Burton claims to have obtained diamonds from a soln. of carbon in molten lead alloyed with about one per cent. of calcium. Iron also dissolves carbon and gives it up again on cooling. The solubility increases with the temp. H. Moissan packed a piece of iron, as pure as practicable, in a carbon crucible with sugar charcoal. The crucible was heated between the poles of an electric arc furnace (700 amps., 120 volts)—Fig. 4. Under these conditions the iron melted and dissolved much carbon. When the temp. had reached approximately 4000°, and the iron was volatilizing in clouds, H. Moissan plunged the crucible in cold water, Fig. 5. The sudden cooling solidified the outer layer of iron. The expansion which the inner liquid core underwent on solidifying must have produced an enormous press. Hence, the carbon separated from the iron under a very great press. After dissolving away the iron, etc., some of the carbon which remained was in the form of boart—black diamonds—some as graphite, and some in the form of transparent diamonds—microscopic it is true. H. Moissan separated as many as 10 to 15 minute transparent diamonds from a single ingot treated in this way. The largest was about ¾ mm. long. He later found that the addition of a little ferrous sulphide, or silicon or iron silicide

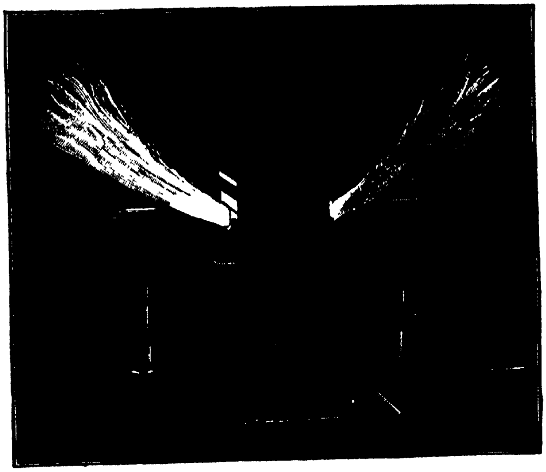


FIG. 4.—Moissan's Electric Arc Furnace.

favoured the formation of the diamonds. The method is thus described by H. Moissan:

> Swedish iron (150 grms.) was cut in fragments, and melted in the electric furnace in the presence of sugar carbon. The saturation of the iron by the carbon at the temp. of the electric furnace is finished in two or three minutes with a current of 400 amperes at 120 volts. The crucible containing the fused metal is removed from the furnace, and we add a solid piece of iron monosulphide (about 5 grms.) which melts at once and mixes with the mass. The metal swells up and abundant gases are given off. After cooling, the metallic mass is treated by acids. The graphite is transformed into graphitic oxide, then into pyrographitic oxide, and the latter is destroyed by a mixture of boiling sulphuric acid into which are thrown about 50 grms. of nitrate of potash in small portions. After several alternate treatments of this residue by hydrofluoric and sulphuric acids, then by fusion with potassium hydrofluoride, it is washed, dried, and placed in methylene iodide having a density of 3·4. The part which falls to the bottom is collected. By the above process no diamonds were obtained, but the result is quite different if the crucible containing the liquid iron with the added iron sulphide is cooled suddenly in a mass of cold water. After the first phenomena of calefaction, the porous graphite crucible is rapidly penetrated by the water. The metallic mass is cooled on the exterior and a solid crust is formed. As we showed before, an internal press. is thus formed and the carbon which deposits in the inner liquid part takes the form of the diamond. The appearance of the metallic masses to which sulphur has been added is sometimes different from ordinary cast iron cooled in water. An external resistant portion is still formed, but the surface of the metal, in the case of sudden cooling, is covered with a black, spongy, and solid layer, which comes from the rapid solidification of the metal while in an emulsion form, the latter being due to the sudden disengagement of gas. If the gases have had the time to come out before the immersion in water, the metal has the ordinary appearance.

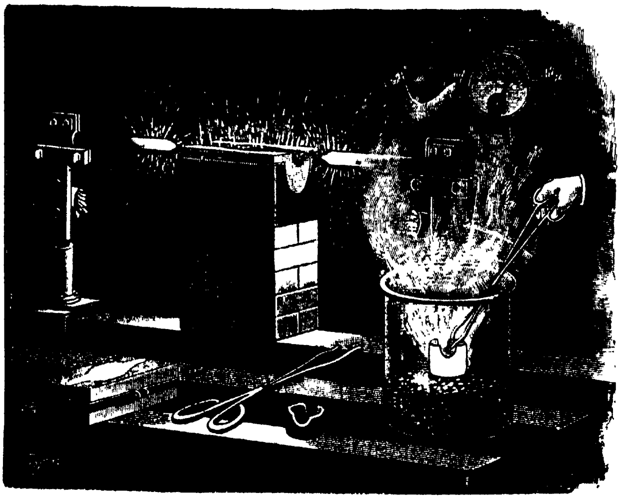

FIG. 5.—Cooling the Solution of Carbon in Iron.

H. Moissan did not get such good results by cooling in a current of coal gas as in water. Modifications were suggested by W. Borchers, C. Friedel, W. Staedel, C. Combes, etc. O. Ruff used alloys of iron with titanium, vanadium, tungsten, and molybdenum. C. Friedel obtained black crystals which scratched glass by heating carboniferous iron with sulphur in a sealed tube at 400°-500°; and M. Berthelot obtained similar crystals by dissolving in iron phosphide. F. Fischer said that the separation of carbon in the form of the diamond can occur only below

700°, otherwise it appears as graphite. In H. Moissan's experiments, the iron containing the carbon in soln. had already solidified so that the carbon could separate only in the form of tiny crystals. Larger diamonds would probably be produced if a substance in which carbon is readily soluble were still molten at 700°.

C. A. Parsons heated a carbon crucible containing iron in an electric furnace, and quickly transferred it to a compression machine, where it was subjected, while still molten and during cooling, to a press. of 11,200 atm. Less crystals were obtained than if the crucible had been cooled in water, although the press. of 11,200 atm. must have been greatly in excess of that of the spheroidal mass of iron in H. Moissan's experiment. He inferred that press. *per se* is not a necessary condition for the production of the diamond in the cooling soln. of carbon in iron. On the other hand, W. Crookes detected diamonds in the carbonaceous residue obtained when cordite is exploded in closed steel cylinders where the press. is estimated to be as high as 8000 atm. and the temp. over 4000°; and Q. Majorana heated amorphous carbon in an apparatus arranged to produce a press. of 5000 atm. by the explosion of gunpowder, and obtained some diamonds. C. A. Parsons concluded that the diamonds in H. Moissan's experiment are formed at about 690°, and that they are derived from the occluded gases of which carbon monoxide is the most important. When the melted mass is slowly cooled no diamonds are produced because the occluded gases escape, but with almost instantaneous cooling, the gases are retained, and diamonds are formed. He believed that high pressures, except in so far as they are developed during the cooling of the melt, and within it, are not essential to success. It is further suggested that carbides like carborundum are first formed, and that the actual reaction is between the carbide, iron, sulphur, and carbon monoxide.

According to A. Rossel, and C. Friedel, small diamonds were found in hard steels which had been produced at high temp., and cooled under great press. L. Franck also claimed to have isolated diamonds from hardened steel. B. Neumann obtained no diamonds from slowly cooled iron, but graphite, carborundum, and corundum crystals were present. According to A. Ludwig, diamond crystals are formed when an electric current is passed through an iron spiral embedded in powdered gas carbon and surrounded by an atm. of hydrogen under great press. The same transformation occurs in the absence of iron, but a much higher temp. is required. H. Hoyermann observed the production of diamond by reducing a mixture of iron oxide with sugar charcoal by means of aluminium. A mixture of iron oxide, sugar charcoal, lithia, and aluminium gave very good results. The crystals are separated from the iron as in H. Moissan's process. No diamonds were obtained with alloys of titanium and iron, calcium, barium, and manganese; but diamonds were obtained from silver-titanium alloys. M. Houdard obtained diamonds and graphite by fusing manganese sulphide with carbon.

J. Morris claimed to have made diamonds by the following process:

> Pure alumina was dissolved in pure hydrochloric acid, and a mixture of lampblack and charcoal was added to the soln. The mass was evaporated, and the alumina was precipitated in the pores of the carbon. The mixture contained by weight rather more carbon than alumina. After further treatment to expel all the hydrochloric acid, the mixture was subjected to the action of carbon dioxide gas at a red heat.

The claim has not been established. F. Göbel stated that some diamonds are present in the carbon formed when carbon dioxide is decomposed at a high temp. by many metals—sodium, calcium, magnesium, aluminium, iron, and silicon—and R. T. Simmler ascribed the action to the dissolution of carbon by the metal at a high temp. and press., and its subsequent separation as diamond. C. Doelter has discussed the reaction.

C. A. Parsons obtained diamonds by heating carbon rods embedded in a mixture of quartz and calcium oxide under high press. H. Fleissner, and B. Neumann found diamonds embedded in some blast-furnace slags. O. Johannsen found some alleged diamonds in blast-furnace slags to be alumina crystals. J. Friedländer dissolved graphite in olivine, $(Mg,Fe)_2SiO_4$, fused in the oxy-hydrogen flame, or in the electric furnace. R. von Hasslinger also obtained diamonds from soln. of amorphous carbon in artificial magnesium silicate magma; and in conjunction with J. Wolf, the most favourable composition of the magmas was studied.

Many guesses have been made in the attempt to explain how diamonds have been formed in nature. In one set of hypotheses, the diamond is considered to be of organic origin and formed at temp. relatively low; in another set of hypotheses, the mineral is supposed to have been formed at relatively a high temp., and possibly also a high press. Thus, D. Brewster [2] supposed that the diamond is a vegetable secretion like gum. Modifications of this hypothesis were suggested by H. R. Göppert, J. Murray, R. Jameson, A. Petzholdt, F. Wöhler, J. D. Dana, etc. G. Wilson, and J. A. R. Smit also assumed that diamonds are of organic origin. R. T. Simmler supposed that diamonds are obtained by the crystallization of carbon from liquid carbon dioxide, because inclusions of this liquid are found in the crystals; but C. Doelter could find no evidence of the alleged solubility of the diamond in that menstruum. From analogous reasons, C. Friedel inferred that the temp. could not have been above the critical temp. of carbon dioxide. E. Lionnet supposed diamonds have been formed by the slow decomposition of carbon disulphide; A. E. B. de Chancourtois, and D. Rossi, by the incomplete oxidation of hydrocarbons in the same way that sulphur is derived from hydrogen sulphide. J. von Liebig assumed that the diamond is formed as the end-term of a successive series of reactions in which the hydrocarbons are de-hydrogenized and polymerized. M. Berthelot has said:

> The action of an elevated temp. on benzene is to form a successive series of hydrocarbons richer and richer in carbon, less and less volatile, and with a higher and higher mol. wt. Carbon is not comparable to a real elementary substance, but it can be better likened to a very condensed hydrocarbon, poor in hydrogen, and possessing a very high eq. Carbon itself represents a limiting state which can be attained only with difficulty and at the highest temp. As known to us, *le carbone est le terme extrême des condensations moléculaires*, that is, of a state as far removed as possible from that of the element carbon, brought into the state of *un gaz parfait* comparable with hydrogen. This explains why carbon is never liberated in a natural state in low temp. reactions, and in this respect it differs from hydrogen and most of the chemical elements.

A. B. Griffiths suggested that carbon possibly dissolves in water at a high temp. and press., and separates in crystals with a fall of temp. and press. F. Göbel supposed that the diamonds have been formed by the action of metals like calcium, aluminium, magnesium, iron, etc., on calcium carbonate. M. Parrot believed that the diamond is of volcanic origin, and is produced by the fusion of carbon at a high temp. followed by a sudden cooling of the liquid; C. C. von Leonhard assumed that sublimation, not fusion, occurred; and J. F. L. Hausmann suggested that a flux has promoted the action. A. Favre inferred that because many of the minerals which accompany the diamond can be formed artificially from chlorides at a high temp., the diamond has been formed by the decomposition of carbon tetrachloride.

The discussion on the synthesis of diamonds—*vide supra*—by the crystallization of carbon from its soln. in fused silicate magmas, and the character of the material which accompanies diamonds, makes it very probable that the diamond has been formed in nature by an analogous process. In the South African mines, for example, the diamonds occur in or near volcanic pipes embedded in a decomposed rock which E. Cohen [3] described as peridotitic tuffa or breccia. H. C. Lewis ascribed the origin of the diamonds to the solvent action of the molten peridotitic magma upon the carbonaceous shales as suggested by E. J. Dunn. In some cases, however, these shales are absent. In support of this hypothesis, W. Luzi showed that at about 1770°, molten blue earth is a solvent of diamonds, and the carbon in soln. in the molten magma might just as well have come from below upwards as have been formed by the attack on carbonaceous matter near the surface. T. G. Bonney, C. F. Williams, D. Draper and W. H. Goodchild, E. Cohen, A. L. du Toit, and G. S. Costorphine have discussed the hypothesis that eclogite is the matrix from which the Cape diamonds have separated. G. F. Kunz and H. S. Washington, and H. D. Miser found diamonds in Arkansas associated with peridotitic rock. H. S. Harger said that the Vaal River diamonds are derived from andesitic lava; and H. Merensky, from pegmatite and diabase. M. Chaper found diamonds in the pegmatite of Bellary, Madras; O. A. Derby, and J. C. Branner in the hydromicaceous schists and itacolumite (quartzite) of Brazil; E. Poitevin and R. P. D. Graham, in the chromite of Coleraine, Canada; T. W. E. David, in the hornblende diabase of Inverell, New South Wales; and J. A. Thompson, and L. A. Cotton, in the dolerite of Copeton, New South Wales. Hence it is concluded that **diamonds are formed by the crystallization of carbon from its solution in fused magmas of different kinds.** Many others [4] have written on the genesis of natural diamonds.

§ 6. The Genesis of Graphite

Allein dennoch bleibt noch Natur unsere Lehrmeisterin.—F. A. QUENSTEDT (1877).

G. Rose [1] showed that a diamond bedded in charcoal at the temp. of molten cast iron, becomes coated with a film of graphite ; while V. A. Jacquelain, and M. la Rosa found that the diamond passes into graphite when heated in the electric arc ; and, added H. L. Fizeau and L. Foucault, F. Fouqué and A. M. Levy, and H. Moissan, at a high enough temp. all the different modifications of carbon pass into graphite. The graphitization of the diamonds and of carbon has been discussed by W. Skey, C. Street, W. Crookes, A. Bettendorff, J. Rudolphs and J. Härden, etc. N. G. Sefström noted the formation of graphite scales in carbon crucibles which had been heated for some time. J. N. Pring and W. Fielding showed that at 2000° boron accelerates the conversion of carbon to graphite. H. Moissan examined the sublimed carbon which collects on the positive electrode of the electric arc, and the distilled carbon obtained by heating a carbon tube about 2 cms. in diameter in a powerful arc furnace. The interior of the tube soon filled with a very light deposit produced by the condensation of carbon vap. Carbon vapour condensed on a cold or on a hot surface furnishes, in all cases, graphite. Hence, *when carbon vapour returns to the solid state it always appears as graphite*. W. Luzi obtained well-defined hexagonal plates of graphite by heating carbon in a silicate magma (finely-ground alkali glass, and fluorspar).

Graphite is formed when carbon is dissolved in a metal at a high temp., and the metal is allowed to cool. Much of the carbon separates in the form of graphite as the soln. cools. Thus, carbon which separates from soln. in cast iron, appears as tabular crystals possessing a metallic lustre; or from iron, iron silicate slags, or iron alloys which have been melted in contact with carbon. This subject has been discussed by G. Charpy, B. Osann, R. von Wagner, P. Schafhäutl, C. C. von Leonhard, etc.

Graphite is obtained by dissolving carbon in a molten metal, the carbon separating as graphite when another element is added. Thus, H. Moissan found the displacement of graphite from cast iron is favoured by silicon, and boron. He further showed that

> (i) At ordinary press., the graphite is purer the higher the temp. of formation; (ii) The higher the temp. of formation, the more the graphite resists the action of nitric acid and potassium chlorate; (iii) Under the influence of press., the crystals and mass of graphite have the appearance of a fused substance; (iv) The small quantity of hydrogen, always found in graphites, diminishes as their purity increases; and (v) Compounds containing hydrogen and oxygen are formed by the action of acids on cast iron; these compounds are not decomposed at a dull red heat, but, like graphite, are destroyed on combustion.

J. W. Döbereiner obtained the crystals of graphite by heating a mixture of iron filings, manganese oxide, and soot; and M. Houdard, by melting manganese sulphide with carbon. H. St. C. Deville passed carbon tetrachloride over molten cast iron; the gas decomposed, the iron dissolved the separated carbon, and, on cooling, furnished hexagonal plates of graphite. He obtained only amorphous carbon when using sodium, zinc, and aluminium in place of iron. H. Moissan found that aluminium does take up carbon at a high temp. and gives graphite crystals on cooling. M. Berthelot obtained only amorphous carbon from molten manganese, but if the temp. be high enough, crystals of graphite are formed. Silver, even at its b.p., dissolves but little carbon, although ingots of silver slowly cooled in the electric furnace are covered with a film of graphite. He found that a number of molten metals were able to dissolve carbon, and give it up again as graphite when the metals cooled—for instance, zirconium, vanadium, molybdenum, tungsten, uranium, chromium, nickel, silicon, titanium, platinum, iridium, and palladium. The graphite crystals can be isolated by dissolving out the metal with aqua regia, or other suitable acid. K. Iokibe found that the optical properties of the graphite and the so-called *temper carbon* from cast iron are the same, so that the latter is really very finely divided graphite.

Graphite is formed by the decomposition of carbides at a high temp. In 1896, E. G. Acheson showed that amorphous carbon can be converted into graphite by heating it to a high temp. In the presence of metallic or other oxides, etc.—*e.g.* silica, clay, alumina, ferric oxide, manganese oxide—capable of forming carbides, the yield is enormously increased. Much less metal oxide is needed than would be required to convert the carbon to graphite, and it is assumed that the carbide acts catalytically. The metal oxide first forms a carbide which is then decomposed into graphite and metal, the latter reacts with the amorphous carbon re-forming a carbide, and so the cycle continues. W. Borchers confirmed these results in 1897; he said:

> All substances which are capable of entering into a chemical combination with carbon, more or less easily dissociable, are also in a condition to further the crystallization of carbon.

I name especially boron, silicon, titanium, zirconium, vanadium, aluminium, cerite metals, chromium, molybdenum, tungsten, uranium, manganese, iron, nickel, etc.; it appears to me, however, that it is not thoroughly determined that combination of carbon, in the form of gases and vap., with hydrogen, oxygen, sulphur, etc., can also bring about crystallization.

Observations on this subject were made by F. A. J. Fitzgerald, K. Iokibe, H. Ditz, O. Mühlhäuser, E. Pietrusky, T. F. Bailey, etc. A. Frank obtained graphite by heating the carbides of the alkaline earth metals, etc., in a stream of carbon dioxide or monoxide, the halogens, or hydrogen halides, nitrogen, phosphorus, arsenic, hydrogen sulphide, ammonia, arsine, phosphine, organic halides, sulphides, or nitrides. A. Remelé and B. Rassow found small quantities of graphite remaining after the decomposition of calcium cyanamide by water, and it appeared to have been formed in the reaction between calcium carbide and nitrogen.

E. L. Grüner obtained graphite in the reduction of ferruginous minerals by carbon monoxide, and M. Jungck, likewise, nickel ores. M. Berthelot showed that graphite may be formed when carbon separates from its combinations with the halogens, sulphur, boron, and possibly oxygen. According to R. Schenck and W. Heller, E. Baur, and A. Smits, the carbon derived from carbon dioxide is finely divided graphite. M. Berthelot also obtained a mixture of graphite and amorphous carbon by the action of phosphorus on sodium carbonate; or by passing ethyl iodide or carbon disulphide through a red-hot tube. G. Dragendorff also studied the liberation of carbon by the action of phosphorus on sodium carbonate; and G. Gore, by the action of phosphorus, arsenic, or antimony on potassium cyanide. H. R. Ellis found that in the action of powdered magnesium on the carbonates of ammonium, calcium, magnesium, strontium, barium, and cadmium, or on carbon dioxide, some graphite always accompanies the carbon which is formed. E. Lionnet decomposed carbon disulphide by a couple—the so-called J. Smithson's pile—formed by wrapping a sheet of tin-foil about one of gold-leaf, and obtained a deposit of crystalline carbon (graphite).

G. Rousseau obtained graphite and diamonds by passing acetylene through the electric arc. F. J. Bergmann made graphite by heating acetylene with hydrogen dioxide to 150° under 5 atm. press., $C_2H_2+H_2O_2\rightarrow 2C+2H_2O$. Acetylene decomposes at about 780°: $C_2H_2\rightarrow 2C+H_2$, and the carbon is in the graphitic state; and H. Erdmann and P. Köthner showed that in the presence of finely divided copper, the decomposition temp. is reduced to 400°–500°. H. Erdmann noted the formation of graphite crystals in the process of making amido-derivatives of naphthalene when the hydroxyl-derivatives and ammonia are heated in an iron autoclave at 250°–300°. According to P. and L. Schützenberger, when pure and dry cyanogen is passed through a porcelain tube at a cherry-red heat, it is only partially decomposed, and even at a bright-red heat the decomposition is very limited, the interior of the tube being covered with a thin, brilliant, blackish-grey coating, with a submetallic lustre resembling that of polished graphite. If, however, there is placed in the hot part of the tube some gas carbon with powdered cryolite sprinkled over the surface, the cyanogen decomposes completely into carbon and nitrogen, even at a cherry-red heat. The carbon separates in a bulky mass of very slender filaments, and, after a time, chokes up the tube. Those portions in contact with the walls of the tube are more compact and somewhat elastic. The carbon is friable, and leaves on paper a mark resembling that made by graphite, but not so bright. When a piece of aluminium was placed along with the gas-carbon, the carbon separated round it in non-elastic filaments, which could be compressed between the fingers into a mass resembling graphite. The filamentous carbon obtained by the decomposition of cyanogen is not identical with any of the established forms of graphite or carbon, and may be taken as a new modification. R. von Wagner also stated that the black azulmic acid obtained by the slow decomposition of hydrocyanic acid contains some graphite. H. N. Warren said that if induction sparks are passed between platinum electrodes in coal gas, graphite is formed. A. Roedel described the extraction of graphite from gas-carbon. P. Pauli found that in the evaporation of the waste-liquors in the preparation of soda, the cyanogen compounds are converted into ammonia and graphite. The reactions were discussed by J. Stingl, and W. Thalheim. The preparation of graphite was described by E. Ryschkewitsch, and K. P. Gregarovitch; and V. Kohlschütter and A. Nägeli studied the deposition of graphitic carbon, $2CO=C+CO_2$, in cobalt, nickel, iron, and silver. K. A. Hofmann and C. Röchling found a hard, lustrous, crystalline form of carbon was deposited when the flame of some of the aliphatic hydrocarbons comes in contact with chemically inert surfaces at a temp. exceeding 650°. A steel surface, probably owing to the intermediate formation of metallic carbides, gives only a deposit of graphitic carbon, whilst flames of burning benzene and naphthalene gave only amorphous, sooty carbon, or, at higher temp., graphitic carbon. The vitreous form of carbon has a sp. gr. at 4°=2·07, is very pure (C=99·06 per cent., H=0·48 per cent.), and has a low electrical conductivity ($\frac{1}{4}$th to $\frac{1}{15}$th of that of Singalese graphite, and $\frac{1}{3}$rd to $\frac{1}{8}$th of that of Acheson graphite). It is also very hard—that prepared at 900° having a hardness equal to that of quartz, that at 1100° having a hardness equal to that of topaz, whilst that prepared at 1300° is harder than carborundum. It is considered to be a form intermediate between graphite and diamond, and its X-ray spectrum shows characteristic lines of both these forms.

The problems connected with our views as to the genesis of graphite in nature have not been solved except with reference to particular districts. Its occurrence in meteorites shows that it is not necessarily of organic origin. The various methods of synthesizing graphite—*vide supra*—show that it could be formed by contact metamorphism. T. S. Hunt[2] assumed:

> The graphite of bedded rocks has been formed by the alteration of coal and similar matters, at temp. below redness; while its subsequent translation into the veins, and its deposition in a crystalline form, together with various other minerals, has been effected under conditions which, although imperfectly understood, probably included aq. soln. at a temp. not far below redness.

J. S. Newberry showed that the trap dykes of the Sonora coalfield (South Mexico) have everywhere metamorphosed the coal into anthracite, and in extreme cases into graphite. L. Jaczewsky supposes the Siberian mineral to have been formed by the transformation of coaly matter in eruptive magmas. M. Diersche supposed graphite is formed by the infiltration of liquid hydrocarbons and their decomposition by the hot lava. It is doubtful if the formation of graphite by the action of the vap. of carbon disulphide, carbon tetrachloride, etc., on heated iron has any geological importance, though possibly the conditions might occasionally be favourable when volcanic emanations contain these gases. E. Weinschenk assumed that metallic carbonyls might yield graphite by their decomposition, but there is no evidence that nature produces these gases. H. I. Jensen postulates thiocarbonyls, $Fe(CS)_4$, analogous to the carbonyls, and assumes that they decompose $Fe(CS)_4=FeS_4+4C$, or $Fe(CS)_4=FeS_2+CS_2+3C$. Like E. Weinschenk, A. Osann ascribed the graphite in the Canadian limestones to their penetration by gases and vap. from neighbouring eruptive magma. F. Cirkel said there can be little doubt that the carbon of these limestones was originally present, and was probably of organic origin; the same process of metamorphism which converted the limestone into marble, converted the carbon into graphite. J. Walther believed that the Cingalese graphite was formed by the decomposition of carbonaceous gases rising from great depths.

The mechanical separation of graphite from the ore is effected by a system involving crushing, screening, washing and levigation, grinding, and grading. The flow-sheets of the process differ according to the nature of the ore and other local conditions. The reduction of the ash of the washed graphite can be effected by chemical treatment. Numerous methods have been proposed, but the cost of many is too great for the processes to be of industrial value. E. Donath[3] said that treatment with hydrochloric acid, sodium hydroxide, and finally hot water will reduce the percentage ash from 30 or 40 per cent. to 2 or 3 per cent. J. Stingl fused the graphite with sodium carbonate, and treated the washed product with aqua regia, and hydrofluoric acid. Gebr. Bessel mixed the graphite with one to ten per cent. of animal or vegetable fat, ethereal oils, resinous matter, petroleum, paraffin, benzene, fusel oil, or ozokerite. The mixture was heated with water until boiling began. The graphite rises to the surface of the liquid, and can be skimmed off; the gangue remains at the bottom. They have also devised some modifications of the process. E. B. Kirby, H. Putz, J. D. Darling, M. F. R. Glogner, C. Winkler, and F. Gottschalk, also modified the process. A. Lang objected to the use of molten alkali hydroxides in the purification because of the possibility of changes in composition. W. Luzi recommended the following process:

> The ore is moistened with conc. nitric acid and then heated. During heating the mass swells considerably in developing peculiar wormlike forms. These forms are chemically unaltered graphite, but in consequence of their fine, delicate structure they are extraordinarily light in weight, so that by washing in water they remain afloat and are carried away, while the constituents of the gangue, which have been completely separated from the graphite by the swelling up of the latter, sink to the bottom by continued agitation of the mass. It appears that graphite, according to this method, can be purified quickly and cheaply; because first, the graphite is not powdered before being moistened with nitric acid, nor is it mechanically cleaned; and secondly, the mass is heated immediately after moistening; and further, the swelling is instantaneous. The washing process afterwards takes little time, while little of the nitric acid is lost, as the process is performed in closed retorts. It is noteworthy that the graphite obtained by this method is plastic, in a very high degree, so that it can be pressed with ease into plates, etc.

H. le Chatelier and S. Wologdine treated the graphite with fuming nitric acid; then fused the washed and dried mass with potassium hydroxide for 30 minutes at a dark-red heat; the washed product was boiled with hydrochloric acid, sp. gr. 1·12; and finally washed with water and dried at a dull red heat. H. Langbein heated the graphite first with sulphuric acid; and treated the washed product with sodium hydroxide. According to B. C. Brodie, graphite is conveniently purified on a small scale by the following process:

> The roughly powdered graphite, freed as much as possible from its impurities, is mixed with one-fourteenth part of its weight of chlorate of potash. This mixture is placed in an iron vessel; conc. sulphuric acid (sp. gr. 1·8) of double the weight of the graphite is added and the whole thoroughly stirred and heated in a water-bath, until no more gases escape; after cooling, the mass is put into water and thoroughly washed. The dry graphite is then exposed in a crucible to a red heat; it swells up considerably and is converted into an exceedingly fine powder. In order to clean the graphite thoroughly, the powder is then subjected to washing and settling in water. If the graphite contains silicates and is to be made applicable to the manufacture of pencils, it is necessary to add a little sodium fluoride to the mixture of sulphuric acid, chlorate of potash and graphite; the silicic acid escapes then as fluoride of silicon. According to F. Gottschalk, if the graphite is heated with a mixture of sulphuric acid and an oxidizing agent it is liable to become oxidized.

J. Löwe, and O. G. Pritchard have modified the process somewhat as follows:

> Eighteen parts by weight of graphite, one part by weight of chlorate of potash are treated with 36 parts of sulphuric acid (sp. gr. 1·8). The whole is gently heated until no more chlorine escapes, the surplus of sulphuric acid is poured off, and a small quantity of sodium fluoride is added to the graphite paste. Finally the mass is thoroughly washed and the graphite exposed to a red heat, when it forms a red spongy mass.

J. B. A. Dumas and J. S. Stas heated the material with potassium hydroxide; washed with water; boiled with aqua regia; washed with water and passed chlorine over the white-hot material. The product is thus freed from iron, silicon, and hydrogen. O. L. Erdmann and R. F. Marchand found a sample with 0·5 per cent. of silica after this treatment. J. L. Gay Lussac digested the graphite with nitric acid, and P. Schafhäutl, with hydrofluoric acid. H. V. Regnault heated the finely powdered graphite with equal parts of sulphur and sodium carbonate until the blue flame of sulphur had disappeared; washed the cold mass with water; with dil. hydrochloric acid; with a dil. soln. of ammonium chloride; then boiled with soda-lye; washed with water; and calcined in a covered crucible. M. Langheinrich, and the Graphite works at Kropfmühl purified graphite by heating a mixture of graphite and coal to 2200°, whereby the impurities combined with the graphite are said to be sublimed. M. Pirani and W. Fehse found the sp. gr. and the proportion of ash decreased on calcination at high temp. W. Gross obtained good results with the flotation method for separating native graphite from gangue.

§ 7. The Preparation of Amorphous Carbon

The term amorphous carbon is applied to a comparatively large variety of carbonaceous substances which are not regarded as diamond or graphite. Though originally intended to imply that these varieties of carbon are non-crystalline, the term is now used for classification purposes without reference to the crystalline character. The term embraces such substances as soot or lampblack, gas carbon, wood charcoal, bone-black, and coke. The various coals are sometimes also included in the term amorphous carbon, although these substances might more accurately be regarded as hydrocarbons, and their study more fittingly belongs to organic chemistry. Amorphous carbon usually contains a small proportion of hydrogen and, maybe, a certain proportion of earthy matter usually regarded as ash. Amorphous carbon is formed in a great variety of ways, which may be arranged in two groups: (1) Metathetical reactions and reactions in which carbon is displaced from combination with other elements; (2) Reactions in which carbon is separated during the thermal decomposition of a carbon compound, a reaction sometimes facilitated by air. Of course, these pyrogenetic processes represent but special modes of formation which could be included in the first group. In some cases what appears to be a mixture of amorphous carbon and graphite is obtained by the solvent action of various agents on metals in which carbon or carbides have been dissolved—*vide* graphite.

(1) *The formation of amorphous carbon by a reaction with other chemical agents.*—H. Moissan[1] found that when fuming sulphuric acid acts on *starch* at 200° for 24 hrs., a black substance is obtained which can be purified by washing with cold water, alcohol, and ether. The product appears to contain a humic acid analogous to that obtained by M. Berthelot and G. André by the action of hydrochloric acid on sugar. H. Moissan regards the homogeneous powder as *un produit de transformation, un acheminement vers l'élément carbone.* After heating it to 400°, it contained: Ash, 2·64; carbon, 79·69; and hydrogen, 2·29 per cent. If *sugar* be similarly treated, and heated, much of the hydrogen compounds are destroyed and its analysis furnished: Ash, 4·26; carbon, 88·21; and hydrogen, 0·75 per cent. Some combined sulphur is also present. H. Moissan found *anthracene* reacts vigorously with a sat. soln. of ferric chloride at 180°, contained in a flask fitted with a reflux condenser. After 24 hrs., a dark brown substance is formed which becomes black on drying. The product was washed with hydrochloric acid, boiling water, benzene, alcohol, and ether. It contained: Ash, 21·29; carbon, 62·17; and hydrogen, 0·91 per cent. The ash contained much ferric oxide, and was not homogeneous; it contained some acicular crystals of hexachlorobenzene. The amorphous carbon so obtained is very impure; H. Moissan called it *un composé carboné de transition.*

S. Porcher passed *carbon tetrachloride* over a layer of heated sodium and obtained carbon quite free from hydrogen. C. Despretz, using a copper anode and platinum cathode, passed an electric current through an alcoholic soln. of carbon tetrachloride for six months; a brown film of carbon was deposited on the cathode. He also passed a feeble electric current for two months through acidulated water using a carbon anode and platinum cathode. The black cathode deposit showed no signs of crystallization. H. Moissan investigated the action of a voltaic couple of aluminium and platinum on hydrocarbons and various organic compounds, but in most cases no decomposition occurred. H. Moissan got very impure products by the action of light or heat on *carbon tetraiodide.* An amorphous powder was obtained by the action of *J. Smithson's couple*, a piece of tin wrapped round with gold-leaf—on a soln. of the tetraiodide in carbon disulphide, during four years; a similar product was obtained by the action of zinc dust. After washing with water, alcohol, benzene, and finally alcohol, the light amorphous black powder contained a little zinc oxide. Sodium, silver, and lead, under similar conditions, reduced the tetraiodide to the lower iodide without the separation of carbon; with magnesium, brown amorphous carbon slowly separates and floats on the liquid. After washing as indicated above, the product contains traces of iodine and magnesium. When the metal is covered with a layer of carbon, further action ceases. These varieties hold water very tenaciously, and if dehydrated by heat, the carbon probably polymerizes. M. Berthelot obtained amorphous carbon by washing the product obtained by the slow oxidation of *copper acetylide* at ordinary temp.

According to H. Moissan, amorphous carbon is obtained when *carbon dioxide* is reduced by a heated metal—*e.g.* the alkali metals, calcium, etc.—he found that if with calcium the heat is applied slowly, carbon and calcium oxide together with a little calcium carbide, are formed, but if the heat is applied quickly calcium carbide and oxide are produced. He also found that at a dull red heat boron burns in dry carbon dioxide. When the porous cylinder which remains is treated with water, amorphous carbon is obtained. Traces of boron can be removed by the passage of chlorine at a dull red heat, and washing the product with water. An analysis gave: Ash, 0·96; carbon, 86·16; water, 12·70 per cent. The Aktiebolaget Graaen claimed to have made pure carbon by the action of iron on carbon monoxide under press. J. P. Wibaut found that carbon prepared by passing *carbon monoxide* over iron oxide in a porcelain tube at 450°-470° was always contaminated with much iron oxide, and all attempts to eliminate this impurity were unsuccessful. V. Kohlschütter and A. Nägeli investigated the carbon obtained by passing carbon monoxide, heated to 500°, over powdered nickel, cobalt, and iron. L. Gruner, R. Schenck and coworkers, A. Smits, and O. Boudouard also studied this reaction—*vide infra.* G. Tammann observed that by the action of mercury vap. on carbon tetrachloride at 600°-700°, mercurous chloride is formed and carbon is deposited. Under high press., 900 to 2760 kilos. per sq. cm., the reaction starts at about 400° and is accompanied by a fall in press. Carbon tetrabromide and tetraiodide react similarly. The carbon so formed retains tenaciously 7-10 per cent. of any water present, after heating at 600° in a stream of nitrogen. The density of the carbon so obtained is high, 2·32 from carbon tetrachloride, 2·51 from the tetrabromide, and 2·37 from the tetraiodide, whilst that of graphite is 2·1-2·3. Carbon obtained similarly from hexachloroethane had d=2·16, that from hexachlorobenzene 2·46 to 2·22, and from carbon disulphide, 2·38. It appears that carbon formed by reactions not involving the formation of water has a higher density than that which is formed with water. On keeping, this dense form of carbon absorbs much water, and, when it is again dried, its density is found to have diminished. A. Franck obtained amorphous carbon by the action of carbon monoxide or dioxide, or mixtures containing these gases, on *acetylene* in a heated tube, or exposed to electric sparks: $C_2H_2+CO \rightarrow 3C+H_2O$; and in place of acetylene the *carbides* of the alkaline earths or other metals, at 200°-250°: $CaC_2+CO \rightarrow CaO+3C$. He also exploded mixtures of carbon monoxide and acetylene under press. exceeding 6 atm. According to M. Berthelot, amorphous carbon is formed when various *hydrocarbons* are decomposed by chlorine or iodine; and H. Moissan obtained a similar result by treating various metal carbides with the halogens or hydrogen halides. G. Gore obtained a deposit of carbon on the cathode during the electrolysis of a molten mixture of sodium hydroxide, silica, and anhydrous *alkali carbonate*; carbon was also obtained by reducing molten alkali carbonate with aluminium; T. L. Phipson, and C. Winkler used magnesium with the carbonates of the alkalies or alkaline earths. G. Gore found that arsenic or antimony is ineffective. He also showed that a mixture of amorphous carbon and graphite was formed by the action of sodium, phosphorus, arsenic, or antimony on molten *potassium cyanide.* W. A. Bone and J. C. Cain obtained carbon by exploding a mixture of *cyanogen* and hydrogen with insufficient oxygen for complete combustion.

The amorphous carbon obtained by reactions at a low temp. is more or less impure; a small proportion of the reducing agent is nearly always present, and is not removed by treatment with the solvents applicable under ordinary conditions. H. Moissan said that the product of the action of magnesium on carbon tetraiodide was the purest he had obtained. Hydrogen also is retained so very tenaciously that M. Berthelot inclined to the belief that the products are true hydrides. Water, hydrogen, and hydrocarbons cannot be removed except by raising the temp., but, added H. Moissan, *pour chasser ces impuretés, il faut le chauffer, c'est-à-dire le polymériser.* Hence, the varieties of amorphous carbon prepared at an elevated temp. are said to be more or less polymerized, and more resistant to chemical action. W. A. Roth and H. Wallasch found it to be impossible to prepare pure, amorphous, and thermally well-defined, carbon.

(2) *The formation of amorphous carbon by the pyrogenetic decomposition, or incomplete combustion of organic compounds.*—H. St. C. Deville stated that amorphous carbon is produced when carbon monoxide is heated to redness, or exposed to the action of electric sparks; but R. Schenck and W. Heller said the product is finely divided graphite—*q.v.* M. Berthelot found carbon monoxide is reduced to carbon by iron and manganese minerals. The carbon obtained by T. Sidot by passing carbon disulphide through a red-hot tube is probably graphitic. H. Moissan obtained amorphous carbon by the pyrogenetic decomposition of carbon fluoride at a dull red heat. M. Berthelot observed that cyanogen is decomposed into amorphous carbon and nitrogen by a stream of electric sparks. P. and L. Schützenberger also studied this reaction. O. L. Erdmann and R. F. Marchand, and M. Berthelot obtained carbon by passing the vap. of volatile organic compounds—*e.g.* hydrocarbons, fats, oils, alcohol, ether, etc.—through a white-hot porcelain tube. H. von Wartenberg obtained carbon by the action of heat, at 500°, on methane: $CH_4 \rightleftharpoons C+2H_2$. Various hydrocarbons and coal gas act in the same way as shown by J. L. Gay Lussac, W. Luzi, I. Szarvsky, H. Colquhoun, E. W. Brayley, M. Berthelot, N. G. Sefström, etc. In 1826, H. Colquhoun noted the formation of *gas carbon* or *charbon de cornue* in gas retorts by the decomposition of hydrocarbons derived from the coal. V. A. Jacquelain found 2·7 per cent. of ash in a sample of gas carbon. According to M. Constant and H. Pélabon, a form of carbon wool is sometimes met with in the upper portions of recuperative coke-ovens, especially at the aperture for the exit of the hot gases. The formation of filamentous carbon is probably due to the decomposition of heavy hydrocarbon vap. by heat.

The carbon wool consists chiefly of grey cylindrical threads with glazed surfaces, sometimes showing a series of expansions, and occasionally bearing bundles of much finer black threads. The average length of the threads is 5 cms., even attaining 8 cms., the diameter varies from 0·03 to 0·15 mm., the black threads being perhaps only 0·002 mm. When heated in dry oxygen, combustion begins at 585° and is complete, only 0·4 per cent. of ash being found. A mixture of nitric acid and potassium chlorate oxidizes the carbon to graphitic acid; and it is therefore graphite.

G. Gore found that the action of red-hot ferric oxide on coal gas is attended by the separation of carbon; silver fluoride and chloride, and lead and cupric chlorides act similarly, but cadmium chloride remains unchanged.

Most organic matter when heated out of contact with the atm.—the so-called dry distillation—is decomposed and a residue, more or less carbonaceous, remains. The product always contains a certain amount of hydrogen, which becomes smaller as the temp. is raised. M. Berthelot[2] believes that carbon *per se* is the limiting state of a series of hydrocarbons, and that many of the so-called varieties of amorphous carbon are really members of the series of extremely condensed carbides which are very stable at high temp. L. Punier's *carbopétrocène* with 96 to 97 per cent. of carbon is another member of the series of pyrogenetic hydrocarbons. N. K. Chaney has reported that a hydrocarbon resembling anthracene, b.p. 360°, can be isolated from charcoal which has been heated to 850°; and H. B. Harned showed that heating charcoal to 1200° in vacuo does not suffice to produce a gas-free carbon. O. L. Erdmann and R. F. Marchand could not remove hydrogen and oxygen from charcoal at a white heat.

When purified sugar is slowly heated much bubbling occurs, and a voluminous residue—*sugar charcoal*—is obtained. The product should leave little or no ash. According to O. L. Erdmann and R. F. Marchand, after heating white hot, the product still contains 0·6 per cent. of hydrogen and 3·1 per cent. of oxygen; and after 3 hrs.' heating in a blast flame, it contains 0·2 per cent. of hydrogen and 0·5 per cent. of oxygen. In order to get rid of hydrogen from the different varieties of carbon, J. B. A. Dumas and J. S. Stas, H. V. Regnault, and H. Moissan recommended passing chlorine for 4 or 5 hrs. over the carbon at a red heat (or 1000°). M. Berthelot and P. Petit followed this treatment by digesting the product with hydrochloric and then with hydrofluoric acid, and washing with water.

In the preparation of the so-called **activated charcoal,** or *active charcoal,* for use as an absorbent in gas-masks, etc., a porous charcoal is prepared at a low temp., 850°–900°; and the adsorbed hydrocarbons are removed. The process of manufacturing active carbon has been described by F. M. Dorsey, N. K. Chaney, A. B. Lamb and co-workers, S. Hiller and L. A. Clarke, L. le W. Hamon and T. H. Byrom, J. N. A. Sauer, A. Zelnecyek, M. T. Saunders, W. L. Jordan, N. Suzuki, A. B. Ray, J. C. Philip and co-workers, K. Scheringa, F. H. Carr, E. G. R. Ardagh, J. E. Teeple and P. Mahler, E. R. Sutcliffe, J. C. Morrell, R. A. Demme, F. Bonnett, O. Ruff and co-workers, V. F. Gloag, etc. The general method of procedure is to heat thin layers of charcoal, screened to 14's mesh, between 350° and 450° in a rapid stream of air with the object of breaking down the hydrocarbons of high b.p. into more volatile substances which are removed at a low temp. The hydrocarbons are oxidized rapidly and the carbon slowly. A current of steam between 800° and 1000° has the same effect. If the primary carbon is heated to a high temp., more or less graphitization occurs, and the product is not activated by the subsequent treatment. The material is charged into retorts in thin layers to prevent as much as possible contact between the hydrocarbon vap. and hot charcoal. A slight suction is maintained in the retort, and most of the hydrocarbons are removed before a dangerous temp. is reached. F. E. Bartell and E. J. Miller have described the preparation of activated sugar, charcoal by charring sugar in a large platinum dish; afterwards heating it to low redness to drive off the greater part of the volatile matter; and then heating the material, reduced to granules the size of wheat kernels, for 24 hrs. in silica tubes at 100°. V. Lenher and F. M. Dorsey purified carbonized material by treating it with selenium oxychloride, washing with carbon tetrachloride, and heating to volatilize the last-named solvent.

The apparent sp. gr. of primary and purified charcoal from some different sources were determined by A. B. Lamb and co-workers. The following is a selection:

	Sycamore	Cedar	Brazil nut	Ivory nut	Cohune nut	Babassu nut	Cocoa-nut	Sawdust	Bituminous coal	Anthracite coal
Primary .	0·158	0·223	0·520	0·700	0·659	0·540	0·710	0·542	0·789	0·830
Activated	0·080	0·097	0·316	0·460	0·502	0·322	0·431	0·365	0·430	0·371

The last three varieties in the list were briquetted before charring. The gas adsorption qualities were at the same time so much improved that N. K. Chaney argued that the so-called amorphous carbon exists in two forms, active or *a-carbon,* and inactive or *β-carbon.* He said the active form is readily attacked by oxidizing agents, while the inactive form resembles graphite in its stability towards oxidizing agents. There is, however, no satisfactory evidence that the so-called inactive carbon is anything different from more or less graphitized carbon. According to N. K. Chaney, the active form results when the carbonization occurs below 600°, and the inactive form above that temp. There is, however, no sharp temp. of demarcation, and no transition temp. has been observed. Inactive carbon is also formed by the decomposition of hydrocarbons. Acetylene below 300° may give active carbon, and above that temp. inactive carbon.

Wood charcoal.—When wood is heated to a high temp. in a closed vessel, much gas and vap. are evolved, and wood charcoal remains. D. Avery obtained what he called a very pure form of charcoal from cocoanut shell. This was strongly heated in closed clay crucibles for some hours, then boiled with nitric acid for 5 or 6 hrs., and washed thoroughly till the runnings were nearly free from acid—the washing taking several days. It was then dried in the air, crushed and sieved, collecting the particles between 1 and 3 mm. diameter. These were dried first in a desiccator over strong sulphuric acid, then over phosphorus pentoxide, and finally heated to redness in a closed platinum crucible and cooled in a desiccator over phosphorus pentoxide. The crucible was heated in a muffle in an oxidizing atm. to avoid the possibility of absorption of hydrogen or other reducing gases from the furnace. The amount of ash in the product was 0·23 per cent., and its hydrogen content was 0·28 per cent. Industrially, wood charcoal is prepared by the incomplete combustion of wood in a limited supply of air. In outline, the process of manufacturing *pit charcoal* is as follows:

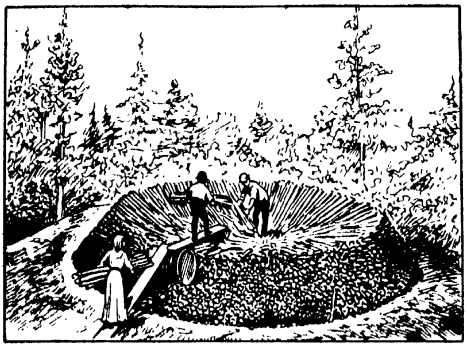

FIG. 6.—Sketch of a Meiler in course of Construction.

Logs or billets of wood are loosely piled into vertical heaps and covered with sods and turf to prevent the free access of air. A shaft is left in the middle of the pile to act as a central chimney or flue; and smaller holes are left round the bottom to admit the air. The pile so prepared is called a charcoal pit or *meiler*. There are several systems of setting or piling the logs; one is illustrated by the sketches, Figs. 6 and 7. In Sweden, rectangular piles are used, and the wood is placed horizontally and transversely. The wood is lighted by brushwood at the centre, and just sufficient air to allow the wood to smoulder is passed through the pile. The volatile matter escapes, and in about fifteen days the fire dies out. Between 80 and 90 per cent. of wood, on the average, is lost by combustion, and the remaining 10 to 20 per cent. is wood charcoal; the process can be used satisfactorily only where wood is cheap and abundant because the method is uncertain and wasteful. The process is still employed in a few places in Europe.

Some valuable gaseous and liquid products are lost in making pit charcoal. In modern processes, the wood is heated in ovens, kilns, or retorts, sealed from the outside air and *kiln, stove, or retort charcoal* results. The operation may be conducted simply for charcoal without recovering the by-products, or the operation may be conducted somewhat similarly to the process used for the manufacture of coal gas. The products of the dry distillation of wood include: solid charcoal in the retort; liquids—wood tar (*Stockholm tar* from pine wood); water containing wood spirit; *pyroligneous acid*, that is, impure acetic acid; acetone and fatty oils; and wood-gas—containing hydrogen, carbon dioxide, carbon monoxide, methane, acetylene, etc. The wood gas is used for illuminating purposes only when the temp. of distillation has been very high. The products are approximately: charcoal, 25·3; methyl alcohol, 0·8; acetic acid, 1·0; tar, 4·0; water, 45·9; wood gas, 23 per cent. The charcoal in the retort retains the form of the wood from which it was prepared. Kiln charcoal is more compact than the pit charcoal—in the former case the charcoal weighs 20 lbs. per bushel, and in the latter case, 16 lbs. per bushel.

The yield of charcoal is about 81 per cent. by volume, 28 per cent. by weight. H. Violette recommended carbonizing the wood by superheated steam.

Coke.—Coke is an industrial fuel obtained as a residue in the dry distillation of coal, *i.e.* by heating coal in a closed vessel out of contact with air. The coal should contain sufficient bituminous matters to cement it into masses at a certain temp.. Coke generally contains between 85 and 90 per cent. of carbon. Coke is used in the manufacture of iron and steel, and in a great many metallurgical operations where its comparative freedom from sulphur and certain other impurities render it more suitable than coal. Coal may be converted into coke by heating it in closed vessels—gas, tar, and ammonia are obtained as by-products; or if coal gas is being manufactured, coke, tar, and ammonia are the by-products. The properties of coke depend upon the nature of the coal from which it is obtained, and upon the way the coal is "coked." The main varieties are: (i) *soft coke*—porous, black, and brittle; it ignites with difficulty, and is used for smith's forges, etc.; (ii) *hard coke*—dark grey in colour, with bright lustre, compact, and with metallic ring when struck, bears great press. without crushing, and is used for furnace work and metallurgical operations generally. Coke may or may not be prepared under conditions where the by-products are recovered. Coke has been made in four ways: (i) in heaps or meilers; (ii) in gas retorts; (iii) in beehive ovens; and (iv) in by-products ovens. Process (i) is so wasteful that it is obsolete. Commercially, spent wine must and yeast, vine twigs, vine wood, grape husks, fruit stones, spent hops, oil-cake, nut-shells, chestnuts, and various kinds of wood are carbonized or charred to furnish the so-called *carbon-blacks* used by painters under various names—like *Frankfurt black*, *Spanish-black*, *vine-black*, *drop-black*, *noir de vigne*, etc. The products do not always correspond with their names; indeed, the trade-name rather indicates the quality of the colour rather than the raw material from which it is made. Certain carbon blacks are made by the dry distillation of some of the lignites with a conchoidal fracture, not the earthy kinds, and also fine bituminous shales.

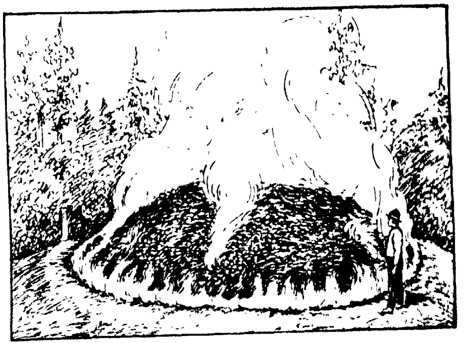

FIG. 7.—Sketch of a Meiler shortly after it has been lighted.

The beehive oven—so called on account of its shape—furnishes an excellent coke, but is rather wasteful. The ovens are built in batteries each of which may include from 20 to 200 ovens. Each oven cokes about 7 tons of coal, and furnishes 4 or 5 tons of coke. The air for burning the coal enters through an opening in the door, and the gases escape through the top flue fitted with a damper. The air supply is diminished from day to day. When no flame is visible, and all the interior is red hot, the openings are luted with clay, and in 24 hrs. (70–84 hrs. in all) the door is opened, and water from a hose is sprayed in the oven, which is then ready for discharging.

Coking in retorts.—The retorts are horizontal chambers built side by side in batteries of 22 to 50. The retorts are worked in pairs—one is discharging when the other is half coked. The retorts are closed except for the exit left for the escape of the volatile products of distillation. The products of distillation are passed through condensers, and the gases are returned to be burnt in the horizontal flues below the retorts. There is a system by which the waste heat from the products of combustion warms up the air—secondary air—which is employed for burning the gas below the retorts. In about 48 hrs., the coke is expelled from the retort by means of a ram, and is at once quenched with water. The retort is recharged through hoppers in the roof, or by a ram-charger. The yield is almost theoretical. The by-products are recovered. The coke is black, hard, compact, and without metallic lustre. There are numerous varieties of by-product coke-ovens.

In nature, there are cases where igneous rocks have intruded bituminous coal seams, and transformed the coal into a kind of *natural coke* sometimes called *carbonite*. It resembles artificial coke but usually contains more volatile matter, and is more compact.[3]

Bone or animal charcoal.—This is made by heating bones, bone-cuttings, blood, etc., in closed retorts. The bones may or may not have been subjected to a preliminary extraction with naphtha or benzene to remove the fat—*degreased bones*; or with superheated steam or water to remove gelatine (glue)—*degelatinized bones*. The products of the distillation include: solid bone charcoal in the retort; liquid—a number of ammonium salts, *bone oil*, bone pitch, pyridine, etc.; and gases of various kinds. The manufacturing processes have been described by B. E. R. and J. A. R. Newlands,[4] T. Lambert, O. Cordel, W. Friedberg, etc. The better quality of bone-black is considered to be that prepared by processes in which the volatile products are entirely disregarded. J. Pilter made animal-black from leather-waste. Bone charcoal contains only about 10 per cent. of carbon, so that it is questionable if it ought to be included with the varieties of carbon at all. T. Lambert gives the following analyses of two chars—the first one is considered good, the second one bad:

C	$Ca_3(PO_4)_2$	$Mg_3(PO_4)_2$	$CaCO_3$	$CaSO_4$	CaS	Fe_2O_3	Alkaline salts	SiO_2
10·76	73·50	6·08	8·69	0·05	0·03	0·16	0·44	0·29
6·83	70·39	8·47	10·92	0·78	0·46	0·63	0·49	10·3

The carbon is very finely divided and disseminated through a porous mass of about 80 per cent. of calcium and magnesium phosphates, and it seems to have specially valuable qualities. N. Gräger purified animal charcoal by grinding the product with 4 to 5 per cent. of a soln. of sodium carbonate, then with water, then with hydrochloric acid, and finally with water. Processes have also been indicated by G. Banfi, G. Hoppe, M. Takahashi, C. Thumb, H. Eisfeld, G. Kriegar, etc. Bones furnish *bone-black*—sometimes called ivory black—the term *ivory black* is also applied to the product obtained by digesting bone-black with hydrochloric acid to remove the calcium phosphates; very little of the ivory black of commerce is made from ivory cuttings. The carbon blacks of vegetable or animal origin, after treatment with dil. acid, also furnish the so-called Paris black used as a pigment. Blood furnishes *blood charcoal*. For the uses of bone-black and animal charcoal, *vide infra*. There are many trade-names for the decolorizing bone-blacks: *norite*, *darco*, *supchar*, *kelp-char*, *carbrox*, *bone-char*, etc. C. H. Hall considers that the active decolorizing agent in bone-black is a mixture of nitrogenous decomposition products of bone-cartilage, etc., with the empirical formula $C_{25}H_{20}N_4O_6$: these products are insoluble in alcohol, ether, benzene, and chloroform, but soluble in aq. ammonia, conc. sulphuric acid, and conc. hydrochloric acid. Soln. in the two last-named acids are precipitated by adding water. T. L. Patterson has described analogous compounds. F. E. Bartell and E. J. Miller, and P. M. Horton doubted if nitrogenous substances are the active agent. O. Ruff said that the activity of charcoal is due to the atoms and atom-groups of foreign materials bound to the surface of the charcoal. These atoms are the cause of the specific property of active charcoal, and they are characterized by the firmness of their linking to the carbon atoms on the surface. Other atoms can easily attach themselves to the surface, but these are readily replaced by others, and are not firmly bound. With every change in the nature of the surface of the charcoal, the absorptive properties are markedly changed.

Lampblack.—When hydrocarbons like wax, fat, coal gas, turpentine, tar, petroleum, acetylene, etc., are burnt in a limited supply of air, carbon seems to be the last element to oxidize, and if the flame be suddenly cooled, by bringing a cold surface in contact with it, much of the carbon is deposited unburnt. The air supply can be arranged so that the maximum amount of smoke is developed in the combustion of the hydrocarbon. The smoke can be collected as soot, the so-called lampblack, or *noir de fumée*, in chambers hung with sacking. The soot which collects on the surface of the "blankets" is scraped or shaken off from time to time. The old and primitive arrangement illustrated by J. B. A. Dumas'[5] diagram, Fig. 8, indicates the general principles of the process:

The apparatus consists of a cylindrical brick chamber ten or fifteen feet in diameter provided with a conical roof which has a small opening near its apex, sufficiently large to maintain a slight draught and which causes the smoke to ascend toward the upper part of the chamber. A cone of sheet iron hangs within the cylinder, and this too has a small hole at the top to allow the gases to escape. At the side and base of the chamber there is a kind of furnace, above the fire of which is placed a pan containing resinous or fatty matters, which are heated to a point sufficient to convert them into vap. This vap. then undergoes sufficient combustion to deprive it of its hydrogen, while most of the carbon remains unconsumed. The smoke ascends into the chamber and is mostly deposited upon the hanging canvas or sacking which covers the walls and upon the inner surface of the iron cone, from which it falls after a certain thickness has been collected. The cone is so held by a chain and pulley that it may be raised or lowered, which operation scrapes the lampblack off the sacking. The lampblack thus prepared is not pure carbon, as it is mingled with resinous and bituminous substances, together with ammoniacal and other matters. By heating it to full redness in retorts which are air-tight, nearly all these impurities are driven off and an almost pure, impalpable black powder remains.

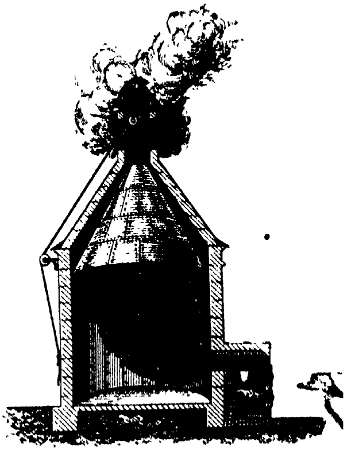

FIG. 8.—Primitive Process for the Manufacture of Lampblack.

The yield is only about 20 or 30 per cent., but the product obtained by this uneconomical process is fairly good. The important point is to keep down the temp. of the flame, for if the temp. be high, the product becomes hard and floury, with poor binding qualities. A great many improvements have been introduced to render it more efficient. The methods of burning the hydrocarbons, devices for cooling the flame, and the arrangements for collecting the soot have been improved by G. Wegelin, F. Meiser, J. Machtolf, etc. R. Thalwitzer burnt mixtures of benzene and oil-gas; A. Geuthe, naphthalene; H. Oishi, camphor; C. S. Bradley, methane; G. Wegelin, tar; and H. Berger and F. Wirth, acetylene or other hydrocarbons with triple-bonded carbon atoms. R. O. Neal, G. L. Cabot, R. Irvine, R. H. Brownlee and R. H. Uhlinger, and others have described the preparation of lampblack from burning natural gas. One process is conducted as follows:

A ring of burners is mounted below a cast-iron disc, with a groove on the rim convex downwards, in such a way that the flame from each burner is divided into two parts. Cold water runs into the upper side of the groove, and away *via* the hollow shaft which rotates the iron disc. This keeps the metal, in contact with the burning gas, cold. Soot is deposited on the groove. As the disc revolves, an automatic scraper removes the lampblack from the grooves of the disc. The lampblack falls into a hopper and is conveyed by elaborate machinery to be ground to the finest powder, sifted, and weighed into sacks.

H. Moissan prepared lampblack from petroleum oil at a dull red heat. It contained: ash, 9·75; carbon, 87·49; and hydrogen, 2·76 per cent. It was purified by successive washings with benzene, alcohol, and ether so as to remove hydrocarbons. The powder was then dried in air and afterwards in an oven at 150°. It contained: ash, 0·28; carbon, 93·03; and hydrogen, 1·12 per cent. The hydrogen comes partly from water and partly from hydrocarbons. H. Braconnot gave for the analysis of lampblack:

C	$(NH_4)_2SO_4$	K_2SO_4	$CaSO_4$	$(Ca,Fe)_3(PO_4)_2$	KCl	SiO_2	H_2O
79·1	0·3	0·4	0·8	0·3	trace	0·6	8·0

together with resinous matters, 5·3; bituminous matters, 1·7; and ulmine, 0·5 per cent. Amorphous carbon is obtained by burning acetylene at the end of a glass tube 6 mm. in diameter, and surrounding the flame by a hollow copper cylinder 3 cms. in diameter and cooled by a stream of cold water. The amorphous carbon obtained by M. Berthelot by decomposing acetylene with a detonator of fulminating mercury contained: ash, 7·87; carbon, 92·48; hydrogen, 0·40 per cent.; and H. Moissan added *ce carbone amorphe est un des plus purs que nous ayons étudiés.* H. H. Lowry studied the relation between the hydrogen content of charcoals and some of their properties—sp. gr., porosity, oxidizability, etc.

In addition to the ordinary process of producing lampblack by the incomplete combustion of hydrocarbons, etc., with a limited supply of air, processes have been devised which are based on the decomposition of gases and liquids by explosion or by electrical processes. Thus, F. Morani exploded a mixture of acetylene and air under press., the temp. of the explosion is higher than that obtained in the ordinary combustion processes; and, in order to keep down the temp., he recommended mixing the acetylene with an exothermal gas like methane, ethane, etc. G. Wegelin tried to utilize the heat developed in the explosion of acetylene to run a combustion engine. L. J. E. Hubon produced *acetylene black,* or *noir d'acétylène* by exploding acetylene in a closed vessel by an incandescent tube, or wire, or by electricity. J. Machtolf decomposed the hydrocarbon gases by electric sparks, or by a fulminating mercury detonator. A. Schneller and W. J. Wisse decomposed gaseous, liquid, or solid hydrocarbons by high tension sparks—10,000 to 40,000 volts.

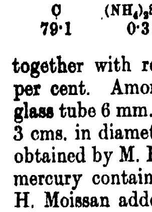

FIG. 9.—The Electrical Precipitation of Lampblack from a Flame.

B. Thieme described an electrical process in which the carbon is separated directly from the flame itself; this has the effect of cooling the flame and at the same time increasing the yield of soot. The principle of the process is illustrated by Fig. 9. If two poles of a source of electricity at about 15 volts be introduced close together in a candle-flame a deposit of soot is formed at the negative pole, and the deposit grows in the direction of the course of the gases. In the technical process, soot is similarly precipitated from the flame, and the apparatus is so arranged that a constant supply of fresh soot is formed at its surface: this prevents the lampblack when once formed from being impaired by the heat. The precipitation is rapid, so that it is not long exposed to the influence of the flame. The product is said to be very fine in texture and specially suited for making printer's ink. The manufacture of carbon black has also been described by R. O. Neal and G. S. J. Perrott, G. S. J. Perrott and R. Thiessen, L. F. Hawley, etc.

T. Svedberg [6] prepared **colloidal carbon** as an isobutyl-alcosol by his electrical process (1. 23, 10). H. Freundlich, and W. R. Whitney and A. Straw obtained suspensions of carbon in soln. of hydroxides, and in picric acid. Mixtures were made with lampblack and water, and with 0·0004, 0·0006, 0·001, 0·002, 0·004, and 0·006*N*-soln. of sodium hydroxide. The maximum stability of the suspension was obtained with the conc. approximating 0·001*N*-NaOH. According to P. C. L. Thorne, carbon sols may be prepared by anodic disintegration, by chemical oxidation, and by the decomposition of organic compounds. A stable carbon sol may be prepared by the electrolysis of a soln. of ammonia for 6 hrs. between carbon electrodes with an anode current density of 0·6–1·2 amp. per sq. cm. and a voltage of 220. After filtering, the soln. had an ammonia conc. of 0·145*N* and gave a solid residue of 0·034 g. per 100 c.c. The residue is insoluble in water, but is peptized again in presence of a trace of ammonia; the excess of ammonia may be removed by boiling, and the sol is then more stable than the original sol, which on dialysis is flocculated when the ammonia conc. falls to 0·039*N*. The ammonia-free sol is deep black in layers greater than 1 cm. thick and brown in thinner layers, and is made up of particles of about the same size as those of metallic sols. The number of millimols of electrolytes necessary to coagulate 1000 c.c. of the given sol was relatively 290; ammonium hydroxide, 9000; sodium chloride, 450; barium chloride, 0·5; and aluminium chloride, 0·3. According to S. Goldberg, colloidal carbon, free from electrolytes, migrates towards the anode with a velocity about $18{\cdot}3\times10^{-5}-13{\cdot}5\times10^{-5}$ cm. per sec. per volt. Dilution and filtration increase the velocity up to about 20 per cent. Acids and bases, irrespective of their nature, reduce the velocity by about the same amount, and at the same time change the colour slightly, but the original colour may be restored by neutralization. Of the salts examined, only those of aluminium have any effect on the migration velocity, and these cause an increase to a maximum with 1/500,000 mols aluminium sulphate, followed by a decrease on further increasing the conc. Colloidal ferric hydroxide coagulates colloidal carbon, but if a quantity so small is added that no coagulation takes place, then the velocity of migration is reduced about 20 per cent.

E. G. Acheson obtained a similar preparation of **colloidal graphite**, which he called *deflocculated graphite*, by treating disintegrated graphite with an aq. soln. of tannin containing from 3 to 6 per cent. by weight of the graphite treated. The results are much more pronounced when the mass of graphite, water, and tannin has been pugged or masticated for a considerable time, say one month. While the effect is very satisfactory with distilled water, the water obtained from rivers, deep wells, etc., is improved by the addition of a trace of ammonia. The presence of carbon dioxide in the water prevents deflocculation. The liquid containing the deflocculated graphite has an intense black colour, and the grain-size of the particles is much finer than is possible of attainment by mechanical means. It will pass through ordinary filter-paper. The addition of a trace of hydrochloric acid causes the graphite to flocculate and settle. E. G. Acheson also suspended the graphite in oil. The two suspensions are used as lubricants, and are known commercially as *oildag* and *aquadag*, where the "dag" is compounded from the first letters of "deflocculated Acheson's graphite." Other tanniferous soln. may be used.

§ 8. The Physical Properties of the Different Forms of Carbon

The clearest and most nearly colourless diamonds without flaws, are most prized as *diamonds of the first water* ;[1] these usually come from India or Brazil. The Cape diamonds usually have a very faint yellow colour, and in consequence, do not command so high a price. An intense coloration combined with transparency is comparatively rare. The commonest colour is yellow, then follow green, red, and blue or violet. The celebrated Hope diamond is blue. C. Doelter attributed the coloration to the presence of the oxides of iron, chromium, manganese, and titanium, which *als inter moleculäre Pigmente vorhanden sind.* Hydrocarbons may also give rise to a yellowish coloration. According to A. des Cloizeaux, some diamonds show a play of colours like the opal. Deep-black diamonds with a brilliant lustre come from Borneo. There is also *le diamant noir* or carbonado. The cloudy diamonds of a lead-grey colour are called boart.

Thin laminæ of graphite are opaque. The lustre may be dull and earthy, or bright and metallic with intermediate varieties. The colour of dense aggregates varies from an iron-black to a lead-grey.[2] H. Moissan found that the graphite derived from molten platinum is deep grey and paler than that from cast iron. H. N. Warren said that graphite from cobalt and nickel is scarcely to be distinguished from lampblack ; that from iron is in large plates ; that from manganese is in the form of brown plates, and that from ferromanganese is also in brown scales; that from chrome iron is paler and harder than that from iron ; and that from chromium resembles silicon. G. Rousseau said that the graphite from acetylene is in black microscopic plates ; and P. and L. Schützenberger, that the graphite from cyanogen is a greyish - black, voluminous, filiform powder. The so-called amorphous carbon is an odourless, tasteless, voluminous, black or brownish - black powder which may or may not have a lustre. W. G. Mixter[3] said that the amorphous carbon prepared from acetylene is porous and without lustre. T. L. Phipson said that that the carbon prepared by the action of magnesium on sodium carbonate is black and resembles charcoal.

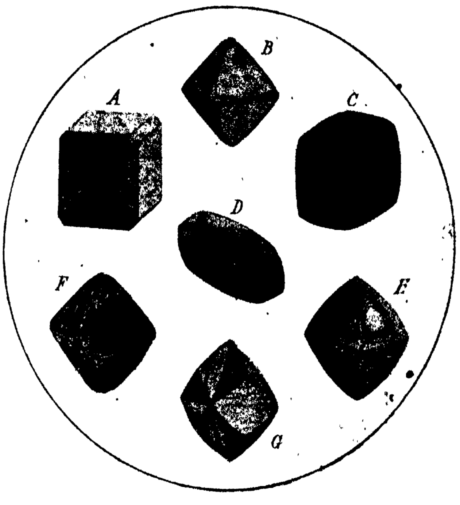

Fig. 10.—Selected Native Crystals of Diamonds.

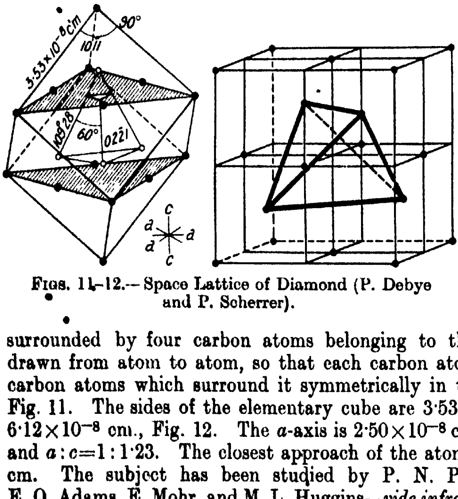
According to Pliny's description,[4] the crystals of adamas are " hexangular and hexahedral ; they are doubly turbinated, running to a point at both extremities ; and, marvellous to say, they closely resemble two cones united at the base." This would apply to the crystals of quartz. The crystals of the diamond belong to the cubic system, and they are often octahedral in habit. There are rhombic dodecahedral, and hexakis-octahedral forms ; the cube with rounded edges is also represented. Tetrahedral forms are also known. In Fig. 10, *A, C, G,* represent selected crystals of Brazilian diamonds ; and *B, D, E, F,* selected crystals of South African diamonds. Many of the crystals are well-developed on all sides, so that they must have grown while freely suspended in some medium ; their edges are not always sharp, but are more or less rounded. The rounded octahedral form is exhibited by the Victoria diamond. Many octahedra have a groove or furrow in place of the octahedral edge. This may be due to some peculiarity in their growth, or it may be an effect of twinning. If a supplementary twin of two tetrahedra have their projecting corners truncated by faces of the inverse tetrahedron, the twin crystal will have the appearance of an octahedron with grooved edges. Twinned crystals are flattened parallel to the twin-plane of an octahedral face as in magnetite. Twinned rhombic dodecahedra are often lenticular. J. R. Sutton found that 1 to 5 per cent. of the diamond crystals of the Kimberley mines are twinned. The faces often show special markings; the octahedral faces may have pits triangular in outline; and cubic faces, pits square in outline. H. R. Göppert also noted that pits with hexagonal outlines are very rare. J. R. Sutton has described overgrowths on the diamond.

Diamonds also have inclusions and cavities. Gaseous or liquid inclusions, observed by D. Brewster, E. Söchting, etc., are not common. H. C. Sorby, and G. A. Kenngott found inclusions of different tints. J. B. A. Dumas, and H. Behrens observed titanic oxide; A. Damour, topazes; E. Cohen, ferric oxide; P. Harting, pyrites; G. Delafosse, and A. des Cloizeaux, gold; and D. Brewster, G. Rose, A. Petzholdt, and C. and G. Friedel, carbonaceous matters. H. R. Göppert imagined that he could detect vegetable debris in diamonds, but this has not been confirmed. According to E. Regener, the scintillation of the diamond is connected with its colour, which in turn is conditioned by impurities. H. Moissan observed carbon inclusions in artificial diamonds obtained from a soln. of carbon in iron; and also some gold in *les diamants noirs* obtained from a soln. of carbon in silver. J. R. Sutton studied the macle formed by carbon particles in the middle of the crystals; and noted inclusions of garnet, ilmenite, olivine, pyrite, mica and zircon in diamonds.



FIGS. 11–12.—Space Lattice of Diamond (P. Debye and P. Scherrer).

W. H. and W. L. Bragg,[5] and A. W. Hull found that the **X-radiogram** of the diamond corresponded with a lattice with carbon atoms arranged on two interpenetrating face-centred cubic lattices, Fig. 11, so that each carbon atom of the one is surrounded by four carbon atoms belonging to the other; and links can be drawn from atom to atom, so that each carbon atom is connected with the four carbon atoms which surround it symmetrically in the manner of a tetrahedron, Fig. 11. The sides of the elementary cube are $3{\cdot}53 \times 10^{-8}$ cm., and the diagonal $6{\cdot}12 \times 10^{-8}$ cm., Fig. 12. The a-axis is $2{\cdot}50 \times 10^{-8}$ cm., the c-axis $3{\cdot}06 \times 10^{-8}$ cm., and $a:c=1:1{\cdot}23$. The closest approach of the atoms in the lattice is $1{\cdot}50 \times 10^{-8}$ cm. The subject has been studied by P. N. Pease, A. W. Hull, F. Rinne, E. Q. Adams, E. Mohr, and M. L. Huggins—*vide infra*, graphite.

Graphite may occur in granular, dense, earthy masses when it is soft and friable. It then lacks a definite external crystalline form, and is known as *amorphous, compact, or earthy graphite*. The so-called amorphous graphite was described by J. N. von Fuchs, F. von Sandberger, and W. Luzi. H. Moissan in his syntheses of graphite, found that some amorphous graphite accompanied the crystalline form; and he found that by press., crystals of graphite acquired the appearance of a fused or vitreous mass. It also occurs embedded in foliated masses, and micaceous, columnar, radiated, or fibrous aggregates of imperfect crystals. Each aggregate of *scaly, lamellar, or flaky graphite* is composed of thin foliated plates of fairly uniform width and ranging up to about 10 cm. in length. Foreign matters may be distributed through the structure and appear as thin films on the surface of the graphite. Well-formed crystals of graphite are rare, and they are nearly always six-sided, tabular, and striated with indistinct faces. The best crystals are usually found in meteorites and in granular crystalline limestones. R. Jameson, F. Mohs, C. F. Naumann, C. Czeck, B. Walter, referred to crystalline graphite as rhomboidal graphite; and R. J. Haüy said that *la forme primitive est un prisme hexaèdre régulier*. H. Erdmann found that the graphite obtained from the naphthalene derivatives furnishes hexagonal crystals, and H. Moissan obtained hexagonal plates from the soln. of carbon in platinum. Pseudomorphs after pyrite have been reported, and L. Fletcher obtained a crystal from the meteorite of Crosby Creek, West Australia, which he regarded as a modification of regular hexagonal graphite, but is more probably a pseudomorph of granite to the diamond. A. E. Nordenskjöld, G. A. Suckow, and W. B. Clarke regarded the crystals of graphite as monoclinic, and gave for the axial ratios $a:b:c=0{\cdot}7069:1:0{\cdot}5089$, and $\beta=88°\ 14'$; and P. Groth (1882) calculated from C. F. Naumann's measurements $a:b:c=0{\cdot}5806:1:0{\cdot}5730$, and $\beta=71°\ 16'$. Later, however, P. Groth accepted G. A. Kenngott's view that the crystals belong to the rhombohedral section of the hexagonal system, and gave for the trigonal crystals $a:c=1:1{\cdot}3859$. H. Sjögren, and P. P. Ewald believe that the crystals belong to the hexagonal system. P. P. Ewald based his opinion on the X-radiogram, but P. Debye and P. Scherrer showed that a mistake had been made. The view that the crystals are trigonal is now generally accepted. The difficulty in fixing the crystal system arose because of the scarcity of satisfactory samples. For the possible existence of a *polymorphic form of diamond* above 1885°, *vide supra*, the action of heat on the diamond.

J. Beckenkamp has discussed the space lattice, and M. L. Huggins, N. H. Kolkmeijer, P. Debye and P. Scherrer, F. P. Worley, and D. Coster the **electronic structure** of the diamond molecule. A. Landé assumed that cohesion in crystals depends on the electrostatic attractions and repulsions between the stationary atomic nuclei, and the moving electrons. The effect of homogeneous atoms on one another when the electronic motions are executed with equal periods is dependent on orbital differences of the electronic motions. Were the phases of the different atoms distributed according to probability, the average force between two atoms over a period would change by chance from place to place, and no regular crystal lattice could result; but rather would a structure with changing mol. distances result, and the density would be irregularly distributed owing to the slow fluctuations in consequence of the alterations of phase. Hence, *the regular structure of monatomic crystals shows that all like atoms have the same phase; or that at every instant, not only the atomic nucleus, but also the corresponding electrons of all like atoms form a lattice, which oscillates about the stationary lattice of the atomic nuclei.* A. Landé further showed that in the free state, the real vol. of the carbon atom is deformed in a definite manner by the neighbouring atoms. H. Thirring also discussed this subject.

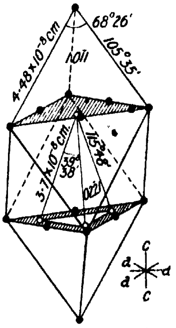


FIG. 13.—Space Lattice of Graphite (P. Debye and P. Scherrer).

A. W. Hull, P. Debye, M. L. Huggins, and P. Scherrer found the X-radiogram of graphite agreed with the trigonal system; and, assuming the sp. gr. 2·2, it appears that the graphite mol. contains eight atoms arranged in parallel planes, at distances $3{\cdot}41\times10^{-8}$ cm. apart; W. H. and W. L. Bragg gave $3{\cdot}42\times10^{-8}$ cm., Fig. 13. The *a*-axis is $2{\cdot}52\times10^{-8}$ cm., the *c*-axis is $5{\cdot}11\times10^{-8}$ cm., and $a:c=1:2{\cdot}03$. The nearest approach of the atoms is $1{\cdot}50\times10^{-8}$ cm. In each plane, the carbon atoms lie at the corners of a regular hexagon so grouped that three alternating corners of the hexagon are occupied by carbon atoms in the plane ⊙, Fig. 14, then the three other corners would be occupied by the plane

O, Fig. 14 above; and the centre of the hexagon in *p* (not occupied) would be *vertically beneath* one of the corners of the hexagon in ⊗, Fig. 14. *The three planes are illustrated by Fig. 14 for atoms which do not lie one above the other.* The atoms in the same plane are represented by the same symbol, and those in different planes by different symbols. The side of this hexagon has a length $1{\cdot}45 \times 10^{-8}$ cm. While the elementary parallelopiped of the diamond is a cube, that of graphite is a rhomboid; the horizontal projections of both these bodies are hexagons. If the cube has one diagonal placed vertically, and the rhomboid is lying on its face, the hexagonal projections are the same. Hence, the ratio of the diagonals of the rhomboid to that of the cube should be the same as the ratio of the density of graphite to that of the diamond. This ratio is 2·2÷3·52=0·62, the calculated values for the diagonals is 6·12÷10·22 =0·598. The agreement is satisfactory, but would be closer if H. Moissan's value 2·11 were taken for the sp. gr. of graphite.

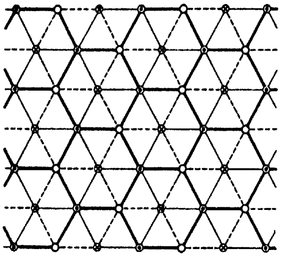

FIG. 14.—Arrangement of Atoms in Graphite.

In the graphite mol., therefore, each carbon atom is coupled with three others in the (111)-plane, all at the same distance and relatively eq.; but the distance from the fourth carbon atom in the plane (above or below) would be greater, and that coupling would be weaker. The weakness of the fourth coupling is shown by the ease with which graphite undergoes cleavage. In the diamond, however, the mol. is perfectly symmetrical, and the four valencies are rigorously the same. While W. H. Bragg holds that the layers of atoms in the lattices of graphite and the diamond are puckered, Fig. 15, P. Debye assumes that the layers are flat. The structure of graphite was also studied by M. L. Huggins. According to W. H. Bragg, it is probable that the benzene and naphthalene rings have a concrete structure in organic compounds. He said:

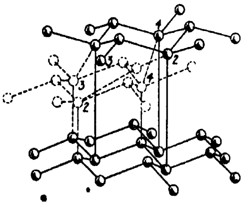

FIG. 15.—Lattices of Graphite (continuous lines), and of Diamond (lower continuous and middle dotted lines).

> The X radiograms of the diamond show that the atoms are probably tied together so that each is at the centre of gravity of four others. The distance from centre to centre is 1·54 A. The rigidity of the diamond and the open character of its structure, imply that great force is required to alter the orientation of any coupling with respect to the other three belonging to the same atom. Were it otherwise, all atoms would seek to be surrounded by as many neighbours as possible; the substance would be close-packed, and its density would be more than double what it is. The structure of the diamond may also be looked on as consisting of a series of puckered layers parallel to a given tetrahedral plane. A sharp blow may cleave the diamond, along one of these layers. If we take a model showing two layers as in graphite, lay hold of the upper layer, and move it to the new position shown in Fig. 15; the structure is now that of diamond. The bottom and second (dotted) lines of Fig. 15 show the diamond as a series of puckered layers parallel to the perfect cleavage planes, which lie perpendicular to the four triad axes which emerge from the corners of the cube. The structure of graphite is obtained by shifting one of two parallel layers from the position of the dotted lines to that of the continuous lines. According to A. W. Hull's measurements, the shortest distance between each pair of atoms lying in the same layer is shortened from 1·54 A.—the diamond spacing—to 1·50 A. The distance between two successive layers has been increased by 1·35 A. A carbon atom in one layer is now at equal distances from its three nearest neighbours in the next layer, the distance being 3·25 A. The bonds between one layer and the next are now greatly weakened; the substance cleaves readily in thin flakes. One layer slides with great ease over the other, though the bonds between the atoms in any layer are at least as strong as before. When all the bonds are of the strong kind, as is assumed to be the case with the diamond, the substance will be very hard, and the diamond is the hardest thing known. When the one set of bonds has been weakened, the substance is softer, as is assumed to be the case with graphite which is used as a lubricant. Probably its efficiency as such depends both on the weakness of the one

set of bonds and the strength of the other. Yet these new bonds are perfectly definite, and the distance between two layers—the distance 3·25 A. between atomic centres—is a perfectly constant and determinate quantity. If the strong bonds between the atoms in a layer remain, and are even drawn a little tighter as occurs when the graphite form replaces that of diamond, it seems very reasonable to suppose that the single ring or multiple rings which are so clearly to be distinguished in the network may be separated out as such without loosening the bonds between their component atoms. In fact, these latter bonds might be expected to tighten even a little more.

H. le Chatelier raised the question whether the so-called amorphous carbon is really non-crystalline. He said:

> Un corps réellement amorphous est un corps dans lequel il n'existe certainement aucune orientation d'aucune propriété physique comme le verre, les liquides ordinaires, les résines, les gélatines, etc. Dans le cas du carbone, corps opaque, souvent pulvérulent, nous n'avons aucun moyen de constater la présence ou l'absence d'une orientation cristalline, toute affirmation à ce sujet est une hypothèse purement gratuite, dépourvue de toute valeur scientifique.

P. Poch found that the X-radiograms show that carbon derived from cyanogen has a more finely crystalline structure than carbon derived from carbon monoxide. P. Debye and P. Scherrer, and G. Asahara showed that the X-radiograms of amorphous carbon give the same interference figures as are obtained with graphite, and therefore suggest that amorphous carbon differs from graphite only by its greater degree of subdivision. Amorphous carbon is graphite in an extremely fine state of subdivision which has not broken up the mol. Hence, they conclude that the diamond and graphite are the only two known modifications of carbon. This view is in harmony with the ideas of P. Groth. P. Poch likewise found the carbon obtained by decomposing cyanogen in the electric spark to be crystalline. The mol. of amorphous carbon need not contain more than thirty atoms, and the grouping would be as in graphite—three atoms lying in the same plane symmetrically with a centre (not occupied), and coupled by equal valencies, while the fourth atom is vertically above or below that plane and held by a weaker valency. The four valencies of carbon are usually considered to be eq., but the existence of tervalent carbon in triphenylmethyl, $C(C_6H_5)_3$, shows that the four valencies are not strictly eq. P. Debye and P. Scherrer suggest that graphite or amorphous carbon forms the prototype of the aromatic compounds characterized by the benzene ring or hexagon, while the diamond is the prototype of the aliphatic or fatty acid series. J. Beckenkamp studied the space-lattice of graphite, and M. L. Huggins, the relation of the space-lattices to the cleavages of graphite and the diamond. E. Ryschkewitsch said:

> The atomic configuration of graphite is characterized, like that of the metals, by the presence of free electrons which make it a good conductor of heat and electricity and confer on it its metallic lustre. Graphite is a better conductor of electricity than mercury, and a better conductor of heat at high temp. than many pure metals; it resembles metals in not being soluble without change in any solvents except liquid metals, and it yields positive C····-ions in sufficient conc. to be electromotively active.

V. Kohlschütter confirmed P. Debye and P. Scherrer's view of the similarity in the constitution of graphite and amorphous carbon. He showed that the physical and chemical properties of graphite vary within such wide limits that no distinct line of demarcation can be drawn between graphite on the one hand and amorphous carbon or soot on the other; and he concluded that all varieties of graphite and amorphous carbon are different physical forms of "black carbon," which is to be regarded as an allotropic modification of diamond. The properties of different samples of graphite depend on the conditions under which it is produced, and its variable character is to be attributed to different degrees of dispersity. V. Kohlschütter added that graphite owes its peculiar properties to its lamellar structure. This type of structure not only accounts for its special physical properties, but also for many chemical properties, such as its resistance to oxidation and to reagents, and for the fact that its formation is favoured when free carbon is produced by a surface reaction. The difference between the densities and heats of combustion of graphite, and amorphous carbon is not opposed to the theory that they are essentially the same form of carbon. The formation of graphitic acid by the oxidation of graphite, but not of amorphous carbon, is due to the peculiar structure of the former and not to the existence of a distinct graphite mol. G. Asahara's observations on the X-radiograms of graphites and amorphous carbons lead to the conclusion that the term " amorphous " should be replaced by the term " very minutely crystalline."

According to H. Lachs, the ultramicroscopic image of colloidal carbon contains a considerable number of very brilliant stationary particles and a smaller number of fine particles that show a slight Brownian movement. Scattered through the entire field are also some very brilliant particles which show pronounced scintillations. This is due to the shape of the particles. If they are rods or plates the amount of light dispersed varies with the orientation of the particle, thus causing sparkling. This phenomenon may be considered as a kind of *ultramicroscopic anisotropy*.

The **cleavage** of the diamond is perfectly parallel to the faces of the octahedron; and this property enables the diamond cutters to chip away projecting corners and inferior parts without the labour of grinding. The fracture is conchoidal. R. Scharizer, and G. Wulff have discussed the cleavage of the diamond from the point of view of the X-radiogram. The cleavage of graphite is basal and perfect like that of mica, furnishing thin folia. The diamond was the hardest substance known to the ancients and it was made the standard, 10, on Mohs' scale of **hardness**; likewise also on J. R. Rydberg's scale.[6] On F. Auerbach's scale, the hardness of the diamond is 2500; corundum, 1150; quartz, 308. The hardness of the diamond enables it to scratch the ruby or corundum. Until recently, it was said that the diamond would cut all other substances and not be cut by any. H. Moissan showed that carbon boride cuts slowly into the diamond, and titanium carbosilicide is almost as hard as transparent diamond. Besides carbon boride, the ruby is scratched by many carbides, silicides, nitrides, borides, and carbosilicides. A variety of boart is superior in hardness to the diamond. The so-called anthracitic diamond of C. de Douhet is of adamantine hardness. Australian and Bornean stones are usually considered hardest. Owing to its hardness, a cut diamond does not show any signs of wear. Many fabulous stories about the hardness of the diamond were rife during the Middle Ages; these were based on Pliny's account of the indestructibility of the diamond. Pliny said that " when struck by a hammer, it returns the blow shattering both hammer and anvil." It was said that the hardness could be overcome by the use of goat's blood, especially if the goat had previously drunk wine or eaten parsley. These tales were rejected by A. B. de Boot in 1609. The brittleness of the diamond is very great, so that in spite of its great hardness, it can be readily pulverized by fracture along the cleavage planes; and use is made of this quality in the preparation of diamond powder for use in the lapidary. The hardness of graphite on Mohs' scale is 0·5 to 1·0; consequently, while the diamond is the hardest of the minerals, graphite is one of the softest. G. A. Kenngott mentioned a variety as hard as gypsum. It leaves a black mark on paper, and owing to this quality it is extensively employed in the manufacture of lead-pencils. Hence the name *graphite—vide supra*, the history of graphite. F. Monier, and A. V. Rakowsky have discussed the hardness of the different kinds of carbon.

R. Boyle,[7] in 1690, found the **specific gravity** of the diamond to be 2·955, and in a table of sp. gr. he gave the value 3·4. The reported values for sp. gr. range from 3·336 of V. A. Jacquelain to A. Liversidge's 3·5585. The values of E. H. von Baumhauer range from 3·5065 to 3·5242, or corrected, 3·50307 at 9°/7·5°, and 3·52063 at 8°/8° respectively. The average may be taken as the best representative value; L. Playfair gave 3·46. Other determinations have been made by L. E. Rivot, P. A. Dufrenoy, W. J. Grailich, A. Schrauf, H. Moissan, Y. Tadokoro, A. Wigand, F. Feilitzsch, G. F. Kunz, M. J. Brisson, F. Mohs, J. J. Berzelius, A. Schafarik, T. Thomson, and E. Donath and J. Mayrhofer. E. Wülfing found the sp. gr. of four high-grade stones varied from 3·524 to 3·530; and, combining these values with those of E. H. von Baumhauer, there results 3·520±0·02 at 4°. Impure diamonds sometimes give relatively high values. A. von Schrötter found sixteen varieties had a sp. gr. ranging from 3·51058 to 3·51947, average 3·51432; and he represented the sp. gr. of the diamond at a temp. of θ° by $3\cdot51432+0\cdot000065\theta$. H. Fizeau found that the sp. gr. attains a minimum value at —38·8°, *vide* thermal expansion. Values for carbonado range from L. E. Rivot's 3·012 to 3·416; E. H. von Baumhauer's extremes are 3·1552 and 3·5111, or, corrected, 3·15135 at 13°/11·1°, and 3·50652 at 14°/11·5° respectively. The values for boart range from 3·47 to 3·56; E. H. von Baumhauer's extremes are 3·5030 to 3·5100, or, corrected, 3·49806 at 14°/12·5°, and 3·50383 at 9°/7·5° respectively. E. Cohen and J. Olie found the sp. gr. of the diamond referred to water at 4°, is 3·519 at +163·6°; 3·510 at —38°; and 3·514 at 18°. T. W. Richards, and E. Peterson gave 3·4 for the at. vol. of diamond carbon.

Reported values for the sp. gr. of graphite range from C. Mène's[8] 1·885 for a sample from Terrenoire, to his 2·585 for a sample from Cumberland. There is considerable doubt about the higher values for amorphous carbon and the lower values for graphite, since mixtures of the two forms may be involved. L. Playfair gave 2·29 for the best representative value; H. le Chatelier and S. Wologdine gave 2·255 at 15°/4° for natural graphites after purification and compression; H. Moissan gave 2·11; while 2·2 is often adopted. M. Debeaupuis gave 1·99 to 2·38; and C. de Douchet, 1·66 for what he called anthracitic diamond from Brazil. R. M. Burns and G. A. Hulett gave 2·20 for the best representative sp. gr. of pure natural graphite, and 2·30 for Acheson-graphite. Graphite produced by the explosion of graphitic acid has a sp. gr. 2·215. The ordinary graphites showed no "drift" or increase in weight with time after immersion in the liquid used in the density determinations. This phenomenon—*drift* as it is called—was studied by H. E. Cude and G. A. Hulett. M. Pirani and W. Fehse found that the sp. gr. of Ceylon graphite fell from 2·26 to 2·18 after calcination at 3000°, and they attributed this to the loss by volatilization of ferruginous impurities, because the ash obtained with graphite calcined to 500° was one per cent., the ash after calcination to 1800° was 0·66; and to 2200°, 0·36; to 2700°, 0·20; and to 3000°, 0·07 per cent. F. Sauerwald made observations on this subject. W. C. Arsem found that after heating to 3300°, the sp. gr. of lampblack was 2·07 to 2·10; of anthracite, 2·13 to 2·18; retort carbon, 2·11 to 2·26; and the diamond, 1·915. Determinations have also been reported by J. N. von Fuchs, J. J. Berzelius, Y. Tadokoro, L. Cellier, C. J. B. Karsten, J. C. Poggendorff, G. A. Kenngott, B. C. Brodie, J. Löwe, H. V. Regnault, C. F. Rammelsberg, W. Luzi, H. Moissan, M. Diersche, and A. Wigand. E. Cohen and J. Olie gave for the sp. gr. of graphite, referred to water at 4°, 2·223 at —163·6°; 2·217 at —38°; and 2·216 at —18°. The at. vol., according to E. Petersen, is 5·3, and, according to T. W. Richards, 5·4. E. Ryschkewitsch and E. Köstermann gave 2·232 ± 0·0013 at 16° for the sp. gr. of graphite which had been fused.

The sp. gr. of the so-called amorphous carbon has been determined by numerous observers, and values ranging from 1·45 for poplar and vine charcoals by G. Werther[9] to A. Frank's value 2·0 for acetylene black have been given. W. G. Mixter gave 1·919 for acetylene black. A. Titoff gave for cocoanut charcoal 1·860, and I. F. Homfray, 1·670. L. Playfair gave 1·87 for the best representative value. H. Violette, W. Hallock, W. Luzi, C. Mène, W. G. Mixter, A. Frank, A. Baudrimont, E. Monier, A. Wigand, L. Playfair, Y. Tadokoro, and F. Exner have made observations on the sp. gr. of amorphous carbon—*vide infra*, Table VI. H. le Chatelier and S. Wologdine gave for lampblack, sugar charcoal, and wood charcoal purified by chlorine and pressed, 1·70 to 1·80. The values for gas carbon range from 1·7 to 2·6. L. Meyn gave for gas-carbon from different parts of the retort the values 1·723, 1·821, 1·982, 2·056, and 2·556 at 18°. The samples with the higher values were probably mixtures with more or less graphite. H. E. Cude and G. A. Hulett showed that the determination of the sp. gr. of charcoal is complicated by a gradual penetration of the liquid into the grains of the solid so that the sp. gr. increases with the time of immersion in the liquid. Thus, the sp. gr. of samples of charcoal after 15 min. immersion in water was 1·829, and after 119 hrs.'

immersion, 1·854 ; with 15 min. immersion in carbon disulphide, 1·915, and after 362 hrs.' immersion, 1·984 ; after 15 min. immersion in benzene, 1·734, and after 286 hrs.' immersion, 1·797 ; and after 15 min. immersion in carbon tetrachloride, 1·596, and after 2856 hrs.' immersion, 1·647. S. McLean gave 1·48 to 1·58 for the sp. gr. of cocoanut charcoal ; 1·32–1·35 for lignite carbonized at 350° ; at 450°, 1·45 to 1·47 ; and at 550°, 1·42 to 1·47. H. L. Buff estimated that the **specific volume** of bivalent carbon in combination is greater than that of quadrivalent carbon. Observations were also made by M. Schalfejeff. For the **atomic volume** of carbon, T. E. Thorpe gave 11·0, and E. Petersen, 6·7 to 8·0. R. N. Pease calculated 0·77 A. for the atomic radii of the atoms in the diamond. T. Graham, and A. Zott discussed the porosity, or rather the permeability of graphite to gases. Owing to the inaccessibility of the surface to liquids when determining the sp. gr. of charcoal, A. W. Williams estimates that the results are low. A specimen with an observed sp. vol. of 0·51 was estimated to have a true sp. vol. of 0·67 c.c. per gram. L. Bell and P. R. Bassett believed that they succeeded in **disintegrating carbon atoms** into helium, etc., by using very powerful carbon arcs. The inference was based on the spectral observations of the " negative tongue " of the arc.

L. H. Adams[10] and co-workers gave $0·18 \times 10^{-6}$ for the **compressibility,** β, of the diamond between 0 and 10,000 megabars press. J. J. Thomson obtained a similar value from his theory of the structure of solids. T. W. Richards gives for the mean change of volume 0·5 unit between 100 and 500 megabars per megabar (0·987 atm.). He found the average compressibility of the diamond to be very small, $0·5 \times 10^{-6}$ megabars, and for graphite he gave the compressibility $3·0 \times 10^{-6}$ at 20° between 100 and 500 megabars. L. H. Adams gave $0·16 \times 10^{-6}$ megabars for the compressibility of the diamond, and J. J. Thomson calculated $0·178 \times 10^{-6}$ from his electron theory. According to W. Spring, graphite agglomerates under press., and H. Moissan showed that when prepared under press., the sp. gr. of graphite can be raised to 2·35. K. Försterling studied the relation between the elastic constants and the sp. ht. of the diamond. A. Landé calculated the compressibility of the diamond from the heat of sublimation, the mol. vol., and assumption as to the space-lattice. A. W. Williams calculated the **attractive pressure** in the surface film on charcoal to be of the order 10,000 atm., and the **internal pressure,** 50,000 atm. J. H. Hildebrand and co-workers discussed this subject.

H. Fizeau[11] found that the coeff. of **thermal expansion** of the diamond is very small, but that it decreases rapidly on a falling temp. He found the coeff. of linear expansion, a, at different temp. to be :

	−38·8°	0°	10°	20°	30°	40°	50°
a . .	$0·0_6 0000$	$0·0_5 0562$	$0·0_5 0707$	$0·0_5 0857$	$0·0_5 0997$	$0·0_5 1142$	$0·0_5 1286$

He also gave for the linear coeff. at 40°, $0·0_5 118$; and for the coeff. of cubical expansion at the same temp., $0·0_5 354$. He represented the length l at $\theta°$, when the length at 0° is l_0, by $l = l_0(1 + 0·0_4 56243\theta + 0·0_6 72385\theta^2)$. W. C. Röntgen gave 0·00000119 at 40°, for the coeff. of linear expansion. J. Joly also found that if 0·00144 denote the length of a diamond at 400° ; l the length at a temp. $\theta°$; and 0·00342 and v the corresponding volumes,

	580°	686°	750°
$(0·00114 - l)/0·00114$	0·00193	0·00265	0·00338
$(0·00342 - v)/0·00342$	0·00579	0·00785	0·01014

The diamond burnt at 850°. From the marked expansion at 750°, J. Joly concluded that the diamond has been formed under press. H. Fizeau gave for the coeff. of linear expansion of graphite at 40°, $0·0_5 786$, and at 50°, $0·0_5 796$; H. Muraoka gave $0·0_5 38$ for a specimen of Siberian graphite, and $0·0_5 095$ for a sample of pencil-graphite. J. Dewar gave $0·0_4 244$ for the coeff. of thermal expansion of graphite between 17° and −190°. H. Fizeau found that coeff. of expansion of anthracite at 40° to be $0·0_4 2078$; and, at 50°, $0·0_4 1996$; for coal at 40°, he found $0·0_4 2782$; and at 50°, $0·0_4 2811$. According to J. Monckmann, the rate of expanson of carbon increases as the temp. rises to 250°, and then decreases.

The **thermal conductivity** of acetylene lampblack was found by W. G. Mixter[12] to be high. According to H. Violette, the thermal conductivity of wood-charcoal increases with the coking temp. Carbon prepared between 150° and 300° shows only a feeble conductivity, but as the temp. of production rises, the thermal conductivity—C.G.S. units—increases until it attains two-thirds the conductivity of iron. R. Weber gave for the conductivity of gas-carbon, 0·0103 at 0°; D. Forbes, $0{\cdot}0_3405$ below 0° for carbon; C. A. Hansen, 0·162 for graphite and 0·0162 for carbon; W. Nusselt, $0{\cdot}0_3156$ for charcoal; H. Hecht, $0{\cdot}0_343$ for coal between 20° and 100°; and F. E. Neumann, $0{\cdot}0_3297$. Y. Tadokoro gave 0·00219 for the thermal conductivity of graphite; 0·00214 for charcoal; 0·00226 for coke; and 0·00099 for coal. The best representative values are taken to be 0·33 for the diamond; 0·0117 for graphite; and 0·000405 for amorphous carbon. J. M. Ordway made some observations on the conductivity of charcoal and plumbago; L. Cellier found the thermal conductivity of graphite, sp. gr. 1·698, to be 0·701; electric light carbon, 0·367 to 0·494 with the sp. gr. 1·467 to 1·567; and gas-retort carbon, 0·400, sp. gr. 1·627. A. Artom, B. Piesch, and H. Muraoka showed that different kinds of graphite have different conductivities; and M. Icole found the thermal conductivity of graphite at $\theta°$ to be $K=0{\cdot}0384-0{\cdot}0_49\theta+0{\cdot}0_693\theta^2$. S. Wologdine and A. L. Queneau studied the conductivity of plumbago or graphite bricks. R. S. Hutton and J. R. Beard found powdered retort graphite (sieved through a mesh 600 holes per sq. cm.) had a conductivity of 0·00040 between 20° and 100°. A graphite crucible is said to conduct heat five times better than a clay crucible. H. Sjörgen, and E. Jannetaz showed that the vertical axis of the crystals is the small axis of the isothermal ellipsoids.

P. A. Favre and J. T. Silbermann[13] found the **specific heat** of the diamond to be 0·147; H. V. Regnault obtained 0·14687 between 8° and 98°; P. J. van Kerckhoff, 0·147; A. Bettendorff and A. Wüllner, 0·1422 to 0·1512; C. E. Carbonelli, 0·10415; A. Wigand, 0·1128 at 10·7°. F. Marcet and A. A. de la Rive, 0·1192 at 6° to 15°. H. F. Weber found for the sp. ht. of the diamond:

	−50·5°	−10·6°	10·7°	140°	247°	606·7°	806·5°	985·0°
Sp. ht. . .	0·0635	0·0955	0·1128	0·2218	0·3026	0·4408	0·4489	0·4589

He represented the sp. ht. of the diamond at $\theta°$ by $0{\cdot}0947+0{\cdot}000994\theta-0{\cdot}00000036\theta^2$; and he gave for the mean sp. ht. between 0° and $\theta°$, $0{\cdot}0947+0{\cdot}000497\theta+0{\cdot}00000012\theta^2$. J. Dewar gave for the mean sp. ht. of the diamond between −18° and −78°, 0·0794; between −78° and −188°, 0·0190; and between −188° and −252·5°, 0·0043. The sp. hts. of the diamond at low temp., said J. Dewar, are less than that of any other substance so far observed. Values for the at. ht. of the diamond were computed by H. V. Regnault, and by A. Bettendorff and A. Wüllner. Collecting the results of W. Nernst and co-workers, F. Koref, G. Ewald, J. Dewar, and H. F. Weber, for the **atomic heat** of the diamond, and applying W. Nernst and F. A. Lindemann's formula (**1.** 13, 12—Fig. 8), there results:

$T°$ K	30°	42°	92°	205°	232°	284°	413°	1169°
C_p (obs.) . . .	0·00	0·00	0·03	0·62	0·86	1·35	2·66	5·45
C_p (calc.) . . .	0·00	0·00	0·009	0·62	0·87	1·37	2·55	5·41
C_v (calc.) . . .	0·00	0·00	0·009	0·62	0·87	1·37	2·53	5·19

P. A. Favre and J. T. Silbermann found the sp. ht. of natural graphite to be 0·20187 and that of graphite from iron, 0·19702; H. Kopp gave for natural graphite, 0·174, and for iron graphite, 0·166; H. V. Regnault gave for natural graphite between 0·1911 and 0·2019, and for iron graphite, 0·1977; and for graphite from tar, 0·1968. P. J. van Kerckhoff gave for natural graphite, 0·2000; Y. Tadokoro, 0·203; A. Bettendorff and A. Wüllner, 0·1933 to 0·2007, and for iron graphite 0·1952 to 0·1969; and H. F. Weber 0·1439 between 0° and 34°; 0·1967 between 0° and 100°; and $0{\cdot}1167+0{\cdot}0008\theta$, between 0° and $\theta°$; and

	−50·3°	−10·7°	10·8°	61·3°	138·5°	201·6°	249·3°	977°	641·9°	822°
Sp. ht. .	0·1138	0·1437	0·1604	0·1990	0·2542	0·2966	0·3250	0·4670	0·4454	0·4539

He also found for flaky graphite the values 0·1605 between 0° and 21·6°; 0·1904 between 0° and 99°; and 0·2350 between 0° and 225·3°. A. Magnus gave for the total heat of graphite between 0° and θ°, $Q=0{\cdot}15200\theta+3{\cdot}8885\times10^{-4}\theta^2-2{\cdot}885\times10^{-7}\theta^3+1{\cdot}4718\times10^{-10}\theta^4-4{\cdot}385\times10^{-14}\theta^4$. A. Wigand obtained for the sp. ht. of graphite 0·1604 at 10·8°; and W. Spring, 0·20212 to 0·20471 for Cingalese graphite. J. Violle represented the linear increase in the sp. ht. of graphite above 1000°, by $0{\cdot}355+0{\cdot}0006\theta$, between 0° and θ°; and if the b.p. is 3600°, 2500 Cals. are evolved on cooling from that temp. to zero. J. Dewar gave for the sp. ht. of graphite between −18° and −78°, 0·1341; between −78° and −188°, 0·0599; and between −188° and 252·5°, 0·0133. W. Nernst found the sp. ht. 0·005 at −244°, and 0·027 at −186° for graphite. L. Cellier gave for the sp. ht. of graphite 0·3055; for electric light carbon, 0·2488 to 0·2667; and for gas-retort carbon, 0·2787. H. V. Regnault, H. Kopp, J. Monckman, and A. Bettendorff and A. Wüllner discussed the at. ht. of graphite.

H. V. Regnault found the sp. ht. of wood charcoal to be between 0·204 and 0·242 at 19° to 99°; for bone charcoal, 0·2608; and for gas carbon, 0·2005; J. Marcet and A. A. de la Rive gave 0·1650 for wood charcoal at 6° to 15°; P. A. Favre and J. T. Silbermann, 0·24150 for wood charcoal, and 0·20360 for gas carbon; H. Kopp gave 0·185 for gas carbon; P. J. van Kerckhoff, 0·2608; A. Bettendorff and A. Wüllner, between 0·2015 and 0·2062 for gas carbon; H. F. Weber, 0·1906 between 0° and 99°, and 0·2340 between 0° and 225·8° for dense amorphous carbon; and 0·1935 between 0° and 99·2°, and 0·2385 between 0° and 223·6° for porous wood charcoal; and A. Wigand gave 0·2040 between 24° and 68°. Y. Tadokoro gave 0·217 for charcoal; 0·201 for coke; and 0·254 for coal. Observations have also been made by D. I. Mendeléeff, K. Puschl, L. Kunz, and J. E. Pionchon. Further, L. Kunz gave for beechwood charcoal:

	435°	561°	728°	925°	1059°	1197°	1297°
Sp. ht. . . .	0·243	0·290	0·328	0·358	0·362	0·378	0·381

J. Violle gave $0{\cdot}355+0{\cdot}00006\theta$, and hence:

	0°	1000°	1500°	2000°	2500°	3000°	3500°
Sp. ht. . . .	0·355	0·415	0·445	0·475	0·505	0·535	0·565
Mol. ht. . .	4·260	4·980	5·340	5·700	6·060	6·420	6·780

L. Kunz's results were represented by the formula: sp. ht.$=0{\cdot}2143+0{\cdot}0001436\theta-0{\cdot}0_8 1975\theta^2$; or the at. ht.$=1{\cdot}64+0{\cdot}00017\theta$. J. Dewar found the value 0·32 between 20° and 1040°; and 0·42, at the temp. of the oxy-hydrogen blowpipe flame impinging on lime; at 2100°, the sp. ht. approximates 0·5. H. F. Weber stated that the sp. ht. of the different forms of carbon approaches a fixed limiting value as the temp. rises; but this J. Monckman denied, and he stated that the sp. ht. of carbon increases fairly regularly up to 250°, but above that temp. falls to one half. H. le Chatelier showed that the sp. ht. of gas carbon increases proportionately with temp., and that the increase is more than was observed by H. F. Weber. He represented the at. ht. between 0° and 250° by $1{\cdot}92+0{\cdot}0077\theta$, and between 250° and 1000° by $3{\cdot}54+0{\cdot}00246\theta$. Observations on the at. ht. have been made by H. Kopp, A. Magnus, A. Bettendorff and A. Wüllner, and G. Schmidt. G. N. Lewis and co-workers found the **entropy** of diamond carbon at 25° and one atm. press. to be 0·6, and that of graphite carbon, 1·3.

J. Violle[14] estimated the **boiling point** of carbon to be 3600°; W. Crookes, about 4000°; H. Moissan, 3500°; and W. R. Mott gave 3700°, and J. J. van Laar, 4040°, for the sublimation temp. at 760 mm. The **melting point** of the diamond must be very high—over 3000°. C. Doelter noted that the corners of fragments of diamond are rounded at 2000°–2500°; but it is doubtful if the diamond can be really melted because of volatilization. The transition of amorphous carbon into graphite at high temp., and the possible fusion of graphite in the electric arc have been previously discussed. The action of heat on the different forms of carbon has been previously discussed specially, and also in connection with the synthesis of the diamond and of graphite. C. Doelter estimates the **transition temperature,** diamond to graphite, to be near 1500°. The guesses which have been made concerning the equilibrium conditions of the different forms of carbon were illustrated by Figs. 2 and 3. The effect of press. on the transition point was calculated by A. König—*vide supra*. According to A. Smithells, if 3500°—*i.e.* 3773° K.—be taken as the b.p. of carbon, and 12 as the vap. density, it follows from Trouton's rule, $12x/3773=13$, that the **heat of vaporization** is 4086 cals. per gram, or 49,032 cals. per gram-atom. A. Thiel and co-workers calculated 125 Cals. per mol, which is much lower than other values. A. von Weinberg also made an estimate by means of Trouton's rule. E. Grüneisen calculated from the relation between the at. ht., C_v, and the coeff. of expansion of the diamond, that the heat of sublimation is 274 Cals., and K. Fajans obtained 287 Cals., from the work of O. Lummer on the variation of the temp. (3940°–4200°) of the positive crater of the carbon arc with press. H. Kohn showed that O. Lummer's temp. estimate is too high, and when corrected, he gives 163·5 Cals. for the heat of sublimation of carbon, and 168 Cals. for that of the diamond. H. Kohn and M. Guckel gave 140 Cals. for the heat of sublimation, M. Padoa gave 150 Cals., and J. J. van Laar 215·7 Cals. The value of this constant is therefore rather uncertain. J. J. van Laar gave 6470° for the **critical temperature** and 2970 atm. for the **critical pressure.**

R. Schenck and W. Heller attempted to estimate the **vapour pressure** of the different forms of carbon by starting from the equation $P=k_1(1+k)/k^2$, where P denotes the total gas press.; k_1 is the equilibrium constant for the system C, CO, CO_2; and k is the equilibrium constant for the system Fe, FeO, CO, CO_2. If k does not vary with the different forms of carbon, then at a constant temp., k_1 for the different modifications of carbon will be proportional to the total gas press., P. A. Thiel and F. Ritter obtained in air:

	3700°	3490°	3250°	2935°	2375°
Vap. press. . . .	760	240	120	20	0·04 mm.

and H. Kohn:

	4190°	4137°	4117°	4081°	4052°	4015°
Vap. press. .	760	608	509	380	327	243 mm.

O. Lummer represented the sublimation curve, or the vap. press., p atm., of carbon by $\log_{10}p=-282400/4·571T+14·645$; J. J. van Laar, and J. A. M. van Liempt gave $\log_{10}p=-47120T^{-1}+9·4$. According to W. Ostwald,[15] "the **heat of combustion** of carbon is one of the most important constants in thermochemistry; it is the foundation of all energy calculations in technical and physiological chemistry." It was first measured by A. L. Lavoisier and P. S. de Laplace, who found that *par le combustion d'une once de charbon* 6 *livres* 2 *onces de glace se fondaient;* this corresponds with the generation of about 7624 cals. by the complete combustion of one gram of carbon.

The calorimetric measurements of the heats of combustion of the different modifications of carbon differ considerably with every experimenter. M. Copisaroff attributes this to the different stabilities of the molecules, which in turn depend on the mode of linkage of the units constituting the molecule, and on the complexity of the molecule itself. The **heat of oxidation** of the diamond to carbon dioxide is, according to P. A. Favre and J. T. Silbermann, 7824 cals. per gram; W. A. Roth and H. Wallasch gave 7869 ± 3 cals.; and T. Andrews, 7678 cals. E. Petersen found 93·24 to 94·55 Cals. per gram-atom; and M. Berthelot and P. Petit, 94·31 Cals. per gram-atom of diamond-carbon, and 94·34 Cals. per gram-atom of boart-carbon. For the heat of oxidation of natural graphite to carbon dioxide, P. A. Favre and J. T. Silbermann found 7796·6 cals. per gram, and for artificial graphite, 7762·3 cals.; W. A. Roth and H. Wallasch, 7855 to 7865 cals. for purified cast-iron graphite; T. Andrews gave 7778 cals. per gram; and L. Grassi, 7883 cals. E. Petersen found 93·36 Cals. per gram-atom, and M. Berthelot and P. Petit, 94·81 Cals. per gram-atom. For the heat of oxidation of amorphous carbon to carbon dioxide,

C. M. Despretz gave 7912 cals.; P. L. Dulong, 7288 cals.; and T. Andrews, 8080 cals. For wood charcoal, P. A. Favre and J. T. Silbermann gave 8080 cals. per gram; for sugar charcoal, 8040 cals.; and for gas carbon, 8047·3 cals.; T. Andrews gave 7678 cals. per gram of wood charcoal. J. Thomson gave $C+O=CO+30·15$ Cals., and $C+O_2=CO_2+96·96$ Cals. M. Berthelot and P. Petit gave 97·65 Cals. per gram-atom of carbon oxidized to carbon dioxide. M. Berthelot and P. Vieille also compared the heat of combustion of the different kinds of carbon. Unlike M. Berthelot and P. Petit, W. A. Roth and H. Wallasch found the heat of combustion of the diamond, sp. gr. 3·503 at 18°, is greater than that of graphite. The former was found to be 7869 cals., and the latter 7830 to 7854 cals. N. I. Nikitin gave for wood charcoal with [C] and [H] per cent. of carbon and hydrogen respectively, $Q=80·51[C]+273·4[H]$. W. G. Mixter stated that at 20° acetylene black gives 7894 cals. per gram at a constant press. and vol. This constant is nearly equal to that for graphite, and is quite different from the results with sugar charcoal, wood charcoal, or gas carbon. Contrasting the heats of oxidation per gram-atom of the three allotropes of carbon, it follows that:

	Diamond	Graphite	Amorphous carbon
Heat of oxidation	94·31	94·81	97·85 Cals.

This means that the **heat of transformation** : graphite to diamond is 0·5 Cal.; amorphous carbon to graphite, 3·04 Cals.; amorphous carbon to diamond, 3·34 Cals. P. Poch found the heat of combustion of carbon derived from cyanogen to be greater than that of carbon from carbon monoxide. W. A. Roth and H. Wallasch consider that there are two well-defined varieties of graphite, α-graphite, including all natural varieties, which has a heat of combustion of 7830–7840 cals., and β-graphite, including artificial varieties, which has a heat of combustion of 7856 cals. The heat of combustion of the diamond is 7869 ± 3 cals.

The heat of combustion of ethane, 370·9 Cals., can be resolved into four separate operations: (i) the heat of dissociation of the C-H linkage, x; (ii) the heat of dissociation of the aliphatic C-C linkage, y; (iii) the heat of oxidation of monatomic hydrogen, v; and (iv) the heat of oxidation of carbon, z. Hence, $-6x+6v-y+2z=370·9$ Cals. J. Thomsen found 155·8 Cals. for the heat of combustion of the CH_2-group in a homologous series of hydrocarbons, so that $-2x+2v-y+z=155·8$ Cals. From these two equations, it follows that $z-2y=96·5$ Cals. Again, W. H. and W. L. Bragg showed that the carbon atoms in the diamond have the aliphatic linkage, so that if y' be the heat of formation of the -C-C- linking in the diamond, the heat of combustion, 94·4 Cals., of the diamond is $z-2y'=94·4$ Cals., which differs by only two Cals. from the value obtained by another process. Hence, the heat of formation of a -C-C- linkage in the diamond is nearly the same as that with the same grouping in aliphatic compounds. From the ionization potential of hydrogen $H+\frac{1}{4}O_2=\frac{1}{2}H_2O_{liquid}+74 \pm 3$ Cals., or $v=74$ Cals. Hence, with a knowledge of the heat of sublimation of the diamond, the first of the above equations is completely solved. The value of this constant is as yet somewhat uncertain.

K. Fajans estimates the heat of formation of a C-H linkage to be 117 Cals.; of a simple C-C linkage, 137·5 Cals.; and the heat of formation of gaseous carbon dioxide from a gram-atom of carbon vap. assumed monatomic is 381 Cals. For carbon in oxygen, making allowance for the heat of sublimation of the diamond, he gives $C_{vapour}+\frac{1}{2}O_2=CO+314$ Cals., and $\frac{1}{2}O_2+CO=CO_2+67·8$ Cals. K. Fajans discussed the energy of at. linkage in the diamond; and A. L. von Steiger, in graphite; W. Swientoslawsky found that the heat of formation of a number of carbon compounds is the sum of quantities made up additively of parts characteristic of single atoms. These characteristics are C-, 68·8 Cals.; H-, 48·2 Cals.; Cl-, 67·4 Cals.; Br-, 23·8 Cals.; and I-, 4·4 Cals. K. von Auwers also discussed this subject.

The anomalies observed in the heats of formation of the aliphatic hydrocarbons led K. Fajans to reject the idea that each carbon and hydrogen atom is respectively associated with four valencies and one valency. He claims that subsidiary valencies are exhibited in carbon compounds by the edges of J. H. van't Hoff's tetrahedron (1. 5, 15). The *edge valencies of carbon* play a considerable part in the internal energies of the compounds. Thus, whereas pentane and isopentane contain an equal number of principal -C-C- and -C-H- linkages, the number of edge valencies is dissimilar. The energy in the -C-C- edge linking is quite appreciable, and it is responsible for the lower heat of combustion of the diamond as compared with that of carbon in aliphatic compounds. Hydrocarbons with side chains contain more edge-linkages, and this is said to explain their higher heats of formation and lower heats of combustion than those of the isomeric compounds without side chains. The subject has been discussed by F. O. H. Binder, M. Padoa, A. L. von Steiger, J. P. Wibaut, H. Beutler, M. Polanyi, A. Thiel, W. Hückel, A. von Weinberg, W. Swientoslawsky, F. Kirchhof, etc.

The very high refracting power of the diamond was commented upon by Isaac Newton in his *Opticks* (London, 1704). The **index of refraction** is larger than that of any other substance. Isaac Newton gave 2·439. The great refracting power explains the remarkable scintillations of light which the diamond produces when properly cut. This subject has been discussed by P. Groth.[16] The index of refraction has been measured by J. C. Jamin, A. des Cloizeaux, J. Becquerel, H. Fizeau, F. Peter, A. Rochon, D. Brewster, W. Haidinger, A. Weiss, J. F. W. Herschel, etc. The mean values of determinations by B. Walter, and E. Wülfing respectively are as follow :

A	*B*	*C*	*D*	*E*	*F*	*G*	*h*	H_1-line
2·40242	2·40759	2·41037	2·41752	2·42692	2·43544	2·45129	2·45922	2·46517
2·40245	2·40735	2·41000	2·41734	2·42694	2·43539	2·45141	—	2·46476

A. Schrauf calculated μ_n for light of wave length λ_n from $\mu_n=2·378531+0·038696\lambda_D^2/\lambda_n^{-2}$, or $\mu_n=2·378531+0·013432\lambda_n^{-2}$. In opposition to the usual behaviour of regular crystals, A. Sella found that the index of refraction increases with a rise of temp., and for the interval 22° to 93°, the refractive index, μ, at $\theta°$, is $\mu=\mu_0\{1+0·00000771(\theta-\theta_0)\}$. P. Gaubert gave between 1·93 and 2·07 for graphite. J. C. Jamin found the index of refraction for coal to be 1·701; and for anthracite, 1·720. F. de la Provostaye and P. Desains, and W. Rosicky made observations on this subject. A. Schrauf gave for the diamond $(\mu^2-1)/D=0·001820$; and $(\mu-1)/D=0·000529$. H. Dufet gave $(\mu-1)^{-1}d\mu/d\theta=0·000015$; and, for the H_α-line, A. Haagen gave $(\mu-1)/D=0·4167$. P. Gaubert rubbed thin plates of graphite between two microscopic slides and obtained minute transparent laminæ which were green in transmitted light, and had a refractive index between 1·93 and 2·07 ; the optical character was negative. J. H. Gladstone said that the **refraction equivalent** of the carbon of diamonds is about 5, while the carbon in hydrocarbons increases as the hydrogen content decreases. F. Peter, A. Haagen, and J. W. Brühl, H. H. Landolt, R. Nasini, M. Zecchini, J. Traube, J. Amar, and A. Schrauf also made observations on the refraction eq., and the at. refraction. The **dispersion coefficient,** said A. Schrauf, is much less than might be anticipated from analogy with the values for organic compounds with a high content of carbon ; he gave $\mu_{Na}-\mu_{Li}=0·008778$; and $\mu_{Tl}-\mu_{Na}=0·008260$; E. Boutan gave 0·0044 for the dispersion coeff. J. H. Gladstone also made observations on the at. dispersion ; and R. W. Wood, on the anomalous dispersion of smoke films.

D. Brewster first noted the marked **double refraction** of the diamond, and observed that it is not what would be expected with isotropic crystals of the cubic system. As A. Schrauf has shown, the diamond is optically uniaxial. J. Dale noted that light is polarized elliptically by the diamond. The double refraction has been observed by many others—*e.g.* F. J. Arago, M. Trécourt and G. Oberhäuser, E. Mallard, H. C. Sorby and P. J. Butler, A. Schrauf, J. MacCullagh, J. Hirschwald, A. des Cloizeaux, etc. E. Cohen found the polarization with some crystals is as marked as in crystals of quartz. The phenomenon has been attributed to inclusions or cracks, but E. Cohen showed that the magnitude of the effect is not dependent on fissures or inclusions. E. Jannetaz regarded the double refraction as evidence of strains in the interior of the crystals; and R. Brauns concluded that the strains have not been produced by rapidly cooling the crystals, but rather by the diamond having been formed under great press. E. Mallard showed that the double refraction is not altered by heating the crystals; and H. Moissan observed the phenomenon with artificial crystals.

B. Walter observed in some diamonds an **absorption spectrum** with bands at $\lambda=4155$, between the G- and h-lines; the effect was marked in some yellow crystals, but feeble in red, green, and brown diamonds; a second band occurred with $\lambda=4710$; and another in the violet and ultra-violet. He attributed the absorption spectrum to the presence of rare earths, while J. Beckenkamp assumed that between the structural units of the diamond other carbon atoms—dissociated or in soln.—are present. M. Melloni found the **emissivity** of graphite for heat is 86, if that of soot is 100. W. W. Coblentz and E. Aschkinass measured the percentage **reflecting power,** R, of graphite for heat for rays of wave-length λ. The former found:

λ	500	600	800	1000	2000	3000	4000	5000	7000	9000
R	22·5	23·5	25·0	26·8	35·2	43·0	47·5	50·5	53·5	57·5

W. W. Coblentz said that with graphite the reflectivity is 23 per cent. in the yellow, gradually increasing to 63 per cent. at 10μ. From this low reflectivity at 2μ in the infra-red, there results a high emissivity, so that a graphitized carbon filament lamp cannot have the same luminous efficiency as the tungsten filament lamp at the same temp., although it has the higher emissivity in the visible spectrum. F. Haber[17] found the **vibration frequency** of carbon for red rays to be $39{\cdot}88\times10^{12}$, and for the violet rays, $10{\cdot}84\times10^{15}$. E. Rutherford and J. Chadwick[18] obtained no evidence of the emission of long-range particles of hydrogen when α-rays pass through carbon.

In 1662, R. Boyle[19] noted the **triboluminescence** of the diamond. He said, in his quaint way:

> Being rubb'd upon my cloaths, as is usual, to excite amber, wax, and other electrical bodies; it did, in the dark, manifestly shine like rotten wood, the scales of whitings, or other putrefied fish. . . . But this light was fainter than that of the scales and slime of whitings, and much fainter than the light of a glow-worm. . . . This glimmering, also, very considerably decay'd, immediately upon ceasing the friction; though the stone continued visible for some time after.

The phenomenon was also observed by J. P. Dessaignes, C. F. du Fay, J. Schneider, G. F. Kunz, L. Becker, J. Bernoulli and J. Cassini, and G. Halphen, etc. The last-named found a specimen with a rose-red glow. In the twelfth century, Albertus Magnus, in his *De rebus metallicis et mineralibus*, found that some diamonds became luminescent when placed in warm water; and in 1672, R. Boyle also observed the **thermoluminescence** of the diamond. He said:

> I found that holding a diamond a while near the flame of a candle, with my eyes turn'd contrary way, and immediately removing it to the dark, it disclos'd some faint glimmering, but inferior to that acquired by rubbing. . . I also brought the stone to some glimmering kind of light, by taking it into bed, and holding it a good while upon a warm part of my naked body.

The thermoluminescence was also noted by C. F. du Fay, T. Wedgwood, etc. B. Gudden and R. Pohl found that a small, clear, transparent diamond showed a **photoelectric effect** in strong electric fields; and it varied with the wave-length of the exciting light, falling continuously from $260\mu\mu$ to about $630\mu\mu$, when its value was zero. B. Gudden and R. Pohl studied the photoelectric conductivity of the diamond, and the relation between the structure and the electrical conductivity. The **photoluminescence** of the diamond, after exposure to light, was noted by F. Hoffmann in 1770. J. Wall also noted that the diamond is a *noctiluca*—to adopt R. Boyle's term—because it shines in the dark after it has been exposed to daylight. He noted that the phosphorescence is extinguished in *cold* water, but is restored when the temp. is restored; R. Boyle previously noted that the glow was not quenched under water. C. F. du Fay, and J. B. Beccari attributed the phosphorescence to the departure or entry of a "coloured sulphur" to or from the diamond. M. de Grosser noted that light filtered through a blue glass was a greater stimulant than light filtered through a red or yellow glass. T. J. Pearsall and A. M. Edwards observed the phosphorescence of diamonds which had been exposed to the light of an electric spark. J. F. Daubuisson, P. Riess, M. Chaumet, J. H. Gladstone, P. Heinrich, E. Becquerel, A. M. Edwards, G. F. Kunz, etc. made some observations on the phosphorescence of the insolated diamonds. G. le Bon found all the Brazilian diamonds he examined were photoluminescent, but only some of those from South Africa. H. Landrin must have made a mal-inference in stating that only cut diamonds are phosphorescent. M. Chaumet noted that diamonds phosphoresce strongly in **ultra-violet light.** O. Rosenheim found that the rays from a phosphorescing diamond, invoked by exposure to a magnesium light, do not affect a photographic plate.

In 1879, W. Crookes observed that diamonds phosphoresce various colours when bombarded by **cathode rays** in a vacuum tube. The gradual conversion of the diamond into graphite by this treatment has been previously mentioned. H. Becquerel found that the **phosphorescent spectrum** of a diamond has two continuous parts from *C* to *E*, and from *F* to *G*. The blue phosphorescence is produced by exposure to ultra-violet light. W. Crookes also studied the phosphorescent spectrum of the diamond exposed to cathode rays in a vacuum tube. The spectrum has a green line, $\lambda=5370$; a greenish-blue line, $\lambda=5130$; and a blue line, $\lambda=5030$. The X-ray spectrum of carbon has been studied by E. H. Kurth, F. L. Mohler and P. D. Foote, O. W. Richardson and C. B. Bazzoni, A. L. Hughes, R. A. Millikan, etc. C. W. Hewlett, and A. H. Compton investigated the scattering of X-rays by the diamond and by graphite, and obtained $\sigma/D=0·199$ for the former, and 0·201 for the latter. A. H. Compton measured the spectrum of the K-rays scattered by graphite. For the absorption coeff., C. W. Hewlett gave $\mu/D=0·551$, and $\mu=0·1084$; E. G. Taylor gave $\mu=0·1134$. F. K. Richtmyer, S. J. M. Allen, and A. R. Olson and co-workers measured the absorption coeff. for different wave-lengths. J. Holtzmark gave $\lambda=42·9$ for the wave-length of the *K*-radiation of carbon. J. A. Becker studied the effect of a magnetic field on the absorption of X-rays. J. C. McLennan and M. L. Clark gave 33·00 and 74·0 respectively for the critical voltages of the L-series of X-rays, $\lambda=373·7\times10^{-8}$ cm. and $166·7\times10^{-8}$ cm., from carbon.

H. Becquerel found that the phosphorescence of the diamond is invoked by exposure to **radium rays**; but not to **X-rays.** E. Newbery and H. Lupton also observed the blue luminescence of a diamond exposed to radium rays, and K. Keilhack said that diamonds are phosphorescent in X-rays. W. Marckwald also observed that diamonds become phosphorescent when exposed to radioactive bismuth or polonium. The diamond, said C. Doelter, is extremely transparent to the X-rays, and this is so characteristic that the effect can be used as a test to distinguish diamonds from other gem-stones. He also found that graphite is transparent to the X-rays, and if a plate of graphite, containing foreign matters, be exposed to X-rays, the enclosures appear as dark shades in the otherwise lighted background. P. Sacerdote found the X-rays had no sensible effect on the colour of the diamond, but A. Meyère, S. C. Lind and D. C. Bardwell found that a discoloration is developed. W. Crookes noted that when exposed to the cathode rays, the colour of a diamond turns brown; H. Moissan said that it is probable some graphite is formed, although P. Sacerdote said that this is unlikely because the discoloration vanishes when the stone is heated. J. A. Becker studied the absorption of cathode rays by carbon. W. Crookes noted that a yellow Bingara diamond became greenish-blue when exposed to radium rays, and A. Miethe observed a yellow tint was acquired under similar conditions. C. Doelter found that a yellow diamond became a deeper yellow, a green diamond became a deeper green, and a brown diamond more orange on exposure to radium rays, but with X-rays the brown diamond became violet-grey. The colour acquired by the diamond on exposure to X-rays, cathode rays, and radium rays, vanishes when warmed to 300°–400°; but is not perceptibly affected by exposure to ultra-violet light. The characteristic X-rays from carbon have been studied by A. L. Hughes, R. A. Millikan, E. H. Kurth, P. I. Lukirsky, etc. C. W. Hewlett found the mass scattering coeff. of X-rays of wave-length 0·712 A., to be 0·184 for liquid mesitylene, 0·198 for graphite, and 0·234 for the diamond. P. A. Ross measured the angles of reflection of X-rays by graphite. G. A. Hemsalech [20] studied the luminous phenomenon which occurs when a plate of graphite is raised to a high temp. by means of an electric current. J. E. P. Wagstaff gave 40×10^{12} for the **vibration frequency** of the diamond and $27·7 \times 10^{12}$ for graphite.

In 1802, W. H. Wollaston,[21] in a paper on *A method of examining refractive and dispersive powers by prismatic reflection,* mentioned the **flame spectrum** of carbon. He said:

> When a very narrow line of the blue light at the lower part of a flame is examined alone, through a prism, the spectrum, instead of appearing as a series of contiguous lights of different hues, may be seen divided into five images at a distance from each other. The first is broad and of a red colour terminated by a bright yellow line; the second and third are both green; and the fourth and fifth are blue.

J. Fraunhofer, J. F. W. Herschel, H. F. Talbot, F. von Wrede, A. Matthiessen, J. W. Draper, A. Masson, and D. Alter made some related observations. W. Swan [22] showed that the spectrum at the base of a candle flame has a number of bands fading away towards the blue with sharp heads on the red side. This spectrum is associated with a greenish-blue light. According to W. M. Watts and H. M. Wilkinson, in the so-called candle spectrum or **Swan's spectrum,** there is first an orange-yellow band, Fig. 16, with heads λ=6188·1, 6120·0, 6052·0, 5999·0, and 5955·0; a greenish-yellow band with heads λ=5435·4, 5585·5, 5540·9, 5500·0, and 5470·0; a green band with heads λ=5165·2, 5129·4, 5101·0, and 5081·9; a blue band with heads λ=4737·2, 4715·3, 4697·6, 4684·0, and 4677·0; and an indigo-blue band with a head fading both ways between λ=4381·9 and 4356·9; an indigo-blue detached line λ=4334·4; and a band between λ=4315·0 to 4234·0. Observations and measurements have been made by L. de Boisbaudran, A. J. Angström and R. Thalén, W. M. Watts, C. C. von Wesendonck, R. T. Simmler, R. Fortrat, A. Mitscherlich, J. Plücker and J. W. Hittorf, C. P. Smyth, J. M. Eder and E. Valenta, J. M. Eder, W. N. Hartley, C. Bohn, G. Gehlhoff, A. Smithells, J. R. Merton, E. Hulthén, etc. The spectrum occurs in the blue or greenish-blue parts of hydrocarbon flames burning in oxygen or gases containing oxygen; in the flame of cyanogen burning in

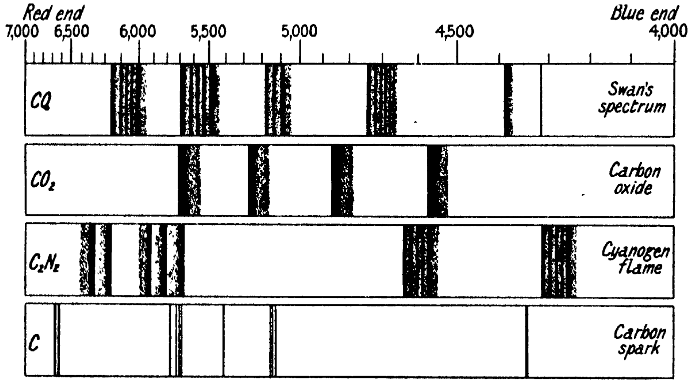

FIG. 16.—Spectra of Carbon and its Oxides, and of Cyanogen.

air; in the ordinary carbon arc in air; and in the spark discharge of many carbon compounds in the gaseous state.

There has been some controversy as to whether W. Swan's spectrum is produced by the element carbon, by a hydrocarbon, or by a carbon oxide. W. Swan considered that the spectrum is produced by a hydrocarbon, but he worked only with gases containing hydrocarbons. On the other hand, J. Attfield ascribed the spectrum to carbon because (i) the flame of cyanogen, C_2N_2, burning in oxygen, amongst other bands, shows this spectrum most brilliantly, when both gases are dry; and (ii) the spark spectrum of well-dried and purified cyanogen, carbon monoxide, or carbon disulphide, at atm. press., shows this same spectrum. The only constant in the composition of these gases is carbon, and therefore the spectrum must be due to that element. It has been objected that the temp. of an ordinary flame is not high enough to volatilize carbon, and hence asked: How can carbon be present in a state of vap. and give a continuous spectrum? H. C. Dibbits answered: Before combustion the carbon is present as a hydrocarbon, after combustion as an oxide; consequently, in passing from hydride to oxide, he argued that there must have been a certain stage of transition when each carbon atom was momentarily free and was able to furnish W. Swan's spectrum. He said:

> In what state of aggregation the free atoms of carbon exist in the flame at the moment of their separation cannot be determined; solid particles they are not, still less liquid; perhaps they are gaseous; and perhaps they are in a state which is not to be likened to any of the three known states. They do not, at any rate, remain long in this state; they combine with oxygen to form carbon monoxide or dioxide, or if they do not immediately burn, they agglomerate to form small solid particles of carbon, which remain for some time glowing in the flame, and are the cause of the bright light; they give then, like all solid bodies, a continuous spectrum which extends the further into the violet, the higher the temp.

In support of this, he explains the failure of the carbon monoxide flame to show W. Swan's spectrum, by stating that in this case the carbon is never free and uncombined. A. Gouy sprayed salts in a finely divided state into the flame, and showed that in the same zone it is possible to obtain the spectra of elements which it would be impossible to volatilize in the flame. Thus, the flame spectra with salts of iron, cobalt, manganese, and silver have the same lines as the spark spectra obtained with the metals. W. M. Watts observed that carbon tetrachloride also gave the characteristic flame spectrum, and J. N. Lockyer obtained the same spectrum when a strong spark did not reveal the presence of hydrogen. The carbon theory was supported by C. Morren, V. S. M. van der Willigen, W. Huggins, J. Plücker and J. W. Hittorf, A. Wüllner, etc.

J. J. Thomson, in his study *On the electrolysis of gases*, suggested a modification of the carbon hypothesis. In passing the electric discharge through chloroform vap., he found that hydrogen and chlorine collected about the negative electrode, but on the positive side Swan's spectrum was observed at first, and this rapidly changed into the carbon oxide spectrum, Fig. 16. With ethyl alcohol, Swan's spectrum appeared on the positive side, and the carbon oxide spectrum on the negative side. With carbon monoxide, there was no difference in the spectra of the gas about the two electrodes, but if a little hydrogen be present, the carbon oxide spectrum appears on the negative side, and Swan's spectrum on the positive side. He thus summarized his conclusions:

> **The view which seems most in accordance with these observations is that the so-called candle spectrum or Swan's spectrum is the spectrum of the carbon when the atom is charged with negative electricity, or of some compound of carbon in which the carbon atom is charged with negative electricity; while the carbon oxide spectrum is the spectrum of carbon when the atom is charged with positive electricity or some compound in which the carbon atom is positively charged.**

While the supporters of the carbon theory rely on the development of the band spectrum in gases free from hydrogen, and all thoroughly dried, the supporters of the hydrocarbon theory, on the other hand, say in effect that it is a mere *façon de*

parler to say that the gases employed in producing the band spectrum are free from hydrogen because it is impossible to exclude all traces of moisture, and if moisture is present, hydrocarbons will be produced in the burning gas. They also emphasize the fact that this spectrum is well developed when hydrocarbons are known to be present. In their *Recherches sur les métalloïdes* A. J. Angström and R. Thalén, after an examination of the spark spectra of carbon in various gases, in the *auréole* between the electrodes, and not in *le trait de feu*—the path of the spark, decided against the carbon theory and supported the hydrocarbon hypothesis. The auréole, when in oxygen, showed the spectrum of carbon monoxide; when in nitrogen, it showed blue and violet bands superposed on W. Swan's spectrum, these were attributed to a compound of carbon and nitrogen; and when in hydrogen, it showed W. Swan's spectrum. Since the discharge from carbon electrodes in hydrogen furnishes acetylene, it is concluded that W. Swan's spectrum is produced by that gas. They state that, in the first instance, they were led to ascribe Swan's spectrum to a hydrocarbon, because of its general resemblance to the spectrum of the oxides of the alkaline earth metals. After describing Swan's spectrum, they said:

> Cette description de l'aspect des raies est tout-à-fait identique à celle donée auparavant par rapport aux raies des oxydes métalliques, et nous pensons que cette analogie remarquable ne peut être entièrement fortuite.

They state that elementary carbon is characterized by a line spectrum, while Swan's spectrum is conditioned by the atm. in which the discharge occurs, for it is found only in the auréole. C. P. Smyth supported the hydrocarbon theory. G. D. Liveing and J. Dewar observed the spectrum of the electric arc between carbon poles in air, chlorine, carbon monoxide and dioxide, hydrogen, nitrogen, nitric oxide, and ammonia. They also examined the flames of some carbon compounds. They concluded:

> In the next place, the green and blue bands, characteristic of the hydrocarbon flame, are well seen when the arc is taken in hydrogen; but though less strong when the arc is taken in nitrogen or in chlorine, they seem to be always present in the arc whatever the atm. This is what we should expect, if they be due, as A. J. Angström and R. Thalén suppose, to acetylene; for we have found that the carbon electrodes always contain, even when they have been long treated in chlorine, a notable quantity of hydrogen. In the flames of carbon compounds, they by no means always appear; indeed, it is only in those of hydrocarbons or their derivatives that they are well seen. Carbon monoxide and carbon disulphide, even when mixed with hydrogen, do not show them; and if seen in the flames of cyanogen, hydrogen cyanide, and carbon tetrachloride mixed with hydrogen, they are faint, and do not form a principal or prominent part of the spectrum. This is all consistent with the supposition of A. J. Angström and R. Thalén.

G. D. Liveing and J. Dewar later admitted that carbon vap. might exist in the cyanogen flame, and they abandoned the acetylene theory. They regarded acetylene to be the means of bringing carbon vap. into existence in flames, and pointed to the invariable presence of this gas in the interior of hydrocarbon flames. They said that acetylene is a highly endothermal substance, but A. Smithells showed that however true this may be, it is probably very erroneous at the temp. at which carbon is given off as a vapour. He also showed that the acetylene flame is exceptionally opaque.

After reviewing the evidence for the carbon theory, A. Smithells concluded that there is no reliable evidence to warrant the supposition that the flames of carbon compounds contain carbon vapour. On the contrary, there is much evidence against such a supposition. He then showed that the hydrocarbon theory resolves itself into a consideration of acetylene and methane as a likely source, since these are the only two hydrocarbons which W. A. Bone and D. S. Jordan found to be stable at high temp. in the presence of carbon and hydrogen. The fundamental difficulty with either acetylene or methane is presented by the appearance of Swan's spectrum in the flame of cyanogen.

The spectrum of the flame of *cyanogen* burning in air, or generally, in oxidizing gases, has been observed by J. F. W. Herschel, H. F. Talbot, H. C. Dibbits, A. Mitscherlich, R. Thalén, R. T. Birge, G. Salet, H. Kayser and C. Runge, H. Crew and O. H. Basquin, F. Exner and E. Haschek, H. Deslandres, F. Jungbluth, A. Hagenbach and H. Konen, J. Haferkamp, J. M. Eder, J. M. Eder and E. Valenta, J. Plücker and J. W. Hittorf, C. Morren, M. Berthelot and F. Richard, A. Kratzer, U. S. Uhler and R. A. Patterson, A. Perot, L. Kilchling, J. Okubo, W. Grotrian and C. Runge, Lord Rayleigh, A. S. Herschel, J. Dewar, C. P. Smyth, H. W. Vogel, W. N. Hartley, H. Crew and O. H. Basquin, A. S. King, A. de Gramont and M. Drecq, E. C. C. Baly and H. W. Syers, etc. The flame spectrum of cyanogen includes (i) $\lambda=7102$ to 5245; (ii) $\lambda=4606\cdot33$ to $4502\cdot35$; (iii) $\lambda=4216\cdot12$ to $4152\cdot88$; (iv) $\lambda=3883\cdot55$ to $3855\cdot06$; (v) $\lambda=3590\cdot48$ to $3584\cdot06$; and (vi) $\lambda=3360\cdot1$. As pointed out by J. Attfield, the spectrum of the cyanogen flame includes Swan's spectrum, with presumably the same origin, and two distinct groups; (i) those at the less refrangible or red end extend into the yellow and green. The sharp edge or head is on the most refrangible side—*i.e.* in the opposite way to the hydrocarbon bands—and the bands fade in brightness towards the red end. They are not seen in any other flame; and (ii) the bands at the more refrangible or blue end which fade in brightness towards the violet. The bands corresponding with Swan's spectrum have presumably the same origin, and are superposed on bands produced by a compound of carbon and nitrogen. The same bands occur much fainter in the flame of cyanogen burning in oxygen, and C. Morren, and W. M. Watts attribute this to the smaller proportion of undecomposed cyanogen at the higher temp. of the flame burning in oxygen. The bands in the red become more brilliant when the cyanogen is burnt in oxygen. In addition to the red and yellow bands, there are bands in the blue, violet, and ultra-violet. These latter bands have been ascribed to carbon, since they have been reported in carbon compounds not containing nitrogen; but G. D. Liveing and J. Dewar, in agreement with A. J. Angström and R. Thalén, attributed the channelled spectra of the hydrocarbon and cyanogen flames to acetylene and cyanogen, and not to carbon itself. The presence of traces of moisture and nitrogen as impurities in the gases employed explains the formation of both cyanogen and acetylene. Hence, the flame of cyanogen may show the hydrocarbon spectrum superposed on that of cyanogen; and in vacuum tubes, containing hydrocarbons, the cyanogen spectrum may be observed. G. D. Liveing and J. Dewar found in agreement with W. M. Watts that the bands in the blue, violet, and ultra-violet appear in the spark spectrum of carbon monoxide at ordinary press. if that gas has been made from potassium ferrocyanide, but not if made from the action of sulphuric acid on dried sodium formate, or by heating a mixture of quicklime and dry potassium oxalate; the bands were stated by W. M. Watts, and J. N. Lockyer to occur in the spark spectrum of carbon tetrachloride, but, added G. D. Liveing, not if all traces of air have been expelled from the apparatus. Similar results are obtained with naphthalene.

The spark spectrum in cyanogen gas, or the spectrum of the ordinary carbon arc in air, is due either to carbon plus cyanogen, or to carbon at a high temp. The less refrangible group of the cyanogen flame spectrum is absent in the spark spectrum. It is difficult to obtain cyanogen of a sufficiently high degree of purity to furnish what might be called the pure cyanogen spectrum, but E. C. C. Baly and H. W. Syers obtained cyanogen in vacuum tubes which, in the electric discharge, showed no trace of the carbon spectra, but yielded a "very beautiful and characteristic cyanogen spectrum." The spectrum differs from that derived from the flame. They said:

> It presents a series of equidistant flutings through the whole of the red and yellow, somewhat recalling those of the positive band spectrum of nitrogen. The cyanogen bands are, however, much wider than the nitrogen bands, and do not show the break in the orange characteristic of the nitrogen spectrum. The flutings under higher dispersion are split into very fine lines.

The admission of air or oxygen into the vacuum tube was at once attended by the appearance of Swan's spectrum. They concluded that Swan's spectrum is not produced by a carbon compound which does not contain oxgyen. A. Smithells also, prior to E. C. C. Baly and H. W. Syers, showed that the brilliant Swan's spectrum from the flame of cyanogen burning in oxygen is not likely to depend on the presence of an irremovable quantity of impurity, and he showed it to be far more probable that *Swan's spectrum is due to carbon monoxide* which is "formed in the primary chemical act of combustion whenever Swan's spectrum appears in the hydrocarbon flame."

W. M. Watts described what he called the four spectra of carbon: (i) W. Swan's spectrum of hydrocarbon flames; (ii) the spark spectrum of vacuum tubes containing carbon monoxide or dioxide, or ethylene; (iii) the spectrum of the flame from Bessemer's steel converter; and (iv) the spectrum of the high tension spark in carbon monoxide or dioxide. He later showed that the spectrum of the Bessemer flame was due to manganese oxide; and that the second spectrum is due not to carbon but to some oxide of carbon, and is not given by ethylene if special precautions be taken to exclude oxygen. When an intense spark, obtained with a Leyden jar and air-break in circuit, is sent through carbon monoxide or dioxide, the spectrum of carbon is obtained. W. M. Watts produced the carbon lines in the spectrum from fused alkali carbonates, and also from the spark between carbon electrodes. The more intense lines in the **line or spark spectrum** of carbon are 6439·4, 6162·5, 6122·5, 5857·8, 5594·6, 5589·0, 5349·7, 5270·5, 4878·3, 4586·1, 4455·0, 4435·1, 4425·6, 4302·7, 4226·9, 3968·6, 3933·8, and 3644·5.

The spark spectrum of carbon has been observed and described by W. M. Watts, W. Wüllner, A. J. Angström and R. Thalén, G. D. Liveing and J. Dewar, W. N. Hartley, W. N. Hartley and W. E. Adeney, J. M. Eder, J. M. Eder and E. Valenta, H. Deslandres, A. de Gramont, F. Exner and E. Haschek, J. Hartmann, A. Hagenbach and H. Konen, W. A. Miller, H. C. Dibbits, W. Huggins, J. Plücker and J. W. Hittorf, C. P. Smyth, W. Spottiswoode, W. Crookes, H. A. Rowland, H. Rubens and H. Konen, H. Finger, H. Reubens and A. Aschkinass, J. Trowbridge, A. M. Herbert, J. Hartmann, etc. The **arc spectrum** has been observed by M. le Rosa, A. Secchi, G. D. Liveing and J. Dewar, R. Thalén, A. L. Foley, W. B. Huff, W. W. Coblentz, S. Procopiu, F. Simeon, etc. The effect of an alternating current on the arc spectrum has been studied by L. Puccianti, H. Crew and B. J. Spence, etc. The effect of an electric spark on carbon vap. in the arc was observed spectroscopically by H. Crew and J. C. Baker. The effect of self-induction on the spectrum was observed by A. de Gramont; and M. Toussaint examined the effect of argon, and of iodine vap. The **band spectrum** has been investigated by J. Attfield, A. Morren, A. Lielegg, C. P. Smyth, G. Salet, W. M. Watts, C. C. von Wesendonck, L. Thollon, G. D. Liveing and J. Dewar, C. Fievez, J. S. Stas, J. N. Lockyer, J. M. Eder and E. Valenta, A. Smithells, H. Konen, P. Lewis, etc. Attempts to establish series formulæ have been made by H. Deslandres, R. Kemp, T. N. Thiele, J. Leinen, H. Kayser and C. Runge, R. Fortrat, O. H. Hindrichs, F. Croze, W. Ritz, J. Halm, F. Jungbluth, J. Haferkamp, A. S. King, A. Fowler and co-workers, T. Lyman, R. J. Strutt, etc. Difficulties have been encountered in separating the lines due to oxygen and those due to carbon. W. Huggins could get this spectrum only from carbon monoxide or dioxide; and A. J. Angström and R. Thalén obtained it in hydrocarbons when they used a large condenser. A. Schuster and H. E. Roscoe showed that the spectra obtained from the different varieties of carbon are identical.

J. Plücker showed that *carbon dioxide* in a vacuum tube gives a spectrum which has, at first, an intense band in the red. This he attributed to carbon dioxide. He found that the carbon dioxide band gradually disappears owing to the slow decomposition of carbon dioxide by the spark. A. Wüllner has given a detailed description of the phenomenon observed at different press., with changes in the character of the discharge, and in the length of the containing tubes. The carbon dioxide spectrum has been investigated by V. S. M. van der Willigen, F. Brasack, W. H. Bair, E. F. Barker, J. N. Collie, E. R. Drew, T. Lyman, F. Himstedt and

H. von Dechend, etc. Neither G. Salet nor A. Smithells could obtain the red line characteristic of carbon dioxide, and the former said that this line belongs to the line spectrum of carbon. A. Smithells worked with carbon dioxide prepared from the liquefied gas, and dried by phosphorus pentoxide. The press. was gradually reduced, and Table III shows the chief consecutive changes. In addition to the carbon oxide spectrum, three other spectra are involved: (i) Swan's spectrum; (ii) The carbon line spectrum; and (iii) The oxygen spectrum. A. Smithells then showed that the so-called carbon oxide spectrum (Fig. 15) is really the spectrum of carbon dioxide—*vide infra*.

TABLE III.—THE EFFECT OF PRESSURE ON THE SPECTRUM OF CARBON DIOXIDE.

Stage of exhaustion.	Ordinary discharge.	Condensed discharge—jar and air-gap.
1	Faint carbon oxide (linear)	Carbon and oxygen lines.
2	Bright carbon oxide (glow)	Carbon and oxygen lines.
3	Brighter carbon oxide	As above with wide gap; with medium gap Swan's spectrum.
4	Very bright carbon oxide	As gap is widened spectrum changes from carbon oxide to Swan's, and to carbon and oxygen lines.
5	Fading carbon oxide	As gap is widened spectrum changes from carbon oxide directly to carbon and oxygen lines.
6	Slow fading of carbon oxide	As before, fading slowly.

The spectrum of the flame of *carbon monoxide* is continuous, but, under reduced press., G. J. Burch observed the flame spectrum shows signs of becoming discontinuous. The spark spectrum is readily obtained from a vacuum tube filled with carbon monoxide. Some of the bands are very close to the bands in W. Swan's spectrum, and the two spectra may easily be confused. C. P. Smyth attributed the spectrum of carbon monoxide to carbon. In the production of the spark spectrum of oxygen, all carbonaceous impurities must be rigorously excluded or else the spectrum will belong to carbon monoxide, not oxygen. The more prominent carbon monoxide bands are: 6079 in the yellow; 5607·5, 5197·0, 5187, 5184, 5182, 5179, 5176, 5173, 5170, and 5167 in the green; the bands 4834, 4823, 4821, 4819, 4817, 4789, 4786, 4510, and 4394 in the blue. The carbon monoxide spectrum has been examined by A. Wüllner, W. M. Watts, H. Nagaoka, A. J. Angström and R. Thalén, J. Plücker, A. de Gramont, W. N. Hartley, E. Hulthén, C. C. von Wesendonck, J. Loos, G. D. Liveing, F. Exner and E. Haschek, M. Tietz, F. Himstedt and H. von Dechend, T. Lyman, etc. A. Smithells examined the effects of different stages of exhaustion on the spectrum of carbon monoxide, and the main features are summarized in Table IV.

TABLE IV.—THE EFFECT OF PRESSURE ON THE SPECTRUM OF CARBON MONOXIDE.

Stage of exhaustion.	Ordinary discharge.	Condensed discharge—jar and air-gap.
1	Swan's spectrum	No discharge.
2	Swan's and faint carbon oxide	Swan's spectrum.
3	Swan's and weak carbon oxide	Swan's spectrum and carbon and oxygen lines.
4	Swan's and carbon oxide equal	Carbon and oxygen lines with a short gap, the carbon oxide is visible; and with a longer gap a faint Swan's spectrum displaces the carbon oxide.
5	Swan's weakening, carbon oxide strengthening	
6	Carbon oxide only	
7	The carbon oxide fades; the spectrum grows in intensity and then fades until the tube is fluorescent	No discharge.

M. Tietz found that the condensed discharge with platinum electrodes at ordinary

atm. press. gave a spectrum with the lines of oxygen and carbon only. Following a hint by G. G. Stokes, A. Smithells demonstrated that in all probability, while the so-called carbon oxide spectrum is the spectrum of carbon dioxide, Swan's *spectrum is the spectrum of carbon monoxide*; and he summarized the arguments *as follows:*

(1) The carbon monoxide and Swan's spectra are strikingly similar, and the actual differences are such as might be expected from the mol. differences of the two oxides.

(2) Carbon monoxide gives Swan's spectrum predominantly except under extreme conditions. If the passage of the discharge is electrolytic—alternate dissociation and recombination of carbon and oxygen—the process in the tube has a chemical feature in common with that occurring in flames showing Swan's spectrum.

(3) Under extreme conditions of gaseous or electrical press., carbon monoxide gives either the carbon oxide or the carbon line spectrum, or both. These extreme conditions correspond to the maximum heating effects of the discharge when the gas might be expected to decompose: $2CO \rightleftharpoons CO_2 + C$, as shown by H. St. C. Deville, and V. Meyer and C. Langer. A black deposit formed on the tube near the electrodes observed by G. D. Liveing and J. Dewar, was found by A. Smithells to be carbon, and was formed only when the carbon line spectrum is visible.

(4) Carbon dioxide furnishes the carbon oxide spectrum most readily, and this remains at high exhaustions. At ordinary atm. press., the gas gives only the line spectrum of carbon and oxygen. A condensed discharge favours the formation of Swan's spectrum. This accords with the facts that carbon dioxide is a good conductor; and when the heating effect of the discharge is intensified, the gas is dissociated into carbon monoxide and oxygen. The condensed discharge in the highly rarefied gas produces the line spectrum of carbon and oxygen. If the oxygen lines are visible, the carbon lines are also visible. The gas is not readily dissociated into carbon monoxide and oxygen under these conditions. V. Meyer and C. Langer's experiments showed that carbon dioxide is not readily dissociated at a high temp., whereas carbon monoxide easily breaks down. In opposition to this, J. N. Collie found that carbon dioxide under low press. is rapidly decomposed by the discharge from an ordinary induction coil—65 per cent. being decomposed in 10 secs. Under similar conditions carbon monoxide was found to be far more stable.

(5) G. D. Liveing and J. Dewar found that the carbon arc-discharge in carbon monoxide gave Swan's spectrum with no trace of the carbon oxide spectrum. This is what would be anticipated if Swan's spectrum is due to carbon monoxide, and the carbon oxide spectrum to carbon dioxide.

(6) The spectrum of the carbon arc in air contains Swan's spectrum together with groups of lines which G. D. Liveing and J. Dewar, H. Kayser and C. Runge, and M. Tietz attribute to cyanogen or to carbon in association with nitrogen. Swan's spectrum is ascribed to the well-known fact that carbon monoxide is formed in the arc. In support of this is G. D. Liveing and J. Dewar's observation that the arc in the middle of a magnesia crucible often shows signs of Swan's spectrum although that of cyanogen is strong. If, however, puffs of air or carbon dioxide are passed into the arc, Swan's spectrum is produced; this also is the case if one of the carbon poles be moistened. The spectrum of the arc under water shows Swan's spectrum alone.

E. C. C. Baly and H. W. Syers supported A. Smithells' theories as to the genesis of Swan's and the carbon oxide spectra. They obtained Swan's spectrum from carbon monoxide when highly purified, but a trace of hydrogen or oxygen changed Swan's spectrum into the carbon oxide spectrum. The chief difficulty, said A. Smithells, is to be found in the frequently recorded observations of Swan's spectrum under conditions which appear to exclude the presence of that gas. The spectrum of *hydrocarbons* has been investigated by C. Morren, M. Berthelot and F. Richard, B. von Lengyel, V. Henri, B. Hasselberg, H. Deslandres, C. Fievez, A. Kratzer, E. E. Brooks, etc. F. W. Klingstedt studied the spectrum of *phenol*; W. C. Holmes, that of *p-cymene*; V. Henri, and W. H. McVicker and co-workers, C. F. Meyer and D. W. Bronk, J. M. Hyatt, J. E. Purvis, that of *benzene*; V. Henri and P. Steiner, that of *naphthalene*; J. W. Ellis, that of *chloroform*; and J. M. Hyatt, that of *anthracene*. H. Konen, and W. M. Watts and H. M. Wilkinson found that organic liquids containing oxygen like *methyl and ethyl alcohols*, *glacial acetic acid*, etc.; and organic liquids not containing oxygen, like chloroform, *carbon tetrachloride*, *ethyl bromide*, *ethylene dibromide*, *aniline*, *pyridine*, *naphthalene*, and *benzene* purified in many cases by repeated distillation over bright sodium, still gave Swan's spectrum. A. Smithells mentioned the great difficulty encountered by H. B. Baker in freeing *carbon tetrachloride* from oxygen; H. B. Baker's, and J. J. Thomson's observations on the important part played by traces of moisture in the passage of electricity through gases; B. Hasselberg's observations that some kinds of glass persistently give rise to carbon and oxygen which bring to light the carbon oxide spectrum; and G. D. Liveing and J. Dewar's observations on the extreme sensibility of the spectroscopic test to traces of impurity.

The **absorption spectra** of the vap. of benzene has been investigated by E. Dickson, L. Grebe, and W. N. Hartley; of toluene, by F. Cremer; of ethylbenzene and para-xylol, meta-xylol, and ortho-xylol by W. Mies; and of chlorobenzene, bromobenzene, iodobenzene, and aniline by H. Koch. The **fluorescent spectra** in general correspond with the absorption spectra. Observations on the spectrum of the *flame from Bessemer's converter* have been made by W. M. Watts, A. Lielegg, G. J. Snelus, W. M. Williams, etc. For the spectra of the sun, comets, etc., *vide* the occurrence of carbon. The **ultra-red spectrum** has been studied by W. H. Julius, E. C. Kemble, C. Schaefer and M. Thomas, J. M. Eder, A. M. Herbert, E. P. Lewis and E. S. Ferry, K. Angström, H. Rubens and A. Aschkinass, H. Lehmann, H. Hermann, E. R. Drew, W. W. Coblentz, A. Bergmann, W. J. H. Moll, etc. The **ultra-violet spectrum** has been studied by G. D. Liveing and J. Dewar, R. A. Millikan, W. W. Shaver, J. C. McLennan and P. A. Petrie, W. H. Fulweiler and J. Barnes, F. Simeon, etc. The influence of *temperature* on the spectrum has been studied by W. M. Watts, etc.; the influence of *pressure* by E. Villari, F. Benevides, G. D. Liveing and J. Dewar, W. J. Humphreys, J. E. Petavel and R. S. Hutton, A. Hagenbach, J. Haferkamp, etc.; and the influence of *magnetism*, by G. Berndt, and R. Fortrat. The series spectra were discussed by A. Fowler.

R. Boyle[23] stated that the diamond has an electrical virtue, for, after being rubbed on cloth, it attracts light bodies, like amber, jet, etc., though in a less degree. R. J. Haüy said that the raw or cut diamonds are positively electrified by friction, but the charge is rapidly lost; graphite, however, develops no frictional electricity when rubbed with resin or shellac. L. B. G. de Morveau, L. V. Brugnatelli, and J. F. L. Hausmann and F. C. Henrici found the diamond to be a very bad electric conductor; graphite and amorphous carbon, on the contrary, are comparatively good conductors. A. Artom found the sp. **electrical conductivity** of the diamond, at 15°, to be between $0{\cdot}211 \times 10^{-14}$ and $0{\cdot}309 \times 10^{-13}$ reciprocal ohms. Measurements were made by J. Königsberger, C. Doelter, H. von Wartenberg, D. E. Roberts, W. Geiss, C. E. Williams, and K. Arndt and F. Körner. J. Priestley noted that charcoal is a good conductor of electricity. According to A. Matthiessen, if the electrical conductivity of silver at 0° is 100, that of graphite ranges from 0·00395 to 0·0693. He also found that the electrical conductivity of purified graphite is eighteen times greater than that of natural graphite; and this shows the importance of the degree of purity of graphite on its physical properties. J. Königsberger and O. Reichenheim found for Cingalese graphite, per cm. cube, the sp. **electrical resistance**, R,

	−185°	−66	0°	21°	61°	89°	105°	147°	191°
R . .	0·00428	0·00335	0·00295	0·00283	0·00265	0·00254	0·00250	0·00238	0·00220

They did not succeed in establishing data for the resistance parallel and perpendicular to the principal axes. The sp. resistance at $\theta°$ between 0° and 280° is $R = 0{\cdot}00291(1 - 0{\cdot}001280\theta)$; H. Muraoka gave for Siberian graphite $R = 0{\cdot}00122(1 - 0{\cdot}000739\theta + 0{\cdot}0_6273\theta^2)$. The decrease in the resistance with temp. is smaller than is the case with amorphous carbon. J. Zellner gave 2–8 ohms for the resistance of Cingalese graphite at 20°; and for a commercial graphite electrode, 12 ohms. F. Streintz gave 14·20 ohms for the resistance of powdered graphite, and H. Muraoka, 12·20 ohms. A. Bartoli found that the coarser the grain-size of the graphite the larger the conductivity. A. Artom gave for Greenland graphite the sp. conductivity $0{\cdot}247 \times 10^4$; Cumberland graphite, $0{\cdot}054 \times 10^4$; and for Siberian graphite $0{\cdot}082 \times 10^4$ reciprocal ohms at 14°. H. Muraoka gave $0{\cdot}0871 \times 10^4$ rec. ohms at 0°, and F. Streintz, $0{\cdot}0705 \times 10^4$; B. Piesch gave for Cingalese graphite,

$0·079\times10^4$ to $0·385\times10^4$ rec. ohms at 0°. L. Cellier gave $13·049\times10^{-9}$ mho for the conductivity of graphite of sp. gr. 1·698; $146·32\times10^{-9}$ for that of electric light carbon of sp. gr. 1·467; $267·88\times10^{-9}$ for the similar material of sp. gr. 1·567; and $185·99\times10^{-9}$ for gas retort carbon of sp. gr. 1·627. Observations have been also made by K. Bädeker, J. Königsberger, W. Geiss, R. von Hasslinger, G. Kirchhoff, F. Auerbach, J. Borgmann, J. W. Howell, F. le Roy, Lord Kelvin, and H. G. Martin. The relative electrical resistances of graphite electrodes were found by C. A. Hansen to be

	25°	400°	800°	1200°	1600°	2000°	2200°
Per cent. .	100	94·0	81·5	66·0	65·0	68·0	69·0

Graphite electrodes which had been fired to 1200° and cooled off gave 91·6 per cent. of the original resistance (100), and similarly at other temp.

Fired at . . .	1200°	1600°	2000°	2400°	2800°	3500°
Resistance cold . .	91·6	87·0	77·6	65·9	50·9	22·4

E. Ryschkewitsch found the resistance, *R* ohms, of different samples of graphite compressed at different press., *p* atm. The results are shown in Table V, where the values of *a* refer to the constant: $R=a/p+0·0075$.

TABLE V.—ELECTRICAL RESISTANCE OF GRAPHITE AT DIFFERENT PRESSURES.

	Carbon, per cent.	Press. in atm.				*a*
		14·5	86·8	151·0	215·5

A. Avogadro, F. von Kobell, W. G. Mixter, and A. Franck observed that, compared with other non-metallic conductors, amorphous carbon is a good electrical conductor. A. Matthiessen found that at 25°, the conductivity of gas carbon is 0·0386, when that of silver is 100 at 0°. W. von Siemens gave $0·0145\times10^4$ mhos for the conductivity of gas carbon at 0°, and H. Muraoka, $0·0204\times10^4$ for gas carbon, and $0·0248\times10^4$ mhos for commercial arc-light carbons. J. Dewar and J. A. Fleming found the sp. resistance of a carbon filament of a commercial incandescent lamp to be

	99°	18·9°	1°	−80°	−100°	−182°
$R\times10^{-9}$ . . .	3835	3911	3953	4054	4079	4180

F. Streintz gave 0·25 rec. ohms for the conductivity of amorphous carbon at 12°; W. Beetz gave for carbon dust $0·0306\times10^4$ rec. ohms; and F. Lucas, $0·0142\times10^4$ at 15°. F. Streintz found the sp. resistance of lampblack is 4000 ohms, and as with electrolytes, the resistance decreases as the temp. is raised. H. Violette found that the electrical conductivity of wood-charcoal increases with the charring temp.; and that prepared at 1500° conducts electricity better than gas carbon. R. Ferrini, H. Tomlinson, and S. Bidwell showed that the conductivity of carbon dust is increased by compression.

J. Borgmann, W. von Siemens, W. Beetz, and H. Muraoka measured the effect of *temperature* on the conductivity. The conductivity increases as the temp. is raised. J. Monckmann stated that the rate of the change of the resistance of carbon with temp. rises up to 250°, and thereafter increases. S. P. Thompson said that the influence of press. on the conductivity is not perceptible. P. W. Bridgman measured the effect of *pressure* on the electrical resistance of massive graphite, but found the results not very reliable. With gas carbon, the resistance at 30° decreases with rising press., and the proportional effect becomes smaller at higher press. The decrease of resistance was 6·86 per cent. at 6000 kgrms. per sq. cm., and 12·07 per cent. at 12,000 kgrms. per sq. cm. At 96° up to 3000 kgrms. per sq. cm. press., the coeff. is about 4 per cent. greater. The resistance decreases linearly with temp. between 0° and 100°, and at 100°, the resistance is 2·56 per cent. less than it is at 0°. With a sample of Acheson-graphite the total fractional increase of resistance under 12,000 kgrms. per sq. cm. decreases with rise of temp., being 4·75 per cent. at 0°, 4·23 per cent. at 50°, and 4·23 per cent. at 100°. The increase is not linear, being 3·44 per cent. at 0° and 6000 kgrms. per sq. cm. The large departure from linearity indicates a maximum, and in no other substance is there any evidence of a maximum or a minimum being reached at high press. The press. coeff. for carbon in the amorphous and graphitic states have opposite signs. K. Arndt and F. Körner measured the electrical resistance of a number of artificial and natural graphites. They also examined the effect of the *grain size* with two samples of graphite; they reported

Grain size	>0·15 mm.	0·06 to 0·15 mm.	<0·06 mm.
Resistance	40	44	52 ohms.
	77	85	123 „

K. Siebel found that the electrical resistance of carbon was raised considerably by *gas absorption*.

E. Aschkinass studied the relation between the electrical conductivity and *reflecting power*; and A. Bartoli compared the conductivity and composition of different kinds of carbon. K. Arndt and W. Fehse, T. C. Mendenhall, O. Boekmann, etc., also made observations on this subject. S. Bidwell found a mixture of finely divided graphite and 20 per cent. of paraffin is a good conductor, but with 30 per cent. of paraffin the conductivity is nearly zero. J. A. Cunningham measured the potential gradient of hot carbon; and J. A. Pollock and A. B. B. Ranclaud, F. Deininger, and O. W. Richardson studied the emission of negative ions by heated carbon. J. A. Pollock and co-workers studied the potential at the surface of heated carbon.

J. Probert and A. W. Soward [24] found that the conductivity is affected by absorbed gases—the magnitude of the effect depends on the nature of the gas. T. Peczalsky found that hydrogen produces no effect on the electrical resistivity of carbon at ordinary temp., or press. up to 33 atm., but the resistance increases considerably when a carbon filament is heated in hydrogen to a high temperature, and the resistance at room temperature after such a heating in hydrogen shows a similar and more marked increase, while if the filament be heated in vacuo to the same temperature the resistance decreases in value. The effect is greater the higher the press. of the hydrogen. According to J. Monckmann, when two rods of carbon, one charged with hydrogen and the other with oxygen, are in electrical contact, the current passes from the hydrogen to the oxygen. The wires and rods are found to have an increased resistance, that of the oxygen rod being the greater. The effect disappears after short-circuiting. If the wires or rods be charged twice in opposite directions, the effect disappears, unless the second charging is of very short duration; in this case, a reversal takes place. With carbon rods at different temp. in contact, reversal occurs at 250°; with a thermoelectric couple of carbon and platinum, the thermoelectric line rises below 250°, and falls above that temp. G. Tammann found that when a cold rod of any substance is dipped in hot carbon powder, it becomes covered with a layer of the powder the thickness of which increases with the difference of temp. between rod and powder. Powders other than carbon do not exhibit this phenomenon, and it is therefore assumed that the effect is not electrical. It is supposed to be due to the occlusion by carbon of the gases given off by the rod. R. D. Kleeman and W. Frederickson studied the electrical charge assumed by a filament of carbon dipping in a liquid.

J. Buchanan placed carbon between zinc and silver in the **electrochemical series.** According to A. Coehn, H. C. Pease, and A. Avogadro, the **electrochemical equivalent** of carbon is 3, if that of hydrogen be unity. C. Fromme measured the **electromotive force,** *i.e.* the potential difference of gas carbon in nitric and chromic acids. A. Voller found that the potential difference of carbon in nitric acid is not much affected by raising the temp. from 0° to 100°. G. Gore measured the e.m.f. of carbon in soln. of potassium chloride, bromide, iodide, and cyanide. S. Marianini measured the potential difference of carbon in sea-water ; M. Faraday, of carbon in hydrochloric acid ; J. C. Poggendorff, of carbon and graphite in soln. of ammonium chloride, potassium cyanide, and potassium ferrocyanide. The use of carbon as the negative pole in batteries has been discussed by G. Wiedemann. D. Tommasi described a cell using a carbon rod surrounded by lead dioxide in one compartment, and a carbon rod with a soln. of sodium or calcium chloride in the other. The reactions are said to be $C+2H_2O=CO_2+2H_2$, and $2H_2+PbO_2=Pb+2H_2O$. C. J. Reed said that 42 cals. of energy are consumed and not generated by such a cell. According to F. Haber and L. Bruner, there is a difference of potential of about a volt between carbon and iron rods immersed in fused sodium hydroxide; and in the electrolyte, the current flows from the carbon to the iron. The iron rapidly dissolves, but it may become passive. If the iron is immersed in fused sodium nitrate, it is covered with a dark skin of oxide, which is difficult to remove ; such iron is passive. The addition of alkali manganate to the sodium hydroxide also produces the passive condition, and the more readily the less water the sodium hydroxide contains. This is explained by the fact that dry sodium hydroxide does not yield any hydrogen when electrolyzed, and therefore, since no hydrogen can be evolved at the surface of the iron, the skin of oxide is formed more completely. Since all sodium hydroxide, especially when fused in contact with iron and air, contains more or less manganate, it appears that iron protected by a skin of oxide and immersed in sodium hydroxide containing manganate is really an oxygen electrode, the part played by the manganate being that of an intermediary, by means of which the atm. oxygen can pass into the ionic condition. The e.m.f. of the combination, passive iron in sodium hydroxide | calomel electrode, was found to be −0·265 volt at 312°, increasing to −0·472 volt at 532°. This e.m.f. is independent of the quantity of manganate in the electrolyte as this is not very small or very large. The e.m.f. of the combination, carbon in fused sodium hydroxide | calomel electrode, varies greatly with the nature of the carbon employed, −0·66 volt being found with artificial graphite and −1·4 with a partially disintegrated, arc-lamp carbon. The carbon is attacked by fused sodium hydroxide, hydrogen being evolved. The more rapid the evolution of hydrogen, the greater is the e.m.f. When a very rapid evolution of hydrogen is produced by heating the sodium hydroxide to 500°, the e.m.f. rises to −1·5 volts. When a platinum tube, through which a current of hydrogen is passed, is substituted for the carbon electrode, the same e.m.f. is observed, namely, −1·48 to −1·5 volts. It appears, therefore, that the carbon electrode is really a hydrogen electrode. That an e.m.f. lower than −1·5 volts is often observed is readily explained by the partial depolarization of the electrode by the manganate present in the electrolyte. It is only when the temp. is sufficiently high to produce a rapid evolution of hydrogen that the full value is observed. When the carbon is once charged with hydrogen, however, it retains the high e.m.f. for some time at lower temp. The carbon electrode is really a hydrogen electrode, the hydrogen being formed by the action of carbon on sodium hydroxide, and the reaction to which the e.m.f. of the cell is due is the formation of water from this hydrogen and atm. oxygen. The e.m.f. of the cell agrees well with the e.m.f. required to decompose into hydrogen and oxygen the small quantities of water dissolved in fused sodium hydroxide. V. Karpen studied these cells.

E. Newbery found that the **overvoltages** of graphite and gas carbon are very variable in both acid and alkali. In acid, that of graphite rises to a very high value at high current density and the electrode disintegrates rapidly. With gas carbon, the disintegration is still greater, whilst the overvoltage is lower. At low current densities, the disintegration is very slight, especially with graphite, but the surface is softened and the whole electrode becomes very brittle. Little or no deposit appears on the cathode. In alkali-lye, even at the lowest current densities, a black deposit is produced on the cathode, but the disintegration of the anodes is much less. No visible change is produced at the anode after passing currents up to 100 milliampères per sq. cm. for half an hour. With a current at 1000 milliampères per sq. cm., a gas carbon electrode gradually disintegrates, the liquid is discoloured, and a shower of small carbon particles falls to the bottom of the vessel. Under similar treatment, a graphite electrode acquires a crystalline appearance and a few particles fall off, but there is very little discoloration of the electrolyte. The crystalline appearance is produced in acid or alkali at high current densities, and, after drying, microscopic examination reveals the fact that the finely divided materials between the larger crystals have been carried away, leaving the crystals themselves almost untouched. A. Günther-Schulze measured the cathode potential of graphite in different gases. J. W. Langley, C. Liebenoff and L. Strasser, F. Exner and J. Tuma, etc., have studied this subject. H. Ayrton, W. Mathiesen, A. E. R. Westman and W. J. Clapson, E. Rasch, and V. L. Crisler studied the potential gradient and general characteristics of the **carbon arc**; W. G. Duffield and co-workers, the recoil press.; and K. T. Compton, ionization in the carbon arc.

The **Volta effect** of the sodium and carbon couple was measured by E. Corminas; and that of the couples gas carbon or wood charcoal with gold or platinum, by A. Bartoli and G. Papasogli. W. Skey measured the Volta effect with graphite and native sulphides. The **thermoelectric force** of the platinum and carbon couple was found by J. Buchanan to be $176+2\cdot07\theta$ C.G.S. units at $\theta°$; and of the carbon and lead couple, $390-1\cdot87\theta$. J. Weiss and J. Königsberger gave $5\cdot3\times10^{-6}$ volt for the thermoelectric force of the copper and carbon couple. H. Muraoka found graphite to be thermoelectrically negative against other varieties of carbon. H. Zahn made observations on the **thermomagnetic properties** of carbon.

According to M. Faraday,[25] amorphous carbon and graphite are but feebly magnetic; and F. Zantedeschi found them to be diamagnetic. A. L. Holtz also said that soot, fir-wood charcoal, and graphite are diamagnetic; P. Pascal found that sugar charcoal, freed from hydrogen and iron, is diamagnetic, the **magnetic susceptibility** is -52×10^{-6} mass units, and it is not affected by six hours' heating in vacuo at a red heat; for the diamond he gave $-0\cdot52\times10^{-6}$ units. S. Meyer gave for graphite at 18°, -8×10^{-6} vol. units; and for the diamond at 13°, $-1\cdot1\times10^{-6}$ vol. units, and $-0\cdot33$ mass units. K. Honda found the magnetic susceptibility of arc carbons at 18° to be $-2\cdot0\times10^{-6}$ mass units; and at 1160°, $-1\cdot5\times10^{-6}$ units; likewise for the diamond, at 18°-500°, he gave $-0\cdot49\times10^{-6}$ units. P. Pascal computed the at. susceptibility of carbon with various linkages. M. von Pirani found the **dielectric constant** of the diamond to be 16·47 for $\lambda=\infty$; W. Schmidt obtained 5·50 for $\lambda=75$; and A. Coehn and U. Raydt, 5·18 to 8·0. M. von Pirani gave 2·4 for wood charcoal of sp. gr. 1·4.

§ 9. The Adsorption of Gases, etc., by Carbon

A. A. C. Swinton [1] found that diamonds contained no occluded neon, krypton, or other rare gas which is set at liberty when the diamond is transformed into graphite. As previously indicated, D. Brewster's discovery of inclusions of liquid carbon dioxide in some diamonds led many to infer that the diamond has been formed in the presence of this gas under press. J. Werth heated boart under water and noted that some gas was given off ; the gas contained : Carbon, 97 ; hydrogen, 0·5 : and oxygen, 1·5 per cent., and he referred the small flame observed in the combustion of the diamond to occluded gas. J. Dewar measured the gases occluded in graphites from different sources, and found :

Source	Vol.	CO_2	CO	H_2	CH_4	N_2
Meteoritic . .	7·25	91·81	--	2·50	5·50	0·10
Borrowdale . .	2·60	36·40	7·77	22·20	26·11	6·66
Siberia . . .	2·55	57·41	6·16	10·25	20·83	4·16
Ceylon . .	0·22	66·60	14·80	7·40	3·70	4·50

While the occluded gas in diamonds is insignificant, the constant presence of hydrocarbons, hydrogen, etc., in amorphous carbon led M. Berthelot to the belief that amorphous carbon is really a hydrocarbon *extrêmement condensé*. O. L. Erdmann and R. F. Marchand were not able to remove all the hydrogen and oxygen from charcoal at the strongest heat of a blast. T. E. Doubt found that the heats of adsorption and evolution by charcoal are equal, and argued that the process is reversible. J. C. Philip and co-workers studied the relation between the temp. of carbonization of charcoal and its adsorptive capacity. A. Vladislavovitsch measured the dehydration curves of charcoals charged with adsorbed water vapour, and found a lag behind the hydration curves. Two per cent. of adsorbed water remained after drying to constant weight ; and much of the adsorbed water is retained even after heating to redness in a current of nitrogen, and it is probably chemically combined with the charcoal. He therefore argued that charcoal is not appropriate for studying the phenomena of adsorption, since its behaviour depends on the nature and past history of the charcoal used.

In 1777, F. Fontana [2] discovered that freshly calcined charcoal, cooled under mercury, has the power of absorbing comparatively large volumes of gas ; and about the same time C. W. Scheele observed that air was also absorbed in a similar way. J. Priestley, L. B. G. de Morveau, J. C. Delamétherie, G. F. Parrot and D. H. Grindel, H. G. Rouppe and M. van Noorden, and S. Saluzzo made some observations on this subject ; and in 1783, C. L. Morozzo showed that the amount absorbed is *specific* in that it depends on the kind of charcoal employed ; and *selective* in that it varies with the nature of the gas. In addition to the observations mentioned below, adsorption has been studied by C. F. Schönbein, H. T. Brown, R. Engel and A. Moitessier, N. F. I. Isambert, J. Böhm, F. Hart, S. G. Hedin, W. Vaubel, A. Wohl and M. S. Losanitsch, G. Craig, A. Berliner, W. Müller-Erzbach, H. Vohl and co-workers, E. Blumtritt, P. A. Favre, H. Violette, M. Böttcher, G. Dreyer and J. S. C. Douglas, etc. According to G. Tammann and H. Diekmann, mercury resting over powdered carbon, dried at 300°, runs below the powder when warmed to 35°.

The effect with different kinds of charcoal.—J. Hunter measured the effect with different kinds of charcoal, and found that that made from the shell of the cocoanut adsorbed the largest proportion of gas—ammonia, carbon dioxide, or cyanogen. K. Hayashi, and A. Piutti and G. Maglia also compared the sp. gr. and the adsorptive power of the different charcoals, and the results of the last-named are indicated in Table VI for temp. between —100° and 550°. Those charcoals marked with an asterisk are from shells and kernels. N. A. Yajnik and T. C. Rana found mulberry charcoal gave better results than that from tali or from acacia in absorbing salts from soln. It will be obvious that although a rough parallelism between density and adsorptive power can be detected in some cases, there are so many deviations from the rule that it is obvious some other factor or factors are involved. M. Berthelot emphasized the fact that charcoal is not pure carbon, and it is probable that the impurities present in the different varieties affect the adsorptive power in different ways. The porosity, in the ordinary sense of the term, is not the determining factor because cocoanut charcoal is one of the densest of charcoals, and yet J. Hunter found it possessed the greatest adsorptive power. N. T. de Saussure considered that the adsorptive power depends on the *area* of the exposed surface: but A. Piutti and G. Maglia state that the amount adsorbed varies with the *structure*, so that, as W. D. Bancroft puts it, narrow pores down to a certain limit adsorb more than the same surfaces would do if the pores were of larger diameter. P. Chappius found that the increased surface produced by grinding is so small in comparison with the total adsorbing surface, that the increased adsorption produced by grinding is inappreciable. In confirmation, L. Gurwitsch, and F. Bergter found that grinding increases the speed of adsorption, but the final result is independent of the grain-size. H. H. Lowry and G. A. Hulett found that no relation exists between the amount of gas—nitrogen, carbon dioxide, or water—adsorbed and the length of time the charcoal has been in use. Differences in the method of preparing the charcoal may change the absorptive capacity 100 per cent. —*vide supra*, activated charcoal. This was also emphasized by H. B. Lemon, and H. H. Sheldon. H. H. Lowry and G. A. Hulett also found that the phenomenon with oxygen is complicated by the superposition of two effects—adsorption and surface combination. O. Ruff and E. Hohlfeld assumed that the activity of the different kinds of charcoal is proportional to the content of certain foreign atoms. The subject was also investigated by J. C. Philip and co-workers and by H. Briggs.

TABLE VI.—ADSORPTIVE POWER AND SPECIFIC GRAVITY OF DIFFERENT CHARCOALS.

Kinds of charcoal.	Vols. of air per vol. of charcoal.	Sp. gr.
Prunus cerasus (Sour cherry)*	280·1	1·6398
Cocus mucifera (Cocoanut)*	251·8	1·4497
Phillyrea media (Jasmine box)	222·4	1·4970
Grevillea robusta (Silky oak)	212·7	1·4383
Abies alba (White spruce)	199·5	1·1901
Castanea vesca (Chestnut)	186·3	1·3000
Buxus sempervirens (Box)	138·5	1·4192
Liospunos kaki (Chinese persimmon)	134·5	1·3398
Populus nigra (Black poplar)	134·1	1·2802
Prunus virginiana (Choke-cherry)	133·0	1·2359
Ceratonia siliqua (Carob)*	131·5	1·6274
Prunus armeniaca (Apricot)*	129·5	1·3994
Juglans regia (Walnut)	118·6	1·3132
Pinus rigida (Pitch-pine)	111·1	1·3114
Robinia pseudoacacia (Common locust)	99·9	1·2218

The effect with different gases.—N. T. de Saussure found the different values indicated in Table VII for the volumes of different gases adsorbed by one vol. of box-wood charcoal at 724 mm. press. and 12°. It was inferred that in general the volume of gas adsrobed is greater the higher its b.p. For comparison, the b.p. of the gases are indicated in the table. The rule is followed roughly, although there

TABLE VII.—THE ADSORPTION OF DIFFERENT GASES BY CHARCOAL.

Gas.	Vol. of adsorbed gas.	B.p. of gas.
Ammonia	90	−35·5°
Hydrogen chloride	85	−82·9°
Sulphur dioxide	65	−10°
Hydrogen sulphide	55	−60·2°
Nitrous oxide	40	−89·8°
Carbon dioxide	35	(−79°)
Ethylene	35	−105°
Carbon monoxide	9·42	−190°
Oxygen	9·25	−182·8°
Nitrogen	7·5	−195·7°
Hydrogen	7·175	−252·6°

are exceptions; and it is probable that the adsorptive power depends on some specific relation between the gas and the charcoal, as well as on the extent of the adsorbing surface. R. E. Wilson found that the number of mols of oxygen adsorbed at any given final press. is very nearly 1·3 times the number of mols of nitrogen adsorbed at the same final press. J. Driver and J. B. Firth studied the adsorption of alcohol, methyl benzoate, carbon tetrachloride, chloroform, benzene, ethyl propionate, ethyl ether, toluene, and carbon disulphide from sat. vap. B. E. Brown investigated the effect of temp. and press. on the adsorption of water by charcoal; and W. Möller, the adsorption of formaldehyde. H. Herbst inferred that with gaseous chloropicrin, benzyl chloride, and phosphorus tribromide, one mol is fixed per six gram-atoms of carbon. S. McLean studied the adsorption of helium by charcoal; A. B. Ray, the adsorption of benzene; and H. Briggs, the adsorption of organic vapours. The adsorption of chlorine was investigated by C. S. Bohart and E. Q. Adams; air, by J. Samejima and K. Hayashi; of hydrogen, and carbon dioxide by R. Lorenz and E. Wiedbrauck; R. M. Winter and H. B. Baker, sulphur dioxide; H. Briggs, nitrogen and hydrogen; A. S. Coolidge, benzene, carbon disulphide, ether, chloroform, carbon tetrachloride, methyl acetate, ethyl formate, and water; and of carbon dioxide and nitrous oxide by L. B. Richardson and G. B. Woodhouse. H. S. Harned found that with chlorine the adsorption is complicated by a reaction between the water present and the chlorine for which the carbon acts as a catalyst. H. Herbst, A. Vladislavovitsch, and R. E. Wilson, and T. Fuwa studied the humidity equilibrium of different kinds of carbon.

The effect of temperature on the adsorption of gases.—N. T. de Saussure showed that the amount of gas adsorbed by a given mass of charcoal decreases as the temp. is raised. P. Chappius found the volume of carbon dioxide adsorbed at different temp. with the press., maintained constant at 472 mm. (when the vol. of gas is reduced to 0°), to be

	0°	14·94°	25·05°	36·06°	44·41°	54·63°	62·59°	70·92°
Adsorbed gas	1156·59	940·25	800·77	665·31	574·40	477·89	411·97	347·73

Thus, the amount adsorbed at 70·92° is but one-third of that adsorbed at 0°. J. Dewar found that at temp. in the vicinity of liquid air the adsorption is remarkably great; thus, the number of c.c. of gas reduced to 0° and 760° mm. press., adsorbed per c.c. of cocoanut charcoal is as follows:

	H_2	N_2	O_2	A	He	CO_2
At 0°	4	15	18	12	2	21
At −185°	135	155	230	175	15	190

The press. of the adsorbed gas at these low temp. is very small. Similarly, J. L. Bärwald found with elderberry charcoal:

	10°	0°	−10°	−50°	−100°	−130°	−150°	−185°
H_2	3	4	4	9	24	44	76	153
O_2	61·7	66·7	70·0	105·0	165·0	215·0	245·0	—
Air	35·0	36·7	40·0	65·0	116·7	165·0	200·0	262·3

The adsorption with nitrogen is nearly the same as with air. A. M. Williams represents the effect of temp. by $\log (v/p)=a+b/T$, where v denotes the amount of gas adsorbed; p, the equilibrium press.; T, the absolute temp.; and a and b, constants not dependent on T. D. C. Henry represents the effect of temp. on adsorption equilibrium by $p=\xi T e^{-\lambda/Rt}$, when ξ is independent of temp., and λ is the internal heat of evaporation.

The great avidity with which charcoal adsorbs air at a low temp. was utilized by P. G. Tait and J. Dewar, in 1874, in the production of high vacua. An ordinary vacuum tube containing a small piece of charcoal would not allow a spark to pass when it was cooled in liquid air. It was found that with a 300 c.c. bulb with air at 15°, and a press. 1·7 mm., and in contact with another bulb containing 5 grms. of charcoal, when cooled by liquid air, the press. fell to 0·00005 mm. A radiometer attached to a charcoal bulb when cooled by liquid air showed no motion when the beam from an electric arc-light was focussed on the vanes.

The effect of pressure on the adsorption of gases.—N. T. de Saussure showed that the adsorption is increased by raising the press., but not proportionally. According to P. Chappius, if the temp. be 0°, and the press. p mm., then the volume, v, of gas, in c.c. at 760 mm. press., adsorbed by 15·119 grms. of charcoal from the *helvella esculenta*, is:

p	1·13	2·23	4·70	9·86	20·12	77·12	335·00	763·38
v	10·50	23·18	52·72	100·57	178·16	438·24	892·76	1165·66
v/p	9·29	10·39	11·22	10·20	8·85	5·68	2·66	1·53

If Henry's law were applicable, the quotient v/p would be constant. Corresponding results were obtained by H. Kayser, and L. Joulin. B. Gustavson found that at low press.—4·6 to 17·4 mm.—charcoal adsorbs the vapour of water and acetic acid proportionally to the press. The velocity of adsorption is greater the lower the press. Below 7·4 mm., the adsorption involves the formation of solid soln.; above that press., simple adsorption occurs. Higher press. were used by E. W. R. Pfeiffer for carbon dioxide and ammonia. A selection from the results is given in Table VIII.

TABLE VIII.—EFFECT OF VARIATIONS OF TEMPERATURE AND PRESSURE ON THE ADSORPTION OF AMMONIA AND CARBON DIOXIDE BY CHARCOAL.

Press. atm.	Observed vol. of gas.			Vol. reduced to 0° and 760 mm.		
Carbon dioxide	12·4°	16·4°	20·4°	12·4°	16·4°	20·4°
2·23	36·42	35·44	34·06	78·43	75·93	71·30
3·57	26·47	25·60	24·87	92·06	87·79	84·36
5·00	20·58	19·92	19·43	101·40	96·77	93·07
6·38	16·73	16·37	15·89	106·76	103·00	98·55
7·22	15·13	14·85	14·61	110·75	106·33	103·06
8·20	13·76	13·30	13·06	114·55	109·66	105·01
Ammonia	13·4°	17·4°	20·4°	13·4°	17·4°	20·4°
2·86	65·00	64·34	64·18	177·07	172·48	169·92
3·57	53·84	52·24	52·95	184·89	180·01	176·90
5·00	40·47	39·97	39·78	199·31	193·26	189·82
6·38	34·15	31·72	31·84	225·09	203·46	200·41

The decrease in the observed (unreduced) vol. with increasing press. is not constant as would be anticipated if Henry's law were applicable. The increase in the reduced vol. with increasing press. becomes less as the press. increases. M. W. Travers measured the press., p, and conc., x, of carbon dioxide and hydrogen occluded by carbon at temp. between −78° and 100° in the former case, and between −190°

and 100° in the latter case. The results show that the relation can be represented by a formula of the type $x^n = kp$, where k is a constant. For hydrogen at $-190°$, n is nearly 3; and for carbon dioxide at 0°, $n=3$, and at 100°, $n=2$. H. Briggs and W. Cooper found that, at 15°, the capacity of commercial gas cylinders when filled with dry hydrogen, nitrogen, or oxygen at a given press. is greater when the cylinders are filled with an adsorbent such as charcoal or silica gel than when empty. At 35 atm., the capacity for nitrogen is increased 66 per cent. by filling with cocoanut charcoal. At higher press., the increase in capacity is not so great. To be effective, the adsorbent must be dry. Sudden outbursts of *firedamp in coal mines* have been found to be the result of releasing immense quantities of gas adsorbed under press. in coal.

The vap. press. of a film of adsorbed gas has no known relation with that of the liquefied gas. The equilibrium vap. press. of a liquid is constant at a given temp. only when the disturbing effects due to gravitation, capillary forces, etc., are eliminated. Hence, the equilibrium vap. press. of a thin film of liquid is not the same as the vap. press. of the liquid *en masse*, and it may vary with the nature of the adsorbing solid. J. Dewar found that at $-185°$, the amounts of hydrogen, v c.c., adsorbed per gram of cocoanut charcoal at a press., p atm., were:

p	1	5	10	15	20	25
v	92	138	156	149	145	138

He assumed that the decrease from 156 to 138 c.c. per gram is due to an experimental error. It is assumed that above 10 atm. press. the adsorption is independent of the press., and that the adsorption has reached a limit. According to H. Kayser, if p denotes the press., and v the vol. of hydrogen adsorbed per c.c. of charcoal, $v = 0{\cdot}6036 - 1{\cdot}35 \log p$, at 0°.

The curve obtained by plotting the amounts of adsorbed gas at different press., and at a constant temp., is called the **adsorption isotherm**; and with J. Dewar's data, the adsorption isotherm is concave to the press. axis. According to H. Freundlich, if v denotes the vol. of the gas adsorbed by 1 grm. of charcoal, at a temp. $\theta°$, when the equilibrium press. is represented by p; and v_0 is a constant representing the vol. of gas adsorbed at $\theta°$ under a press. of 1 cm., the **adsorption isotherm equation** has the form:

$$v = v_0 p^{1/n}; \quad \text{or,} \quad p = \left(\frac{v}{v_0}\right)^n;$$

where n is a constant. This empirical equation usually takes the eq. form: $(x/m)^n = kp$, or $n \log (x/m) = \log (kp)$, where n and k are constants, and x represents the amount of gas adsorbed by a mass m of solid. The exponent $1/n$ is less than unity, and geometrically it represents the slope of the logarithmic curve.

The equation $u = kC^{1/n}$ can be derived from the following hypotheses. Let the free surface energy of a bare surface (in vacuo) be σ_0 ergs sq. cm.; and the free surface energy of the same surface covered with a unimolecular layer of gas be σ_1. When the system is in equilibrium, let u denote the area of the bare surface, and u_1 the area of the surface covered, then the fraction $u/u_1 = \zeta$ will denote the fraction of the surface covered. Let σ denote the free energy of the whole surface when the range of mol. action is small. Then, $\sigma = \sigma_0(1-\zeta) + \sigma_1$; or, $\sigma = \sigma_0 - (\sigma_0 - \sigma_1)u/u_1$. From J. W. Gibbs' equation (1. 13, 22), $u = -Cd\sigma/RTdC$, and by differentiation and substitution,

$$u = \frac{C}{RT} \cdot \frac{\sigma_0 - \sigma_1}{u_1} \cdot \frac{du}{dC}.$$

By integration, writing $\log k$ for the integration constant, and putting $n = (\sigma_0 - \sigma_1)/RTu_1$, it follows that $\log u = (1/n) \log C + \log k$, or $u = kC^{1/n}$, as above. Similarly, for adsorption from dil. soln., D. C. Henry concluded that the greater the value of n at a given temp., the greater the work done in the orientation of the surface mol, such that if W denotes the non-osmotic work in the adsorption of a mol of solute from a dil. soln., $n - 1 = W/RT$.

F. W. Küster employed a form of this equation where $1/n = \frac{1}{2}$ for the partition of ether between water and caoutchouc. A. M. Williams has deduced an equation:

where α and β are functions of the temp. H. Freundlich also tried C. Kröker's formula:

$$\lambda=\beta(a/v)^{-1/n}$$

where a denotes the original amount of solute before adsorption; a/v is the original conc. of the substance, and λ, β, and n are constants, but, as J. W. McBain has shown, it is very unsatisfactory. The equation has been discussed by *I. M. Kolthoff, W. Ostwald, M. Polanyi, D. C.* Henry, M. Geloso, S. Wosnessensky, A. Eucken, D. Reichinstein, B. Iliin, L. Berényi, etc. The general equations for different types of adsorption have been discussed by B. Gustaver, D. C. Henry, W. Ostwald and R. de Izaguirre.

The mean value of $1/n$ in the isotherm equation is always less than unity, and it changes over moderate ranges of press. up to one atm., and it rises with temp., *e.g.* M. W. Travers' observations on the absorption of carbon dioxide by charcoal show that

	−78°	0°	35°	61°	100°
$\frac{1}{n}$ . . .	0·13	0·30	0·46	0·48	0·52

A. E. M. Geddes represented his values of v and p by $v=0{\cdot}0602p^{0{\cdot}565}$; the following is a selection of the observed and calculated values of v:

p . . .	41·5	194	340	453	602	698	703
V Obs. . .	1·7	4·0	5·4	6·5	7·6	8·6	8·9
V Calc. . .	1·7	4·0	5·5	6·4	7·6	8·3	8·4

A. Reychler found that for the absorption of carbon dioxide by blood charcoal, $n=1$, and $v=0{\cdot}00024p$, which means that the amount of gas adsorbed is proportional to the partial press. of the carbon dioxide in the vap. phase. As shown by A. M. Williams, with gases which are not copiously adsorbed, and where p is accordingly small, the value of n approximates to unity, as is the case, for example, with A. Titoff's observations on the adsorption of hydrogen by charcoal. This is shown by the linear curves, Fig. 17, over moderate press. The isotherm equation then reduces to $v=v_0p$, which is the same as Henry's law. A. M. Williams found the adsorption isotherm of sulphur dioxide and charcoal runs the same course as a typical vap. press. curve. With gases copiously adsorbed—*e.g.* ammonia or carbon dioxide—the work of I. F. Homfray, L. B. Richardson, etc., shows that the isotherm bends round quickly so that the curves tend to become parallel to the press. axis, showing that a large increase in press. produces only a slight increase in adsorption, Fig. 18. L. B. Richardson's observations on ammonia and carbon dioxide show that through a limited range of press., the degree of adsorption is in fair agreement with the logarithmic form of H. Freundlich's equation; but at higher press., the adsorption rapidly decreases, indicating that at each temp. there is reached a maximum which cannot be increased by increasing the press. Observations on the effect of press. were made by A. Pickles, etc.

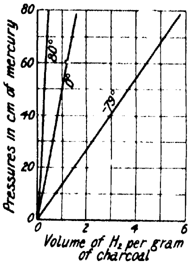

FIG. 17. — Equilibrium Pressures of Hydrogen adsorbed by Charcoal.

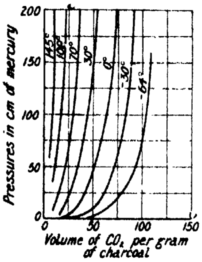

FIG. 18. — Equilibrium Pressures of Carbon Dioxide adsorbed by Charcoal.

According to Lord Blythswood and H. S. Allen, if p denotes the press. of air at the time, t, reckoned from the commencement of the adsorption, by charcoal, and p_1 is the final press. when the adsorption is completed, $\log(p-p_1)=a+bt$, where a and b are constants. From this it follows, by differentiation, that the *velocity of adsorption*, at any instant, is proportional to the quantity of air yet to be adsorbed before the saturation limit is reached. F. Bergter represented the rate of adsorption of nitrogen between 0·38 and 9·6 mm. press. by the expression $v=v_0(1-0\cdot95e^{-35t}-0\cdot05e^{-0\cdot15t})$, where v_0 is a constant, and v denotes the vol. of gas (reduced to 18° and 760 mm) adsorbed by a gram of charcoal; and for air, the corresponding expression is $v=v_1t/(a+t)+v_2t/(b+t)$, where v_1, v_2, a, and b are constants—*vide infra*, the mechanism of adsorption.

If M denotes the total weight of gas held by 1 grm. of absorbent; M_1, that part of the gas which is adsorbed; and p, the press., A. M. Williams' relation can be written $\log(M/p)=A_0+A_1M_1$, where A_0 and A_1 are constants, and $M=M_1+kp$, where k is a constant. H. Briggs defines the *prehensility*, σ, of the substance for a particular gas at a particular temp. as the slope of the curve representing the amount of gas adsorbed and the press., so that $dM/dp=\sigma$; and therefore $\sigma=e^{A_0}+k$. In this way he found the prehensility of plumstone and cocoanut charcoals for nitrogen to be respectively 9×10^{-2}, and $4\cdot5\times10^{-2}$; and likewise for hydrogen, $1\cdot2\times10^{-3}$ and $0\cdot6\times10^{-3}$.

The adsorption of mixed gases.—The proportions of constituents adsorbed from a mixture of gases has not been closely studied. H. Freundlich found that when charcoal charged with a gas is introduced into an atm. of a more readily adsorbed gas, the former is displaced by the latter, and in rather a larger proportion than would have been predicted from the adsorption coeff. of the individual gases. F. Bergter found that oxygen at 0·5 to 10 mm. press. is adsorbed 30 to 40 times as strongly as nitrogen, and that the presence of oxygen increases the amount of nitrogen absorbed. J. Hunter noted that the presence of adsorbed water favoured the adsorption of ammonia by charcoal, possibly owing to the dissolution of some of the ammonia in the adsorbed water. J. Matwin noted that a kilogram of charcoal will reduce the sulphur content of illuminating gas in 10 cub. metres of gas to 2·92 grms. by the adsorption of carbon disulphide and carbonyl sulphide. The more porous varieties of charcoals were the most effective. W. Hempel and G. Vater studied the adsorption of mixtures of hydrogen with acetylene, ethylene, methane, and ethane, and of nitrogen with ethane. When the different constituents of a mixture of gases are adsorbed in the same ratio as they occur in the mixture, a separation will not be possible; and when the ratio of the two gases adsorbed by the charcoal differs from the ratio of their proportions in the gas phase a kind of fractional separation will be possible. Thus, J. Dewar used the energetic adsorption of hydrogen by wood charcoal at low temp. to separate this gas from neon, helium, etc., which are adsorbed to a far smaller extent. W. Ramsay, and S. Valentiner and R. Schmidt found the process to be easy and rapid of application. E. Rutherford, R. W. Boyle, J. Satterly, C. Porlezza and G. Norzi, and A. Ritzel have studied the adsorption of the radioactive emanations of radium, thorium, and actinium by charcoal. Technical applications have been discussed by E. Berl and co-workers, H. Carstens, E. B. Miller, G. A Burrell and co-workers, etc. J. Dewar showed that the composition of the gases adsorbed by charcoal from air at −185° is virtually constant—actually between 56 and 58 per cent. oxygen—and it is not markedly influenced by press. If the gases given by charcoal (sat. by air at −185°) be collected as its temp. slowly rises to −15°, then, the percentages of oxygen in the air evolved are as follows:

	1st	2nd	3rd	4th	5th	6th	litre
Per cent. oxygen . .	18·5	20·6	53·0	72·0	79·0	84·0	— mean 56

No sign of the oxidation of carbon by the adsorbed oxygen was noted—*vide infra*. D. C. Henry studied the adsorption of mixed gases. H. Herbst studied the effect of moisture on adsorption by charcoal. H. B. Lemon and K. Blodgett showed that with mixtures of nitrogen and oxygen, one gas interferes with the adsorption of the other. L. B. Richardson and J. C. Woodhouse found that with mixtures of carbon dioxide and nitrous oxide, the total adsorption can be calculated from the adsorption isotherms of the individual gases.

The density of the gas adsorbed by charcoal.—According to A. Mitscherlich, *the cells of wood charcoal are, on the average,* $\frac{1}{2400}$*th in. in diameter; and he calculated that* more than one-third of the gas condensed in the pores of the charcoal is in a liquid state on the walls of the cells; and that the thickness of the layer of carbon dioxide covering the walls of the cells is 0·000002 in. Gases like ammonia, hydrogen chloride, and sulphur dioxide which are adsorbed in greater quantities than carbon dioxide will furnish denser layers. Hence, he concluded that the gases in contact with solids must be in a particular state such as they do not present when in a free state; and since the thickness of the condensed layer of gas must vary, the attraction is not manifested solely on the gas in immediate contact with the solid, but acts at variable distances. G. Quincke estimated that 1 c.c. of box-wood charcoal has a surface area of 220,000 sq. cms.; and assumed that the density of the adsorbed gas near the surface is the same as that of the solid, and rapidly decreases in density in passing from the solid to the free gas. S. Lagergren estimates that a gram of charcoal has a surface of 4 sq. metres when it is composed of 1·4 billion particles. H. H. Lowry and G. A. Hulett found that the apparent sp. gr. of charcoal is 1·07; the capillary volume is about 0·42 c.c.; and the area of the capillaries is not more than 200 sq. metres per gram. A. B. Lamb and co-workers estimated that the pores of charcoal, assumed to be cylindrical, have an average diameter of 5×10^{-7} cm., and that one c.c. of absorbent charcoal has a surface area of about 1000 sq. metres—the apparent sp. gr. is about 0·4. I. Langmuir claimed to have shown that when gases are adsorbed on solid surfaces, the thickness of the adsorbed layer is never greater than the diameter of a molecule. I. Langmuir worked at low press. R. E. Wilson, C. Terzaghi, A. B. Lamb and A. S. Coolidge, and M. H. Evans and H. J. George have shown that the adsorbed layer may be several molecules thick; and E. Edser further demonstrated that the mol. attraction is appreciable at distances as great as 100 times the mol. diameter.

According to E. W. R. Pfeiffer, and A. Winkelmann, if D be the density of the adsorbed gas, and D_0 the density of the gas in a free state, the density of the gas at a distance n from the surface of the solid will be $D_0+f(n)$, when $f(n)$ is an unknown function of n. At the limiting surfaces, $f(0)=D-D_0$; and $f(h)=0$, where h is the thickness of the adsorbed layer of gas. If S be the surface area of the body, and m the mass of the adsorbed gas,

$$m=S\int_0^h f(n).dn$$

E. W. R. Pfeiffer assumes that $f(n)$ decreases uniformly from $n=0$ to $n=h$; and the calculation is then the same as if the whole surface S is covered with a layer of uniform density, $\frac{1}{2}(D-D_0)$, of thickness h. The mass of the adsorbed gas is therefore $m=\frac{1}{2}(D-D_0)Sh$. Observations show that if v be the volume of the adsorbed gas, $m=vD_0$. Combining the last two equations, and solving for h, it follows that $h=vD_0/\frac{1}{2}(D-D_0)S$. Since 13·76 c.c. of carbon dioxide at 12·4° and 8·2 atm. press. are adsorbed by a c.c. of charcoal, and if 1 c.c. of the charcoal has a surface area of 570,000 sq. cms., it follows that $v/S=24\times10^{-6}$ cm. If the density of the charcoal is 1·4, $D=1·4$, and the density of the carbon dioxide at 12·4° and 8·2 atm. press. is $D_0=0·01539$, and hence the thickness of the adsorbed layer of gas at this temp. and press. is $h=0·52\times10^{-6}$ cm.

J. Dewar calculated the apparent densities of some gases adsorbed by cocoanut charcoal at low temp., and the results are given in Table IX. They show that the

TABLE IX.—THE DENSITIES OF GASES ADSORBED BY CHARCOAL.

Adsorbed gas.	Temp.	Density.	
		Adsorbed gas.	Liquefied gas.
Carbon dioxide	15	0·70	0·80
Oxygen	—183°	1·33	1·12
Nitrogen	—193°	1·00	0·84
Hydrogen	—193°	0·06	0·07
Helium	—258	0·17	0·12

densities of the adsorbed gases are of the same order as those of the liquid gases; and, in some cases, they are greater. At higher temp., the adsorption and apparent condensation would both be smaller. According to W. D. Harkins and co-workers, the liquids which penetrate into the micropores of charcoal are compressed by a force due to molecular attraction which acts as a press. of 20,000 atm. or more.

The heat of adsorption.—Heat is evolved when solids are wetted by liquids —*vide* the Pouillet effect.[3] C S. M. Pouillet gave 1·16° for the magnitude of this effect (**1**. 9, 9). N. T. de Saussure observed that when gases are adsorbed by solids, heat is evolved. P. A. Favre made the following observations of the heat of adsorption in cals. per mol. at ordinary temp.:

	NH_3	CO_2	N_2O	SO_2	HCl	HBr	HI
Heat of adsorption . .	7,200	7,300	7,400	10,450	9,700	15,500	22,000
Heat of liquefaction .	5,000	6,250	4,400	5,600	3,600	4,000	4,400

The heats of liquefaction are added for purposes of comparison. He found that the heat of condensation from gas to liquid is less than the heat of adsorption, and hence concluded that the density of the adsorbed gas is greater than that of the liquefied gas. J. Dewar added the following values at −185°:

	H_2	N_2	A	O_2	CO
Heat of adsorption . .	1,600	3,686	3,636	3,744	3,416
Heat of liquefaction . .	238	1,372	—	1,664	—

P. Chappius measured the heat of adsorption of ammonia by wood charcoal at different stages of the adsorption, and found for the quantity of heat, Q, cals. evolved when a vol., v, of gas is adsorbed by 2·350 grms. of charcoal:

v	25·79	58·02	59 09	59·27	61·55	59·02	62·77
Q	8·55	20·24	21·45	21·03	22·07	23·54	30·87
Heat per c.c. . . .	0·3298	0·3488	0·3630	0·3701	0·3586	0·3989	0·4910

Consequently, the quantity of heat produced per c.c. of charcoal is less the greater the quantity of gas already adsorbed. According to S. McLean, the thermal effect in the adsorption of air, oxygen, nitrogen, and carbon dioxide, expressed in cals. per c.c. adsorbed, is greatest with oxygen owing to the production of carbon monoxide and carbon dioxide. The largest heat production per gram of adsorbent was obtained with carbon dioxide. The amount was not entirely accounted for by the latent heat of vaporization, indicating that some process other than condensation takes place. Coarser kinds of charcoal form carbon dioxide during oxygen adsorption more readily than others and adsorb more oxygen. The heat effect expressed in terms of the ratio of the observed thermal effect to the saturation effect when v c.c. of sulphur dioxide are adsorbed per gram of charcoal was found by A. M. Williams to pass through a minimum and a maximum value, and finally to run parallel to the adsorption axis:

v	8·0	103 5	176	210	242	361	454
Heat effect . . .	1·870	1·426	1·306	1·443	1·417	1·257	1·012

H. L. F. Meslens, and H. Gaudechon have measured the evolution of heat which occurs on wetting wood charcoal with a number of organic and other liquids. The first-named found that when 97 grms. of bromine are added to 11 grms. of charcoal, the temp. rises 30°. The sudden compression of water raises the temp. of water about 0·0013° per atm., hence, H. L. F. Meslens concluded that rise of temp. observed when charcoal is wetted with water, corresponds with a press. of 893 atm. The force of adsorption is then given as follows:

	Water	Bromine	Ether	Alcohol	Carbon disulphide
Force of adsorption	893	3,100	4,620	3,080	13,090 atm.

I. F. Homphray satisfactorily compared the mol. heat of adsorption, Q, calculated from the formula $Q=2T^2(d \log_e p)/dT$, with the observed results. A. M. Williams, and A. Titoff obtained expressions for the heat of adsorption.

A. B. Lamb and A. S. Collidge found the heats of adsorption, Q, indicated in Table X, *where Q denotes the mol.* heat of adsorption of the vap. per normal c.c. of vap. and 10 grms. of charcoal; L, the mol. heat of vaporization; $Q-L$ then denotes the difference between the heat of adsorption and the heat of vaporization, *i.e.* the so-called *net heat of adsorption.* If v c.c. of vap. are adsorbed, the amount of heat, Q, adsorbed per c.c. of vap. is $Q=mv^n$, where m and n are constants. The constant m varies little from vap. to vap.; and n is nearly unity. The variations of m and n are generally in opposite directions. This agrees with the observation that the molar heats of adsorption of the various liquids are not very different. A. Titoff's observations on the heats of adsorption of carbon dioxide and ammonia are, respectively, Q=0·138 and 0·293 Cal. per c.c.; the heats of liquefaction L=0·052 and 0·187 Cal.; and $Q-L$=0·086 and 0·105.

These results are all in agreement with the inference that *the net heat of adsorption is practically constant for the different liquids observed, when referred to equal vols. of adsorbed liquid.* The heat of adsorption is therefore assumed to be due to the attractive forces of charcoal on the liquid, and for a given vol. of liquid, or for a given vol. of filled capillary space, the amounts of heat liberated are nearly the same for all the liquids studied. Assuming that the net heat of adsorption results from the force of attraction of the charcoal acting on the liquid, the magnitude of the attractive force can then be calculated from the heats of compression of the liquids. Values for the heats of compression, dQ/dp cals. per c.c. of liquid at atm. press., and 0°, are indicated in Table X. The quotient of the net heat of adsorption by the heat of compression then represents the magnitude of the attractive forces, and these are evidently nearly constant, and average 11,100 atm. If the heats of compression, dQ/dp cals. at press. approaching 12,000 atm., be substituted for those at one atm. press., the absolute value of the attractive force is about 37,000 atm. per c.c. of liquid adsorbed by 10 grms. of charcoal.

TABLE X.—HEATS OF ADSORPTION OF THE VAPOURS OF SOME ORGANIC COMPOUNDS.

A. B. Lamb and A. S. Coolidge further found that the molar adsorption represented by the number of c.c. of gas adsorbed at a fixed gas press., say 20 mm., is inversely proportional to the mol. vol. of the liquid. R. A. Smith ignored the effect of press. on adsorption, and assumed that at atm. press., charcoal adsorbs gases in vols. which are multiples of the vol. of hydrogen adsorbed. It required some juggling with the data to make the assumed law appear even plausible. P. P. Kosakewitsch studied the equilibrium conditions of adsorption.

L. Gurwitsch studied the heat of wetting of charcoal, and regarded this as a kind of measure of the attractive force between adsorbent and adsorbed substances.

He found that oxygen compounds have a greater heat of wetting and are more adsorbed by adsorbents containing oxygen—or are *oxyphilous*—while hydrocarbons are more adsorbed by charcoal or are *carbophilous*—*vide* clay.

Adsorption from solutions.—In 1785, J. T. Lowitz[4] showed that coloured liquids are decolorized by filtration through charcoal; M. Guilbert stated that the decolorizing power of wood charcoal is improved by exposing it to sunshine for some time while in a wet state; and in 1810, P. Figuier, in his *Mémoire sur la décoloration du vinaigre et nouveau procédé pour décolorer cet acide, et autres liquides végétaux par le carbone animal*, emphasized the marked action of animal charcoal. The fact was utilized by the sugar-refiners of France to clarify their beet-sugar syrups. According to A. Payen, the sugar was boiled with water and about one-sixth of its weight of bone-black for about ten minutes, and the syrup strained. The subject was discussed by A. Bussy, and C. L. Cadet de Gassicourt, etc.; indeed, the early studies on the decolorizing power of "char" were mainly directed to the beet-sugar industry. The strained char was at first discarded, but its regeneration was shown to be practicable about 1825. Soon afterwards, the use of granular char and true filtration was made possible. T. L. Patterson studied the reason why the charcoal slowly deteriorates during revivification. The use of granular char in place of the powder greatly facilitated the handling of the material, and it does not clog the filter presses like the dusty and sooty "blacks." Animal charcoal is also used for decolorizing other liquids—paraffin, fats, glycerol, etc. The adsorption of air by the charcoal may oxidize certain constituents and darken instead of bleach the liquid. Although animal charcoal stands unrivalled as a decolorant there are quite a number of decolorizing blacks which have special trade-names—the *eponit* of F. Strohmer, and the *karbos*, *carboraffin*, *molasocarb*, etc., described by C. F. Bardorf.

As with the adsorption of gases, T. Graham showed that the absorptive action on soln. is selective and specific. In Table XI, a few examples are selected from T. Graham's results. T. Graham, and A. W. Hofmann found that 2 ozs. of animal charcoal removed 0·5 grain of strychnine from half a gallon of beer; W. L. Dudley removed the rank odour of raw whisky by filtration through charcoal; and W. Skey freed dil., but not conc., sulphuric acid from nitric acid by shaking with charcoal. Alkaloids are adsorbed from soln., so much so that purified animal charcoal is considered particularly effective as an antidote if administered immediately after the alkaloid has been swallowed. Observations on the decolorizing power of different forms of carbon have been made by E. F. Anthon, E. Bauer, A. Bruno and P. T. d'Auzay, M. Cari-Mantrand, E. Filhol, F. E. Thomas, H. Freundlich and G. Losey, F. Glassner and W. Suida, F. Guthe, L. Pelet-Jolivet and co-workers, L. Rosenthaler and co-workers, H. Schwarz, J. Stenhouse, J. Renner, R. Brimmeyr, K. Vierordt, H. Bodenbender, C. Thumb, H. Eisfeld, G. Krieger, F. E. Bartell and E. J. Miller, E. Spörry, P. M. Horton, J. C. Bock, A. B. Bradley, etc. T. Graham showed that the decolorizing power resides entirely in the charcoal, and not in the earthy matters

TABLE XI.—ADSORPTION OF INDIGO AND SUGAR FROM AQUEOUS SOLUTIONS.

Source of carbon.	Indigo soln.	Sugar syrup.
Blood calcined with potassium carbonate	5·0	20·0
Blood calcined with calcium phosphate	12·0	10·0
Blood calcined with lime	18·0	11·0

Animal charcoal washed with acids	1·87	1·6
Animal charcoal washed with acids and calcined with alkali	45·0	20·0

associated therewith. T. Graham, and P. Cazeneuve also stated that the nitrogen adsorbed by animal charcoal has no perceptible influence on its decolorizing powers If the charcoal has been calcined at a very high temp., it loses its decolorizing power. The colouring matters are not destroyed but merely withdrawn from soln., and may be extracted from the charcoal by a suitable solvent. O. C. M. Davis found that the order of adsorption of iodine from different liquids is not the same with different kinds of charcoal. Thus, with animal charcoal, the decrease is in the order: *chloroform, alcohol, ethyl acetate, benzene, and toluene*; with sugar charcoal, *chloroform, toluene, ethyl acetate, benzene, and alcohol*; and with cocoanut charcoal, toluene, chloroform, benzene, alcohol, and ethyl acetate. The adsorption of organic matters from soln. has been investigated by A. Bogojawlensky and V. Humnicky, P. Chappius, O. C. M. Davis, S. Fineschi, H. Freundlich, L. Hermann, R. O. Herzog, J. Hunter, H. Lührig, L. Pincussen, H. R. Kruyt and C. F. van Dunn, I. M. Kolthoff, A. Pickles, L. Rosenthaler and F. Türk, F. Glassner and W. Suida, E. Knecht and E. Hibbert, G. Joachimoglu, H. Rheinboldt and E. Wedekind, L. Joulin, J. Matwin, H. L. F. Melsens, L. Michaelis and P. Rona, A. Reychler, R. A. Smith, etc. G. Lockemann and M. Paucke have studied the adsorption of arsenic acid by charcoal; and L. and P. Wöhler and co-workers, the adsorption of benzoic acid. Observations on the adsorption of salts from soln. have been made by A. E. Esprit, N. Schilow, L. Liebermann, E. Harms, L. Walkhoff, S. Brussoff, K. Stammer, F. E. Bartell and E. J. Miller, S. Odèn and H. Andersson, P. Rona and L. Michaelis, T. Tadokoro and S. Sato, H. Schwarz, H. Reichardt and D. Cunze, H. Morawitz, K. Birnbaum and A. Bomasch, E. F. Anthon, R. Dupouy, H. Pellet, W. H. Heintz, C. Decharme, G. A. König, E. C. C. Stanford, F. Smith, H. Leplay and J. Cuisinier, E. Moride, W. Wallace, F. Wibel, H. Schulz, F. Knapp, etc. According to H. Hartleben, all alkali chlorides are adsorbed to the same extent by animal charcoal. N. A. Yajnik and T. C. Rana found that temp. has very little effect on adsorption of a substance by charcoal. An increase of temp. produces an increase in adsorption. With an increase in the dilution of a substance in soln., the relative amount of adsorption increases, but at higher conc. the absolute amount of adsorption is greater than at lower conc. Adsorption depends to some extent upon the chemical nature of a substance, sodium, potassium, lithium, and magnesium chlorides, belonging to the same group in the periodic table, possess lower adsorption values than strontium and calcium chlorides. In the adsorption of binary mixtures three things may be observed: (*a*) The presence of a foreign substance may have no effect on the adsorption of another substance and so adsorption depends very little on the ionization of a substance. (*b*) A substance may be adsorbed less in presence of another substance than it would be if it were alone in soln. In figurative words, an adsorbent may be poisoned with regard to one substance by the presence of another. (*c*) The adsorption of a substance may be increased in the presence of another substance or that of one may be increased at the cost of the other. The adsorption of mixtures follows no general rules, and so the effect of one substance on the adsorbability cannot be predicted. The adsorptive power of wood charcoal approximates to, or even exceeds, that of animal charcoal when the former has undergone a heat treatment. With some exceptions, the adsorption numbers with different charcoal can be arranged in the same order. This shows that adsorption also depends upon the chemical properties of a substance. A. Fodor and coworkers studied the adsorption of amino-acids, polypeptides, egg-albumin, and acetic, lactic, and tartaric acids by animal charcoal; H. Freundlich and M. Wreschner, the adsorption of uranium X_1, and of thorium; and M. A. Rakuzin, the adsorption of gum arabic. A. Pickles studied the velocity of adsorption.

The adsorption of ions is different from the adsorption of neutral mols. in that the adsorbing surface thereby acquires an electrical charge. The electrical charge is determined by the number of ions fixed per unit surface area. The electric charge of the adsorbent determines cataphoresis and electro endosmosis; and the peptization of the adsorbent is also facilitated by the electric charge, and this subject has been discussed by W. D. Bancroft, J. N. Mukherjee, and others (3. 23, 8). W. D. Bancroft showed that in general an insoluble electrolyte will adsorb ions markedly, so that a soluble salt having a common ion will tend to peptize a sparingly soluble electrolyte; and conversely with coagulation. In the case where the charge on the surface is due to a strong chemical adsorption of ions of one kind, then, assuming that there is no chemical affinity acting on the ions of opposite charge, a layer of the latter will be electrically attracted and held near the adsorbent, and an eq. amount of ions of opposite sign will remain in the liquid. The observations of G. von Elissafoff on glass and quartz are in agreement with J. N. Mukherjee's calculations. At low conc., the density of the electric charge on the surface increases to a maximum, and at higher conc., falls gradually towards a null-value when the oppositely charged ions are univalent; but, as shown by the observations of R. Ellis, F Powis, L. Riѐty, S. W. Young and R. Neal, H. R. Kruyt, H. A. McTaggart, etc., when the oppositely charged ions are multivalent, or are complex organic ions, the charge passes through a null-value, reverses its sign, reaches a second maximum, and then slowly diminishes. J. N. Mukherjee attributes the negative charge of surfaces in contact with water to the chemical nature of the adsorbed anions or cations.

He suggests that with the simpler electrolytes, the cations are usually simple, while the anions are more or less complex. The anions are therefore subject to the chemical affinity of the surface atoms, while the chemical action on the cations is small. If the chemical affinity acting on the anion of the electrolyte is stronger than the electrostatic attraction of the surface on the cation, then the initial charge of a surface in contact with pure water can be due either (*a*) to the strong adsorption of an ion of a minute quantity of suitable electrolyte associated with the solid, (*b*) or to the adsorption of hydroxyl ions from water. On the addition of an electrolyte the density of the electric charge will increase at low concentrations because of the chemical adsorption of the anion. The electrical adsorption of the cation is smaller as the chemical adsorption has been assumed to be stronger. Besides, the electrical charge of the surface is also not at its maximum. As the surface becomes more and more covered by the anions the rate of adsorption of the anions rapidly decreases. Also, the electric charge repels the anions, and those only can strike on it that have sufficient kinetic energy to overcome the potential of the double layer. The number of collisions is thus not proportional to the conc. but rises more slowly. Near about the point where the surface becomes saturated the value of the rate of adsorption of the anions will be almost zero. On the other hand, the electrical adsorption increases continually with the conc. and the increase of the charge. It is apparent that soon a balance will be reached between the chemical adsorption of the anion and the electrical adsorption of the cation. The minimum charge will correspond to the stage when the rate of adsorption of the cation is just equal to the rate of adsorption of the anion. Beyond this conc., the charge will decrease rapidly, and when the surface has been sat. with the anion the subsequent variation in the charge is simply due to electrical adsorption. As the electrically adsorbed *multivalent* cations impart a positive charge to the surface, the adsorption of the cation decreases and the *electrical adsorption* of the anion becomes possible. As long as there is a positively charged surface the adsorption of the anion will increase more rapidly with the conc. than that of the cation. *A second maximum will thus be reached and a decrease in the charge will follow.* The electrical adsorption of the anion is small because of the smallness of the positive charge and an initially existing negative charged surface. A further reversal of the charge is not possible, and, in fact, has never been observed.

The action of acids and alkalies.—J. Perrin, F. Haber and Z. Klemensiewicz, A. T. Cameron and E. Oettinger, etc., have shown that, unlike most univalent ions, hydrogen and hydroxyl ions impart to the surface a charge of the same sign as they carry. In the case where the surface is chemically inert towards the hydrogen and hydroxyl ions, or to the dissolved acid and alkali with which it may be in contact, F. Haber and Z. Klemensiewicz, W. B. Hardy, and A. M. Williams have shown that the adsorbed water mols. behave as a solid layer; and the surface is neutral in contact with water; and that the mols. of water in the adsorbed layer are in thermodynamic equilibrium with the mols. of the water in the body of the liquid. The water mols. are ionizing at a definite rate, and for equilibrium as many ions are uniting to form neutral water mols. According to J. N. Mukherjee, the neutralization of the ions in the adsorbed layer will be very small because the mols. here behave like a solid layer, and the surface will be neutral. If an acid is added to the water, *the neutralization of the $H^{\cdot}$- in the surface layer with the OH'-ions in the liquid* will be very small, but not necessarily so with the neutralization of the OH'-ions in the surface layer with the $H^{\cdot}$-ions in the liquid. This means that a corresponding number of $H^{\cdot}$-ions will remain in the surface layer in excess of the OH'-ions. This resulting charge on the surface will increase with a rise in the conc. of the $H^{\cdot}$-ions in the liquid. The opposing factors are: (i) The proportion of $H^{\cdot}$-ions striking the surface decrease as the positive charge of the surface increases, since only those ions can enter the surface which have a sufficient kinetic energy to overcome the electrical repulsion; and (ii) the electrical adsorption of the anion of the acid in the soln.

When the surface is not chemically inert, and there is a preferential adsorption of one of the ions, J. Perrin, G. von Elissafoff, R. Ellis, F. Powis, etc., have shown that surfaces in contact with water are usually negative owing to the preferential adsorption of OH'-ions. This may be related with the potential quadrivalency of oxygen. According to J. N. Mukherjee, in contact with pure water the surface has a layer of adsorbed water and a number of hydroxyl ions. The amount of hydroxyl ions adsorbed by the surface will, in general, be small, as the concentration of the hydroxyl ions is very small in pure water. If, however, the adsorption is very strong the surface will have a considerable negative charge. On the addition of an alkali the negative charge of the surface will increase, due to (i) the preferential adsorption of hydroxyl ions will increase, and (ii) the number of hydrogen ions being formed at the surface will be more and more neutralized by hydroxyl ions in the liquid. A maximum will be reached when the surface is saturated by preferential adsorption. Since the chemical adsorption of hydrogen ions is assumed to be absent, on the addition of an acid the negative charge will decrease owing to electrical adsorption till the surface becomes neutral. At this concentration of the acid, the surface has an adsorbed layer of water, and an equal number of hydrogen and hydroxyl ions. An increase in the positive charge is due to the neutralization of the hydroxyl ions being formed at the surface by impinging hydrogen ions in the liquid. *The maximum charge due to acids thus gives a measure of the hydration of the surface.* The difference between the maximum charge observed with acid and with alkali gives a measure of the amount of hydroxyl ions that is required to saturate the surface. E. J. Miller showed that the hydrolysis of some salts is increased during adsorption by charcoal. H. Lachs stated that substances of a similar electric charge are able mutually to replace one another on an adsorptive surface unity. The results were satisfactory for the adsorption of acetic acid, bromine, and benzoic acid from aq. soln. by blood charcoal. For bromine, with the standard equation $(x/m)^n = kC$, $n = 2{\cdot}4$, and $\log k = 0{\cdot}974$; and when C is expressed in millimols per litre, and x/m in millimols per gram of charcoal.

O. C. M. Davis found the above formula represented satisfactorily his observations on the distribution of iodine between charcoal and various organic liquids, and he obtained results with various charcoals which agreed with the assumption that the adsorbed iodine consists partly of a surface condensation and partly of a solid soln., but D. Schmidt-Walter considered that the alleged slow diffusion of iodine from the surface to the interior of the charcoal is a mal-inference, for he attributed the phenomenon to a slow reaction between iodine and the organic liquid where the charcoal acted as a catalyst. G. Wiegner represented the distribution of sucrose and lactose between charcoal and water by the same formula; which also represents the distribution of potassium chloride between stannic oxide and water (J. M. van Bemmelen); and between charcoal and water (H. Lachs and L. Michaelis). Other formulæ have been discussed by H. Freundlich, J. M. McBain, W. Ostwald, I. M. Kolthoff, G. C. Schmidt, G. von Georgievics, R. Marc, G. Trümpler, O. Dietl,

A. M. Williams, etc. H. Freundlich, and G. C. Schmidt showed that the same state of equilibrium with acetic or benzoic acid, charcoal, and water is attained by starting from both sides, so that in these cases the process is reversible. P. J. Moloney and D. M. Findlay studied the selective adsorption as a means of purifying insulin and similar substances.

The selective adsorption of a salt from a soln. will appear to be reversed and the soln. will become more concentrated if relatively more of the solvent than of the solute is absorbed. This is called **negative adsorption.** S. Lagergren, for example, noted the negative adsorption of some chlorides and of ammonium bromide by charcoal; A. E. Esprit, of ammonium iodate, dichromate, and chromate by charcoal; and M. A. Rakuzin and G. F. Pekarskaja, with Bismarck-brown by gelatin, etc. J. Tadokoro and Y. Nakamura measured the adsorption with soln. of potassium iodide by charcoal made from different starches; and Y. Osaka obtained similar results with aq. soln. of sodium chloride, sodium sulphate, and potassium sulphate and with blood charcoal. With potassium chloride, the adsorption is positive when the conc. is relatively high, and negative when the conc. is low. This shows that the amounts adsorbed increases only up to a certain critical point as the conc. of the soln. is increased; any further increase in the conc. of the soln., the surface gives up some of the salt or the amount adsorbed is actually less than is the case with weaker soln. The theory has been discussed by J. N. Mukherjee, and M. A. Rakuzin. According to F. T. Trouton, there are possibly two modes of adsorption. In one, there is a simple increase in the conc. of the soln. in the surface layers; and in the other, with conc. soln., there is a deposition analogous to the solid form.

The cause of the diminution in the conc. of the adsorption layer at a certain critical value of the conc. is difficult to understand. Something analogous has been observed by Lord Rayleigh in the thickness of layers of oil floating on the surface of water. As oil is supplied the thickness goes on increasing up to a certain point; beyond this, on further addition of oil, the layer thins itself at some places and becomes much thicker at others, thicknesses intermediate to these being apparently unstable and unable to exist. As helping towards an explanation of the diminution in the adsorption layer we may suppose that as the strength of the soln. is increased from zero, the adsorption is at first merely an increased density of the soln. in the surface layer. For some reason, after this has reached a certain limit, further addition of salt to the soln. renders this mode of composition of the surface layers unstable, and there is a breaking up of the arrangement of the layer with a diminution in its amount. We may now suppose the second mode of deposition to begin to show its effect with a recovery in the amount of the surface layers and a further building up of the adsorption deposits. On account of passing through this point of instability the process is irreversible, so that the application of thermodynamics to the phenomenon of adsorption is necessarily greatly restricted in its usefulness.

A possible cause of the instability in the adsorption layer which occurs at the critical point may be looked for in the alternations in the sign of the mutual forces between attracting particles of the kind suggested by Lord Kelvin and others. Within a certain distance apart—the mol. range—the particles of matter mutually attract one another, while at very close distances they obviously must repel, for two particles refuse to occupy the same space. At some intermediate distances the force must pass through zero value. It has for various reasons been thought that, in addition, the force has zero value at a second distance lying between the first zero and the mol. range, with accompanying alternations in the sign of the force. Thus, starting from zero distance apart of the particles, the sign of the force is negative or repulsive; then, as the distance apart is supposed to increase, the force of repulsion diminishes, and after passing through zero value becomes positive or attractive; next, as the distance is increased the force diminishes again, and after passing through a second zero becomes negative for a second time; finally, the force on passing through a third zero becomes positive, and is then in the stage dealt with in capillary and other questions.

The mechanism of adsorption.—In order to distinguish the condensation of gases on free surfaces from the absorption of gases in the molecular interstices or throughout the mass of the absorbing liquid or solid, H. Kayser[6] adopted a suggestion by E. du Bois-Reymond, and called the former case *adsorption.* The term is also applied to the withdrawal of a solute from a soln. by a solid. This may be due to (i) the formation of definite chemical compounds; (ii) the formation of solid soln.; and of mixed crystals; and (iii) surface condensation. W. Mecklenburg's definition of adsorption is a condensation or combination at the surface only without the interpenetration of the adsorbed substance throughout the mass of the adsorbent. J. W. Gibbs' deduction of his equation (1. 13, 22) also assumes a definition of adsorption analogous to this. J. W. McBain employed the term *sorption* to include both the surface condensation, and interpenetration. The general opinion of most investigators is that with gases adsorption is due to the mere condensation of gas on the capillary and other surfaces of the solid. The very name was intended to emphasize this view of the phenomenon. The preceding estimates of the thickness and density of the adsorbed film, and of the magnitude of the attractive force between the solid and gas assume that the adsorbed gas in a condensed form is spread over the exposed surface of the solid, and that the surface tension of the charcoal is lowered by the presence of the gas.

S. Lagergren considers that adsorption by solids in contact with aq. soln. is due to the compressed state of the water in the surface layer. S. Arrhenius, indeed, has drawn attention to the parallelism between the amounts of different gases adsorbed by charcoal and the coeff., *a*, of J. H. van der Waals' equation (1. 13, 4), and he regards this as definite evidence of the compressed state of the surface layer. J. J. Thomson showed that Laplace's theory of capillarity leads to the conclusion that in the surface layers chemical actions, etc., which are absent in the body of the liquid, may occur. J. W. Gibbs' thermodynamical treatment of adsorption (1. 13, 22) has been amplified by S. R. Milner, W. C. McC. Lewis, and F. G. Donnan and J. T. Barker. This attributes adsorption to changes produced in the surface tension of the solvent in the boundary layer. This view is adopted by H. Freundlich. Observations show that the amount adsorbed from a soln. is often greatly in excess of that computed from J. W. Gibbs' equation. This arises from the circumstance that here the attempt is made to explain adsorption in terms of the diminution of surface energy, or of a layer under a great internal press.; otherwise expressed, only one source of change in the free energy of the surface layer is considered. G. Bakker showed that if the density of the surface layer is different from that of the liquid in bulk, a second term is needed to represent the change in free energy. At low temp., this second term may be negligible in comparison with the surface tension itself, but at high temp., the second term may be relatively large because the surface tension is small and the saturation press. large. A. M. Williams has also emphasized the effect of the variation in the surface of an adsorbent while it is adsorbing; and S. Arrhenius also emphasized the chemical aspect of the adsorption of gases by solids, since, in addition to the attractions between the mols. of a gas in the surface layer, there is also the chemical attraction of the surface atoms and the mols. of the gas. L. Michaelis and P. Rona also show that the assumption of special forces at the surface fails to account for the facts, and that it is necessary to assume that adsorption is an effect of chemical affinity. They showed that charcoal has a great capacity for adsorbing substances with a chain of carbon atoms.

C. Hoitsema assumed that hydrogen occluded by palladium (*q.v.*) is in the at. state and his isothermal at 0° is almost the same as that obtained by M. W. Travers at −78° for carbon dioxide. There is, however, no satisfactory evidence to show that the adsorption of hydrogen by carbon is attended by such a change. Both P. D. Zacharias, and M. W. Travers favoured the hypothesis that the process involves a kind of clogged diffusion. Thus, H. H. Sheldon says that the action is dual, since besides the surface action, there is a diffusion into the more inaccessible channels, which cannot be expected to take place until the easily accessible or directly exposed parts are saturated. On the other hand, J. W. McBain observed that this assumption does not agree with his observations on the influence of press., where it is shown that the same length of time is taken for hydrogen to diffuse at 160 mm. press. as is taken at 20 mm. press., while P. D. Zacharias' hypothesis predicted that it would occupy 64 times as long. I. F. Homfray regarded the process as one of dissolution or absorption rather than adsorption or surface condensation.

The objection to the soln. hypothesis is that Henry's law does not hold, but she attributes the deviations to the high conc. of the soln. It is assumed that the simple gas laws are valid for dil. soln. but not for conc. soln. The main objection to the soln. hypothesis, said L. B. Richardson, arises from the improbability that equilibrium between the gas and solid phase would be attained so quickly as the 0·5–2·0 hrs. actually observed. J. W. McBain combined the soln. and the surface condensation hypotheses by showing that when carbon is placed in hydrogen, at the temp. of liquid air, there is a rapid decrease of press. for a few minutes, and this is followed by a slow decrease continuing for several hours. It is supposed that the first rapid action is due to surface adsorption, and the slower action is caused by the penetration of the gas into the material of the charcoal by adsorption to form a kind of solid soln. The absorption of carbon dioxide at low temp. gives evidence of the same phenomena, but not at higher temp. J. B. Firth's observations on the sorption of iodine by different forms of carbon at 25°, show that while the first rapid condensation occurs in a few minutes, the slower absorption may extend over months and years. E. F. Lundelius studied the adsorption of iodine from soln. in different solvents. G. Wiegner and co-workers found the adsorption of fatty acids from aq. soln. is augmented when $2N$-NaCl is used in place of water. B. Gustaver also considers that the isotherms of the adsorption by charcoal of the vapour of water, alcohol, and acetic acid show a well-marked point of inflexion. The first part of the curve is taken to represent the reversible adsorption, and the second part is supposed to be due to the condensation of liquid in the pores of the charcoal. J. R. Katz argued that the application of H. Freundlich's adsorption formula is not a sufficient proof that the fixation of water by charcoal is one of surface adsorption, and he plotted the fixation isotherm and the heat of sorption as a function of the quantity of fixed substance. The curve has an almost horizontal middle part like that also obtained with fresh silicic acid. Assuming that the form of the curve is due to the existence of systems of microcapillaries, the radius of the capillaries is calculated to be 1·2–2·6$\mu\mu$. J. R. Katz, however, considers it more probable that the effects observed are due to the difficult moistening of the solid by water.

L. B. Richardson explains the adsorption process in the following words :

> Layers of gas, decreasing in density outwards, are condensed through the surface energy of the solid at the boundary surfaces. An equilibrium between free and adsorbed gas is thus established. Through a limited range, increase of press. causes increase in quantity of gas adsorbed in a fairly definite logarithmic ratio, but as the press. increases beyond these limits, the relative amount of adsorption becomes less, the density of the surface layers cannot be increased on the former scale ; in other words, it becomes increasingly difficult for additional quantities of gas to take their places in the already crowded surface region. A point should finally be reached at which increased press. would cause no measurable increase in adsorption. In the same way the crowding effect causes a decrease in the relative amount adsorbed at constant press. with a lowering of the temp. At low temp., the possibility exists that a small portion of the total gas in the solid phase is absorbed (dissolved) in the structure of the charcoal. This portion is relatively slow either to enter or to leave the charcoal structure.

M. Faraday, in 1834, implied that in the catalytic effect of platinum on the combination of hydrogen and oxygen, there is a kind of combination at the surface, so as to form a transition layer more than one mol. thick. He said :

> The surface is dependent on the natural condition of gaseous elasticity combined with the exertion of that attractive force, possessed by many bodies, especially those which are solid, in an eminent degree, and probably belonging to all, by which they are drawn into association more or less close, without at the same time undergoing chemical combination though often assuming the condition of adhesion, and which occasionally leads, under very favourable circumstances, to the combination of bodies simultaneously subjected to this attraction. . . . The sphere of action of particles extends beyond those other particles with which they are immediately and evidently in union, and in many cases produces effects rising into considerable importance.

The failure of the theories of adsorption based on the assumption that the phenomenon is determined, in all cases, solely by surface energy led to the hypothesis that chemical affinity is also concerned in the process—*vide supra*—and this is in harmony with M. Faraday's conception of the adsorption of gases. This view seems the more probable when the preferential or specific nature of adsorption is taken into consideration. This aspect has been particularly emphasized by W. D. Bancroft (**3.** 23, 8), and the idea has been developed by I. Langmuir. The work of A. Eucken, and R. Lorenz and A. Landé agrees with the assumption that adsorption and mol. surface forces are identical.

T. F. E. Rhead and R. V. Wheeler consider that the fixation of oxygen by carbon involves the formation of a more or less indefinite compound, C_nO_{n+x}, because the adsorbed oxygen cannot be removed by exhaustion alone, and by increasing the temp. during exhaustion, not oxygen, but a mixture of carbon monoxide and dioxide in proportions dependent on the temp. at which the carbon has been heated during the fixation of the oxygen—presumably: $C_nO_{n+x}=xCO_2+(n-x)CO$ is evolved. The hypothesis was intended to explain phenomena attending the oxidation of carbon rather than the phenomena of adsorption. L. B. Richardson observed no signs of the formation of such compounds in his study of the adsorption of carbon dioxide by charcoal; and A. Eucken showed that in the case of the adsorption of argon by charcoal, it is unlikely that the adsorbed mols. are held by the attractions of chemical forces; and the adsorption forces are similar to forces responsible for condensation phenomena, they are almost independent of temp., and extend over a relatively small distance which is of the same order as the mol. radius. This can be taken to mean that there is an indefinitely large intermediate range of phenomena between the two limiting cases where the chemical forces are indefinitely small, and the surface tension large.

A. Eucken further considered that the adsorbed film of gas on the surface of a solid is a kind of transition layer where the mols. are attracted from a distance to the surface; and G. Bakker employed a similar hypothesis in developing a theory of surface tension, for he assumed that the mols. in the transition layer are attracted to one another by a force which is an inverse exponential function of the distance between them. F. Haber has further emphasized his belief that the forces concerned in adsorption phenomena may be brought in close connection with chemical affinities. He said:

> The study of the action of X-rays on crystals has shown that ordinary crystalline salts are not systems in which one anion and one cation form a mol. which is separated from the next, but that one cation is probably bound to all the surrounding anions and one anion to all the surrounding cations. In consequence of that, we may feel inclined to consider the possibility of chemical forces acting between the atoms or ions in the surface of the solid precipitates and the mols. or ions in the final layer of the surrounding liquid, *i.e.* in the adsorption layer. We may remember that there are good reasons for the belief that chemical forces are of electrical character, and we know from electro-osmosis and similar phenomena that electrical forces are always acting between the surface of the solids and the adjacent layer of fluid.

The peculiar relations of the surface atoms or mols. to the other mols. of a liquid or solid led I. Langmuir to assume that they are unsaturated chemically, and are surrounded by an intense field of force. In consequence, when the gas mols. impinge against such a surface, they do not, in general, rebound elastically, but are held there by the field of force (residual valence) of the surface atoms of the solid. The length of time which elapses between the condensation of a mol. and its subsequent evaporation depends on the surface forces. Adsorption is a result of this time-lag, for if the surface forces are weak, evaporation may occur very shortly after the condensation, and only a small fraction of the surface becomes coated with a layer of adsorbed mols.; and if the surface forces are intense, the rate of evaporation will be negligibly small and the surface will become completely covered with a layer of mols. of the gas. The number of layers of mols. so retained on the surface will depend on the sphere of action of the surface of the solid. A. B. Lamb and A. S. Coolidge showed that the films of adsorbed gas are at least one, and usually many mols. thick; and in support of this view, they quoted G. Quincke's observation that the sphere of action of silver has a radius of 6×10^{-6} cm. which is more than the diameter of a mol., *vide supra*. I. Langmuir, and H. S. Harned adapted the kinetic theory of gases to the adsorption theory. The former started from the relation $\mu = p(2\pi MRT)^{-\frac{1}{2}}$, or $\mu = 43{\cdot}75 \times 10^{-6} p(MT)^{-\frac{1}{2}}$, representing the rate of bombardment of the gas mols. on a solid surface (**1**. 13, 2), when μ is the number of molecules striking unit surface per second, M the mol. wt., T the absolute temp., p the press., and R the gas constant in ergs per degree. It was shown that for an ideal gas, the rate of bombardment is proportional to the press.; and further, that the fraction of the solid surface covered or the quantity of gas adsorbed at the press. p is $a_p/(\nu + a_p)$, where a is a constant denoting the fraction of the total number of mols. of the gas that leads to a condensation on the surface—it is usually close to, and can never exceed, unity. Here, ν denotes the rate at which the gas would evaporate if unit area of the surface were completely covered.

In the simplest case, it is assumed that (i) the adsorbed layer is one mol. thick; (ii) all mols. of gas which impinge on the layer of mols. already on the surface, rebound and do not condense; and (iii) the ratio of the number of mols. condensing on unit surface in unit time, to the number evaporating from that surface in the same time, is constant throughout the process. The rate of adsorption will then be proportional to the bare surface; so that if A denotes the absorption capacity by weight per gram of charcoal, and K the weight of gas adsorbed per gram of charcoal in the time t, the rate of adsorption dK/dt, will be:

$$\frac{dK}{dt} = k(A-K); \quad \text{or} \quad k = \frac{1}{t} \log \frac{A}{A-K}$$

where k is a constant. I. Langmuir deduced

$$\frac{N}{N_0} \nu_1 \left(1 + \frac{a}{\nu_1} \mu\right) = \frac{1}{t} \log \frac{\theta_1}{\theta_1 - \theta'}$$

where N_0 represents the number of the elementary spaces per sq. cm. of surface, N is Avogadro's number, θ_1, the fraction of the surface covered at equilibrium; and θ', the fraction covered in a time t. The member on the left of the last equation should be a constant when the press. and temp. are constant. Again, if the sphere of action of the mols. at the surface of the solid extends beyond the film one mol. thick, a fraction of a second layer will be adsorbed. Assuming that the ratio of the number of mols. condensing on the first layer to the number evaporating from that layer is constant, then, for the first and second layers respectively:

$$\frac{dx}{dt} = k_1(a-x); \quad \text{and} \quad \frac{dy}{dt} = k_2(xF-y)$$

where x is the amount on first layer in time t; a is the amount on first layer when t is infinite; k_1 is the constant of the first reaction; y is the amount on second layer in time t; k_2 is the constant of the second reaction; and F is a coeff. such that aF equals the amount on the second layer when t is infinite. Here $x+y=K$, and $a+aF=A$. H. S. Harned tested these relations with chloropicrin and carbon tetrachloride vapour, and found the observed results in general agreement with I. Langmuir's hypothesis.

§ 10. The Action of Oxygen, and Water on Carbon

Observations on the combustion of the diamond have been described in a special section in connection with the action of heat on the diamond. E. H. von Baumhauer[1] showed that the flame is bluish-violet resembling that of burning carbon monoxide. G. Rose detected small corrosion pits on the surface of a diamond which had been heated to about 1000°. H. Moissan gave for the **ignition temperature** of different kinds of diamond in oxygen: Yellowish-black diamond, 690°; hard black diamond, 710°–720°; transparent Brazilian diamond, 760°–770°; Cape diamond, 780°–790°; Brazilian boart, 810°; Cape boart, 790°; and hard boart, 800°. G. Rose said that flaky graphite burns less readily and compact graphite more readily than the diamond—thus, after burning 13 min. flaky graphite lost 27·45 per cent.; the diamond, 97·76 per cent.; and compact graphite, 100·00 per cent. R. Blindow also said that flaky graphite burns less readily than the diamond. H. N. Warren noted that the graphite which separates from a soln. of carbon in ferromanganese is not so difficult to burn as that from manganese, while that from chromium was the most difficult to burn; H. Moissan said that the graphite similarly derived from platinum ignites in oxygen at 575°; and that from iron at 670°. H. Moissan gave 300°–500° as the ignition temp. of amorphous carbon in dry or moist oxygen. Amorphous carbon which has been heated at an elevated temp. is more difficult to burn in oxygen than charcoal carbonized at a lower temp. H. Valerius said that the temp. of burning carbon is 1678°. Demonstration experiments illustrating the combustion of carbon, graphite, and diamonds have been devised by R. Blindow, A. P. N. Franchimont, A. W. Hofmann, B. Lepsius, E. Prime, J. Volhard, and C. J. Woodward.

H. Karsten said that finely divided amorphous carbon is oxidized in dry air at ordinary temp., and carbon dioxide is formed. R. A. Smith noticed a peculiarity in the relations of oxygen to charcoal which was not exhibited with hydrogen, nitrogen, and carbon dioxide. The absorption continued for a month, and when the attempt was made to drive off the oxygen by heat, carbon dioxide in place of oxygen was evolved. This observation was confirmed by H. Kayser, and J. Böhm. H. H. Lowry and G. A. Hulett considered that there is evidence of a slow reaction between carbon and adsorbed oxygen at ordinary temp. resulting in the formation of a non-volatile oxide. M. Aubert, indeed, said that large masses of finely divided wood charcoal may ignite spontaneously when exposed to air. F. C. Calvert, however, could detect no evidence of the formation of carbon monoxide or dioxide by the oxygen adsorbed by purified charcoal—the adsorbed oxygen could oxidize ethyl alcohol to acetic acid; and ethylene to carbon dioxide and water. These reactions do not occur with carbon monoxide or dioxide in place of oxygen. The evidence is not always satisfactory because in some cases there is the uncertainty whether the charcoal used contained hydrocarbons, which, as previously indicated, are very likely impurities in charcoal. H. H. Lowry and S. O. Morgan showed that at 450° the rate of oxidation of different samples of charcoal is roughly proportional to the amount of chemically combined hydrogen present, and to the extent of surface exposed. W. Skey showed that at a red heat, the oxygen is probably removed from the adsorbed air by oxidation because nitrogen alone was given off by the cooled charcoal.

H. Moissan found that carefully charred bituminous coal is slowly oxidized at 100° by dry or moist oxygen at atm. press., and this without visible combustion. F. H. Storey and D. S. Lewis obtained evidence of oxidation at 200°; E. Blumtritt, at 140°; and G. Craig, at a red heat. As previously indicated, J. Dewar did not detect any appreciable oxidation of carbon to carbon monoxide or dioxide by adsorbed oxygen between −185° and −15°. C. J. Baker verified R. A. Smith's statement that the moist oxygen adsorbed by carbon at −12° was given up as carbon dioxide when the carbon was heated to 100°. O. Meyerhof and H. Weber studied the **self-oxidation** of charcoal in alkaline soln. When animal charcoal is suspended in dil. alkali-lye, oxygen is absorbed and carbon dioxide formed; 4 cals. of heat are evolved per c.c. of oxygen used. The velocity of oxidation is increased 60 per cent. when air is replaced by oxygen. The self-oxidation is a surface effect and is inhibited by various urethanes to different extents. The inhibition is due to a displacement of the adsorbed substance from the surface, while the adsorbed hydroxyl-ion is not affected. The degree of oxidation is proportional to the amount of adsorbed hydroxyl-ions.

For the rise of temp. which occurs when **water** is mixed with carbon, *vide* W. Skey,[2] C. S. M. Pouillet, etc. A. Scholtz found a finely ground charcoal dried at 100° absorbed 65 per cent. of water before any supernatant liquid appeared; and with up to 30 per cent. of water, the powder appeared sensibly dry. J. C. Poggendorff noted that if carbon electrodes are used in the electrolysis of water, carbon monoxide and dioxide are given off. According to P. Degener and J. Lach, if freshly calcined animal charcoal be moistened with as much water as it can adsorb, and layers 6–8 cms. deep are exposed to air and light, hydrogen peroxide and ozone are formed. E. H. von Baumhauer observed that diamonds are not changed when heated to whiteness in water vapour. A. P. Dubrunfaut found that sugar charcoal burns when heated electrically in an atm. of water vapour, or in moist air; and B. Lepsius made a similar observation. C. J. Baker showed that neither carbon monoxide nor carbon dioxide is produced when water is boiled with carbon at 100°. F. Clément and J. B. Désormes found that when water vapour is passed over red-hot charcoal, in a porcelain tube, a mixture of hydrogen and carbon monoxide and dioxide is formed. R. Bunsen noted that the system attains a stationary state when the proportions of these gases are 4 vols. of hydrogen, 2 vols. of carbon monoxide, and one vol. of carbon dioxide, but J. H. Long showed that the products are not distributed in the simple proportions assumed by R. Bunsen, for the proportion of carbon monoxide steadily decreases as the carbon is oxidized. According to J. Lang, the reaction between carbon and steam begins at about 600° when 20·4 per cent. of carbon dioxide, and 0·9 per cent. of carbon monoxide are produced along with hydrogen; and at a higher temp., carbon monoxide appears, and the proportion of carbon monoxide increases until the carbon monoxide itself begins to be oxidized by the steam. This proportion is independent of the depth of the carbon through which the gases pass. It was therefore inferred that the primary reaction is $C+2H_2O\rightleftharpoons 2H_2+CO_2$, but there are a number of side reactions: $CO_2+C=2CO$; and $CO+H_2O=CO_2+H_2$. The reactions have been studied by A. Naumann. P. Farup investigated the reaction $C+H_2O\rightleftharpoons CO+H_2$. H. A. Neville and H. S. Taylor found that alkali carbonates, alkaline earths, and various salts promote the reaction between steam and carbon. Potassium carbonate is the most active salt catalyst. R. T. Haslam and co-workers showed that the reactions $C+H_2O=CO+H_2$ and $C+2H_2O=CO_2+2H_2$ take place at the surface of the carbon and are unimolecular. C. Sandonnini also inferred that carbon is not a catalyst for a detonating mixture of hydrogen and oxygen, and that from 300° to 500° it absorbs oxygen, which it gives off at a higher temp. as carbon monoxide and dioxide. Nickel accelerates the reaction.

In 1794, Mrs. Fulhame assumed that the presence of moisture is necessary for the combustion of charcoal in air; and in 1871, A. P. Dubrunfaut inferred from some inadequate experiments that carbon does not burn in oxygen without the intervention of water vapour. J. B. A. Dumas denied this by some inconclusive experiments in which carbon and oxygen, dried by potassium hydroxide and sulphuric acid, were found to burn completely to carbon dioxide. He asked: *les gaz desséchés par ces procédés, sont-ils absolument privés d'eau?* and added that it would be difficult to affirm that the gases thus desiccated are absolutely dried since *il n'y a rien d'absolu dans le monde matériel;* but it is certain that any trace of water which remained could not be detected in any known way. The weakest part of J. B. A. Dumas' work was in the drying of the carbon. H. B. Baker has proved, in a most convincing way, that carbon and oxygen, when highly purified, do not readily combine together at a high temp., for, on heating purified charcoal in well-dried oxygen to redness in glass tubes, he observed no glow or scintillation (which is immediately produced in the presence of water-vapour); but on opening the vessels, part of the oxygen was found to have combined with the carbon, forming carbon monoxide and carbon dioxide. Whilst these experiments show the great influence of steam in bringing about the union of carbon and oxygen, they do not decide the question whether charcoal and oxygen would combine at all in the complete absence of moisture. W. G. Mixter added that it has not been decided if carbon would remain unburnt in oxygen if both reagents were perfectly dried, since carbon always retains some occluded hydrogen which burns to water. The subject was also discussed by R. H. Bremridge, K. Broockmann, etc. Mrs. Fulhame explained the function of water as follows:

> During the combustion of charcoal in air, the carbon attracts the oxygen of the water and forms carbon dioxide, while the hydrogen of the water unites with the oxygen of the air to form a new quantity of water equal to that decomposed. Hence the carbon of the charcoal does not unite with the oxygen of the air, as Lavoisier supposes, but with the oxygen of the water contained in that gas.

L. C. A. Barreswill[3] showed that if carbon be burnt at a low temp., carbon dioxide is almost exclusively formed, and the same result is obtained if air be passed through a thick layer of carbon at a low temp.; but at a white-heat, the product is nearly all carbon monoxide—*vide* carbon monoxide. In confirmation, A. Ledebur found, at the following approximate temp.:

	350°	440°	520°	700°	1100° approx.
CO . .	21·4	27·6	28·6	37·4	98·7 per cent.
CO_2 . .	78·6	72·4	71·4	62·6	1·3 „

According to W. Hempel, at a high temp. carbon monoxide and mere traces of carbon dioxide are produced, and the product is not influenced by the presence of much or little oxygen. F. C. G. Müller discussed this subject. According to R. Ernst, the composition of the products of combustion depends almost exclusively on the temp. The formation of carbon dioxide begins at about 400°, and at this temp. there is already a small quantity of carbon monoxide produced. The maximum production of carbon dioxide occurs at about 700°, and amounts to some 20 per cent. of the products (including the nitrogen of the air used); up to this temp. the formation of carbon monoxide is but small, hardly exceeding 3 per cent.; the oxygen, however, is entirely used. At higher temp., the carbon dioxide rapidly disappears, giving place to carbon monoxide, until at 995° this gas amounts to 34 per cent., the remainder being atm. nitrogen. It must be noted, however, that the rate of passage of the air was much reduced in those experiments in which the highest temp. were maintained; no reason is assigned for this. There was no further change in the composition of the products up to the highest temp., 1092°, at which M. Ernst experimented. The production of carbon monoxide could not be induced at a lower temp. by altering the other experimental conditions. It is concluded that carbon monoxide is the only oxidation product of carbon at 1000°, and that producer gas should be prepared at this temp. By substituting carbon dioxide for air, it was proved that this gas is never entirely reduced to carbon monoxide by the hot fuel, so that, where the production of carbon monoxide is preceded by that of carbon dioxide, some of this gas must appear among the products of combustion; it may be concluded, therefore, that the carbon burns directly to carbon monoxide at the high temp. O. Manville showed that the formation of carbon monoxide and dioxide by the direct action of oxygen on carbon depends on the nature of the carbon; on its physical and chemical state, the velocity of the current of oxygen, and on the time. When carbon has been heated in vacuo, and cooled slowly, and the operation repeated many times, the temp. at which it unites to form the oxides are higher than the initial values. This effect may partially be due to the gradual removal of hydrocarbons.

It was assumed that the first product of the reaction is carbon dioxide, $C+O_2=CO_2$; and that in a secondary reaction, the carbon dioxide is reduced to the monoxide, $CO_2+C=2CO$. This view is adopted by D. I. Mendeléeff, F. Haber, and others. J. Lang also inferred that carbon dioxide is the first product of the reaction, because when oxygen was passed over gas carbon contained in a glass tube heated to 500°, it was found that the carbon dioxide was not reduced. The products of combustion varied with the speed of the passage of the oxygen, the carbon monoxide formed being less the slower the gas-stream, and disappearing altogether with very slow streams. Hence, argued J. Lang, the carbon monoxide found with quick streams was produced by the reduction of the carbon dioxide first formed, owing to local heating of the carbon. With very slow streams no local heating would occur, and therefore there was no reduction of carbon dioxide. H. B. Dixon claimed that these experiments merely show that carbon dioxide is the end-product of the reaction when oxygen is slowly passed over coke at 500°; and they do not contradict the hypothesis that carbon monoxide is the first product of the oxidation of carbon.

A mixture of oxygen and carbon monoxide was passed at different speeds over carbon heated at 500°. With slow gas streams the whole of the oxygen was converted into carbon dioxide, and the carbon monoxide passed through the tube unchanged. With rapid streams more carbon monoxide was found in the products than was present in the original mixture, some of the carbon dioxide first formed being reduced by the carbon. J. Lang, therefore, concluded that, since the oxygen was converted into carbon dioxide under such conditions that the carbon monoxide present was not acted on, the carbon dioxide must have been formed without the intermediate formation of carbon monoxide. H. B. Dixon was unable to confirm J. Lang's experiments; and, indeed, obtained contradictory results.

In 1861, P. Tunner, and, in 1872, I. L. Bell argued that carbon monoxide, not carbon dioxide, is the first product of the combustion of carbon, so that the primary reaction is $2C+O_2=2CO$, and the secondary combustion of the monoxide furnishes carbon dioxide: $2CO+O_2=2CO_2$. It will be observed that the theory of probability and the simple kinetic hypothesis (2. 18, 4) make the reaction: $C+O_2=CO_2$ much more likely to occur than $2C+O_2=2CO$. H. B. Baker showed that when a stream of thoroughly dried oxygen is passed over charcoal at a red heat, no glowing occurs, but a little carbon dioxide and much carbon monoxide is formed, the oxygen in all cases being in excess. The drier the materials, the less the amount of carbon dioxide produced. On the other hand, when a mixture of carbon and platinum black was heated to redness in oxygen no glowing was observed, but a portion of the oxygen united with the carbon, forming carbon monoxide only. Since moisture and platinum both induce the union of carbon monoxide with oxygen, and in the absence of these substances carbon monoxide is the main product, the results "seem to point to the conclusion that carbon first burns to carbon monoxide." H. B. Baker also passed mixtures of oxygen and nitrogen, not specially dried, over purified carbon between 400° and 500°, and found that the proportion of carbon monoxide increased as the temp. was lowered, and as the proportion of oxygen in the mixture was diminished. Hence it was inferred that the carbon monoxide in these experiments could not be due to the reduction of carbon dioxide because carbon monoxide is not reduced by charcoal at 500°. C. J. Baker found that dried carbon which had absorbed dried oxygen at 12°, yielded only traces of gas on raising the temp. until, at 450°, the gases evolved consisted almost exclusively of carbon monoxide. He therefore concluded that carbon is burned directly to carbon monoxide by adsorbed oxygen. H. Wieland confirmed H. B. Baker's observation that carbon burns slowly in dry oxygen at 730°. H. B. Dixon, and H. B. Baker found that purified charcoal does not reduce well-dried carbon dioxide at about 630°. All this favours the assumption that carbon burns to carbon monoxide, but, as H. B. Dixon stated, " a decisive proof is still required." It was not found possible to show that the rate of either $C+O_2=CO_2$, or $2C+O_2=2CO$, can proceed at temp. under which the rate of $CO_2+C=2CO$, is inappreciable.

H. B. Dixon's work on the burning of gaseous carbon compounds leaves little room for doubt that in burning gaseous carbon compounds, carbon monoxide is produced before carbon dioxide. For example, H. B. Dixon, E. H. Strange, and E. Graham showed that the velocity of the explosion-wave is higher when the gas is half-burnt to carbon monoxide than when there is enough oxygen present to burn it completely. Moreover, the substitution of inert nitrogen for the additional mol. volume of oxygen required for complete combustion produces less retardation. So far as the propagation of the explosion-wave is concerned, therefore, the second mol. of oxygen is inert. This is well shown by the following rates of explosion :

Mixture of gases . .	$C_2N_2+O_2$	$C_2N_2+2O_2$	$C_2N_2+O_2+N_2$
Rate of explosion . .	2728	2321	2398 metres per second

Further, the flame is not only propagated more quickly, but the press. is higher and the reaction completed sooner in the first than in the second case. The only conclusion to be drawn from these results is that the formation of carbon monoxide precedes that of carbon dioxide.

In every case where attempts have been made to find if carbon oxidized to carbon monoxide or dioxide, both gases occur among the products of the reaction. Hence, it is not at all unlikely that we are dealing with concurrent reactions, say:

$$mC+\tfrac{1}{2}(n+m)O_2<\begin{matrix}(m-n)CO\\ nCO_2\end{matrix}$$

H. E. Armstrong suggested that carbon monoxide and dioxide are produced by the breaking down of a complex oxide of carbon; and T. F. E. Rhead and R. V. Wheeler developed the idea. At no temp. at which the rate of oxidation of carbon can be measured were they able to show that there is a primary formation of carbon dioxide or of carbon monoxide. Some carbon monoxide is produced during the oxidation of carbon at low temp. under conditions which do not admit of the reduction of carbon dioxide by carbon. On the other hand, carbon dioxide is undoubtedly produced at low temp. in quantities which cannot be accounted for by the supposition that carbon monoxide is first formed and then oxidized to carbon dioxide. Their measurements of the rates of the various reactions between oxygen, carbon monoxide, carbon dioxide, and carbon lead to the conclusion that in the burning of carbon, the two oxides are produced simultaneously. Neither of the oxides is the primary product of the oxidation in the sense that it takes precedence over the other. They assume that the oxygen is first fixed by the carbon so as to form what they call " a loosely formed physico-chemical complex " to which no definite mol. formula can be assigned, but, they say, which can be regarded as an unstable complex C_xO_y, where the symbol has a different meaning to that usually employed in chemistry. H. H. Lowry and G. A. Hulett support this hypothesis. During combustion, each oxygen mol. which comes into collision with the carbon becomes fixed in so far as it is rendered incapable of further progress by the attraction of several carbon mols. They added :

A considerable evolution of heat takes place during this attachment of oxygen mols., so much so that some of them eventually acquire sufficient energy to seize hold of a carbon atom and depart with it as carbon dioxide. Some of them become torn apart in the process —become atomized—and leave the carbon mol. as carbon monoxide. This formation of a complex, and partial decomposition as fresh oxygen mols. become attached, goes on until the carbon becomes "saturated," the products of combustion during this period (a comparatively short one) being C_xO_y, CO_2, and CO. After the carbon has become sat. there is an alternate formation and decomposition of the complex. Each oxygen mol. that impinges on the carbon is at once seized hold of to form the complex, but the energy set free when this occurs decomposes an eq. proportion of the complex formed from previous oxygen mols. So that, finally, when air is passed over sat. carbon maintained at a constant temp. by the application of an external source of heat, carbon dioxide and carbon monoxide appear in the products of combustion in volume sufficient to account for the total volume of oxygen in the air originally passed. In the normal burning of carbon, therefore, the carbon dioxide and carbon monoxide found as the apparently primary products of combustion, arise from the decomposition, at the temp. of combustion, of a complex the formation of which is the first result of the encounters between oxygen and carbon mols.

The reaction : $2C+O_2=2CO$.—The rate of the reaction : $2C+O_2=2CO$ has not been investigated. F. Pollitzer calculated for this reaction, $K=C_{O_2}/C^2{}_{CO}$; and $\log K=-13148T^{-1}-1·75\log T+0·000634T-4·2$. The free energy of the reaction $F=60100+8T\log T+20·4T-0·0029T^2$; the thermal value of the reaction $Q=60100-3·5T+0·0029T^2$. Hence, at the absolute temp.

	0°	300°	1000°	2000°
F . . .	60,100	71,800	101,600	141,300
Q . . .	60,100	59,300	59,500	64,700

The reaction : $C+O_2=CO_2$.—P. Farup determined the rate of the reaction : $C+O_2=CO_2$ between oxygen and graphite or arc-lamp carbon, at 455°, 485°, and 515° ; and between air and graphite at 485° and 515°. If x denotes the per cent. by vol. of carbon dioxide formed in the time t, the rate of formation of carbon dioxide is assumed to be :

$$\frac{dx}{dt}=k(a-x)\,;\quad\text{or}\quad k=\frac{1}{t}\log\frac{a}{a-x}$$

where k is the velocity constant and a is the initial volume of oxygen.

	455°		485°			515°		
x . .	2·39	1·62	7·46	5·40	3·73	20·17	11·58	7·67
k . .	0·11	0·10	0·32	0·33	0·38	1·21	1·16	1·24

Similarly experiments with air gave $k=1·605$ at 515°, and 0·485 at 485°. For oxygen, at a temp. $\theta°$, $\log k=a+b\theta$, and between 455° and 515°, the ratio $k_{\theta+10}/k_\theta$ is 1·50 ; and for air between 485° and 515°, 1·52. T. F. E. Rhead and R. V. Wheeler also made measurements of the rate of oxidation of wood charcoal at 350°, 400°, and 500°. A rise of temp. of 150° from 350° to 500° increases the rate of the reaction five- or six-fold. They noted at 350° and 400° respectively 0·20 and 0·60 per cent. of carbon monoxide ; and at 500°,

Time, t min. . . .	0	30	45	60	120
Total press., P mm. .	465·2	435·0	424·3	418·3	408·4
Partial press., p_{CO} mm. .	—	37·4	38·6	41·0	36·7
Partial press., p_{O_2} mm. .	96·4	18·7	8·9	3·3	—
k	—	0·0237	0·0230	0·0244	—

At the end of 30 min., at 500°, the gases contained 8·6 per cent. of carbon monoxide. They found similar rates with air and oxygen, and since the reduction of carbon dioxide by carbon at these low temp. is inappreciable, they concluded that no amount of local heating of the carbon can explain the formation of this carbon monoxide.

For the equilibrium constant $K=C_{O_2}/C_{CO_2}$, F. Pollitzer gave $\log K=-21350T^{-1}-0·4$, so that for $T=1273$, $\log K=-17·1$, the observed value is

—16·27. W. Nernst calculated the free energy of this reaction to be $97700+1\cdot828T-0\cdot00007T^2$, from which he inferred that the reversible combustion of a gram-atom of carbon by oxygen to carbon dioxide at atm. press. is 98,240 cals. at $T=300°$; and since the thermal value of the reaction at room temp. is 97,650 cals., it follows that *the heat of combustion of carbon at atmospheric temperatures is almost completely convertible into external work.*

The reaction : $CO_2+C\rightleftharpoons 2CO$.—The reversibility of the reaction $CO_2+C\rightleftharpoons 2CO$ was discovered by H. St. C. Deville[4] with his *le tube chaud et froid*, for it was known that heated carbon reduces carbon dioxide to the monoxide, and he observed that when carbon monoxide is heated to a temp. rather lower than the m.p. of silver, a little carbon dioxide is formed, but above 1000° none could be detected. This is in accord with general principles (2. 18, 4), for the reaction $2CO=CO_2+C$ is exothermic evolving 39 Cals., hence, the quantity of carbon monoxide is increased by raising the temp. I. L. Bell noted that the decomposition is accelerated by finely divided metals—nickel, cobalt, iron, etc. R. Schenck and co-workers also found that the reaction is greatly accelerated by finely divided iron, nickel, or cobalt, but not by the oxides of these metals. With nickel and cobalt the reaction at 445° behaves as if it were bimolecular : $2CO=C+CO_2$, and between 256° and 445°, monomolecular : $CO=C+O$ followed by $CO+O=CO_2$. P. Sabatier and J. B. Senderens explain the catalysis by assuming the cyclic reactions $M+CO=MO+C$, and $MO+CO=M+CO_2$. These reactions have also been studied by F. Zimmermann, A. Smits, M. Bodenstein and C. G. Fink, L. Gruner, E. Berger and L. Delmas, etc. H. A. Neville and H. S. Taylor found that the reaction between carbon and carbon dioxide is accelerated by the presence of alkali carbonates, alkaline earths, carbonates, sodium chloride or silicate, borax, nickel, or copper. Potassium carbonate is the most active salt catalyst. Reduced nickel promotes the reaction. It is assumed that the adsorption of carbon dioxide by carbon is augmented at 445° by these accelerating agents which alone show no absorptive capacity for the gas. R. T. Haslam and co-workers say that the reaction between carbon and carbon monoxide is unimolecular, and takes place at the surface of the carbon—*vide* carbon monoxide.

O. Boudouard studied the equilibrium conditions from right to left at 650°, 800°, and 925°. He used iron, nickel, and cobalt as catalytic agents ; and from left to right without catalysts. The importance of the reaction in producer-gas practice has attracted other workers—M. Mayer and J. Jacoby, K. Arndt and G. Schraube, T. F. E. Rhead and R. V. Wheeler, J. K. Clement, etc. R. Schenck and F. Zimmermann found that it is not the metal oxides, but rather the reduced metals which act catalytically. This does not agree with O. Boudouard's conclusion. R. Schenck and F. Zimmermann's results at low temp. do not agree with those of O. Boudouard ; the latter said that the dissociation of carbon monoxide is complete at 445°, while the former obtained 52·8 per cent. as the equilibrium value. There is a difference in the value of the constant $K=C_{CO_2}/C^2{}_{CO}$ obtained with different kinds of carbon ; and R. Schenck and W. Heller obtained 1 : 5 : 5·5 for the values of K with graphite, carbon from carbon monoxide, and wood or sugar charcoal. The difference is a consequence of the law of mass action, for if p denotes the vap. press. of carbon, K is really equal to $K'p$, where K' is a constant ; and since the vap. press. of carbon varies from one modification to another $K'p$ will be constant for any particular modification of carbon used. For equilibrium, the results indicated in Table XIII have been observed. F. Pollitzer found that at a constant press., $K=C_{CO_2}/C^2{}_{CO}$, and $\log K_p=8200T^{-1}-1\cdot75\log T+0\cdot0006T-3\cdot8$. K. Jellinek and A. Diethelm gave $\log K_p=8300T^{-1}-1\cdot78\log T+0\cdot000686T-3\cdot876$. Their data are indicated in Table XIII.

T. F. E. Rhead and R. V. Wheeler found that the effect of temp. and press. on the equilibrium can be represented by H. le Chatelier's formula :

$$500\int Q\frac{dT}{T}+(N_2-N_1)\log_e p+\log_e\frac{C_1{}^{n_1}C_1{}^{n'_1}\ldots}{C_2{}^{n_2}C'_2{}^{n'_2}\ldots}$$

where Q denotes the total heat of the reaction at T° K. ; p, the press. in atm. ; N_1 and N_2 the numbers of mols. on the left and right sides of the equation respectively—the subscripts 1 and 2 respectively refer to the initial systems ; $n_1, n'_1, \ldots$ and $n_2, n'_2, \ldots$ represent the number of molecules of the different substances taking part in the reaction ; and $C_1, C'_1, \ldots$ and $C_2, C'_2, \ldots$ denote the conc. of the different substances concerned in the reaction. For the system $2CO \rightleftharpoons CO_2 + C$; when $p=1$, with the system in equilibrium, $(N_2-N_1)\log_e p=0$; and if $Q=39$ Cals., the equation becomes $19500T^{-1}+\log_e(C^2_1/C_2)=k$. For variable press., assuming that the heat of the reaction is $Q=38055+2\cdot02T-0\cdot0031T^2$, the equation becomes $\frac{1}{2}QT^{-1}+\log_e p+\log_e(C^2_1/C_2)=k$.

TABLE XII.—PROPORTIONS OF CARBON MONOXIDE IN EQUILIBRIUM WITH CARBON DIOXIDE IN THE PRESENCE OF CARBON AT DIFFERENT TEMPERATURES AND ATMOSPHERIC PRESSURE.

Temp.	O. Boudouard.	M. Mayer and J. Jacoby.	G. Schraube.	T. F. E. Rhead and R. V. Wheeler
700°	58·67	60·11	63·44	—
750°	75·94	75·94	78·60	—

1050	$0\cdot7470\times10^{-3}$	0·4	17·78	28·53	40·06
1100	$0\cdot5260\times10^{-3}$	0·1	12·00	24·09	32·47

The reaction : $2CO+O_2 \rightleftharpoons 2CO_2$.— H. St. C. Deville[5] investigated this reaction in the vicinity of 1200° in his *le tube chaud et froid*. The subject was investigated by R. Bunsen, J. M. Crafts, E. Mallard and H. le Chatelier, O. Hahn, C. Langer and V. Meyer, H. B. Dixon and H. F. Lowe, A. Jaquerod and F. L. Perrot, M. Berthelot etc. F. Haber and A. Moser investigated the reaction at 445° and 518° by measuring the e.m.f. of a gas cell with a solid electrolyte. H. le Chatelier and E. Mallard, and N. Bjerrum employed the explosion method. I. Langmuir used heated wires ; L. Löwenstein, W. Nernst, and F. Emich used the vapour density method. F. Pollitzer computed that the heat of the reaction $Q=135210+3\cdot5T-0\cdot0027T^2$; and $\log K=-29600T^{-1}+1\cdot75\log T-0\cdot00058T+3\cdot4$. If p be the partial pressures of the components; P, the total press. ; and x, the degree of dissociation of the carbon dioxide, then, as in the case of water, $K=p^2_{CO}p_{O_2}/p_{CO_2}$; or $K=x^3/2(1-x)^2$; and when $P=1$, x is very small, so that $K=\frac{1}{2}x^3$, or $\log K=3\log x-\log 2$; hence, $3\log x=-29600T^{-1}+1·75\log T-0·00058T+3·4$. Hence, given either x or T, the other can be calculated. W. Nernst and H. von Wartenberg found for $x=0·00419$ per cent., T obs.=1300°, calc. 1375°; and for $x=0·029$ per cent., T obs.=1478°, and calc. 1560°. For the percentage degrees of dissociation of carbon dioxide at different press. and temp., *vide* Table XIV. J. E. Trevor and F. L. Kortright calculated the percentage dissociations and heats of dissociation, Q, indicated in Table XV. M. Pier found that the calculated values for the dissociation of carbon dioxide are higher than the observed, and this is taken to mean that the sp. ht. of the gas increases more rapidly above 2000° than is allowed for in the calculation. N. Bjerrum found for the dissociation at the absolute temp. T,

TABLE XIV.—PERCENTAGE DEGREES OF DISSOCIATION OF CARBON DIOXIDE AT DIFFERENT TEMPERATURES AND PRESSURES.

§ 11. The Chemical Properties of Carbon

Carbon, like nitrogen, is chemically inert at ordinary temp., but at high temp. it becomes one of the most active elements; for instance, it will displace oxygen from its combinations with various metals. With the exception of fluorine, and possibly under special conditions, oxygen, J. Thomsen[1] was right in saying that carbon does not unite with other elements at ordinary temp. When compounds are formed at higher temp., the products are usually very stable, and do not readily react or unite with other compounds. As R. Schenck and W. Peller showed, amorphous carbon in general is a more energetic reducing agent than graphite. He also inferred from the vap. press. that the diamond is more reactive than graphite, but the inference is open to doubt, for H. Moissan showed that the higher the temp. of formation, the less reactive is the product. R. Schenck and W. Heller added that for any given temp. in a blast-furnace worked with wood-charcoal the composition of the gaseous mixture will be different (richer in carbon monoxide) from the gaseous mixture of a furnace worked with coke (which is allied to graphite). H. N. Warren said that the reactivity of graphite obtained from a soln. of carbon in the metals varies with the nature of the metal from which it has been formed. Thus, that from chromium is less reactive than that from iron, nickel, or cobalt.

A. Morren[2] could not detect the slightest change in weight by heating a diamond white hot in an atm. of **hydrogen**. E. H. von Baumhauer noted a change in colour with green and brown diamonds, but the colour of other varieties and the translucency were not affected. H. Moissan also observed no change in weight when Cape diamonds were heated to 1200° in hydrogen. In a paper: *Formation par synthèse, au moyen de la pile, d'un carbure d'hydrogen*, C. Morren observed that hydrogen can be made to unite directly with carbon. M. Berthelot added that the union does not occur if the sparks are derived from an induction coil, but acetylene is formed with an electric arc in hydrogen. He also stated that no appreciable combination occurred when carbon is heated in hydrogen up to the temp. at which porcelain softens. He also noted the reverse action in that acetylene, methane, and naphthalene were decomposed into carbon and hydrogen when heated to 1400° in quartz tubes. W. A. Bone and J. C. Cain heated sugar charcoal in hydrogen at a white heat and obtained methane. W. A. Bone and D. S. Jerdan observed the formation of no acetylene or other unsaturated hydrocarbon, but found that at 1200° between one and two per cent. of methane is produced. Larger results showed that the gases are generated in definite proportions until equilibrium is attained when the hydrogen contains 7 to 8 per cent. of acetylene, 1·25 per cent. of methane, and 0·75 per cent. of ethane. J. N. Pring and R. S. Hutton found that at 1700°, traces of acetylene are formed and the proportion of that gas increases as the temp. rises to 2800°. The amount of methane upwards of 1000° is very small, and appears to be smaller the higher the degree of purity of the carbon. A part of the gas is decomposed by the hot walls of the tube. J. N. Pring said that above 1100° carbon unites directly with hydrogen, but the velocity of the reaction at 1200° is very slow; about 0·35 per cent. is formed in 22 hrs.; and at 1500°, 0·17 per cent. was formed in 2 hrs. The reaction is accelerated by platinum, so that at 1200°, 0·55 per cent. was formed, and at 1500°, 30 per cent., and W. A. Bone and H. F. Coward found that at 1150° a mixture of 0·03 grm. of carbon with platinum gave a 95 per cent. conversion into methane in 17 to 20 hrs. J. Sand and co-workers, and H. von Wartenberg have studied the statics and dynamics of these reactions.

According to W. A. Bone and D. S. Jerdan, when, by means of an alternating current at 160 volts, sparks are passed between carbon electrodes in hydrogen, for half an hour, a mixture of hydrogen with 1·51 per cent. hydrogen cyanide, 9·85 per cent. of acetylene and ethylene, and 2·46 per cent. of methane was obtained; and with the press. at 40 to 60 volts, the hydrogen contained 1·00 per cent. hydrogen cyanide; 8·08 per cent. acetylene and ethylene, and 1·62 per cent. of methane. The formation of hydrogen cyanide was attributed to the presence of a little nitrogen in the hydrogen. The rate of formation of the hydrocarbons is at first very great, and equilibrium is attained in about an hour.

The equilibrium conditions of the exothermal reaction $C+2H_2 \rightleftharpoons CH_4$ were studied by M. Mayer, V. Altmayer, J. N. Pring, and D. M. Fairlie. M. Mayer and V. Altmayer worked between 475° and 625°, using nickel as catalyst. They found at one atm. press.:

	475°	500°	550°	600°	625°
Vol per cent. CH_4 .	69·86	62·53	46·69	31·68	24·75

J. N. Pring and D. M. Fairlie worked between 1000° and 1700° at press. between 7 and 200 atm. The condition of equilibrium is $[CH_4]=K[H_2]^2$, and they found at

	1200°	1275°	1300°	1450°	1500°	1575°
K . .	0·00244	0·00140	0 00136	0·00091	0·00078	0·00062

H. von Wartenberg gave generally for the hydrocarbon reaction $mC+\frac{1}{2}nH_2 = C_mH_n+Q$ cals., where $[C_mH_n]=K[H_2]^{\frac{1}{2}n}$; and $\log K=QT^{-1}-(\frac{1}{2}N-1)1·75 \log T-(0\ 8n-3)$. From the heat of formation of methane $Q=18,900$, $\log K=9·3$; for ethylene, $Q=23,000$, and $\log K=6·5$; and for butylene, $Q=35,000$, and $\log K=3·2$. For the reaction $2C+H_2 \rightleftharpoons C_2H_2$, $\log K=-8750T^{-1}+1·6$. At $T=2000°$, $\log K=2·8$. This corresponds with about 0·1 vol. per cent. of acetylene in the hydrogen at one atm. press.

M. Mayer and V. Altmayer found that carbon is rapidly hydrogenized to methane when treated with **calcium hydride.** The action of **oxygen** and of **water** on carbon has been discussed in a preceding section. B. L. Vanzetti showed that the so-called *carbon hydrate* obtained from metal carbides by dissolving away the metal, is really carbon with adsorbed water. G. Lemoine[3] and others have noticed that **hydrogen dioxide** (*q.v.*) at ordinary temp. is rapidly decomposed by wood charcoal; and J. B. Firth and F. S. Watson studied the effect of different kinds of carbon.

According to H. Moissan,[4] **fluorine** and carbon combine with great energy even at the ordinary temp. Lampblack, purified and dried, immediately becomes incandescent; wood charcoal takes fire spontaneously, with the projection of brilliant sparks. Denser forms of carbon must be heated to 50° or 100° before they will become incandescent. Ferruginous graphite from cast iron unites with fluorine below a dull red heat; Ceylon graphite, purified by fusion with potash, requires to be heated to a somewhat higher temp.; gas carbon burns in fluorine only at a red heat; the diamond is not affected when heated to redness in a current of fluorine. The products are gaseous, and are usually mixtures of different carbon fluorides. The action of fluorine on an excess of one of the lighter forms of carbon, care being taken that the temp. does not rise very high, yields a colourless gas—carbon tetrafluoride, CF_4. The action of fluorine on carbon at a red heat yields a gaseous carbon fluoride which is not decomposed by electric sparks, is not absorbed by aq. or alcoholic potash, is almost insoluble in water, but dissolves in alcohol. A small quantity of a solid product is obtained at the same time. Both J. L. Gay Lussac and L. J. Thénard found that if charcoal be freed from hydrogen and moisture, by ignition in vacuo, it does not combine with **chlorine** even at a white heat. However, if an electric arc be formed between carbon rods in an atmosphere of carbon tetrachloride, the latter is rapidly decomposed into its elements; if the arc be maintained in an atmosphere of chlorine, crystals of hexachlorobenzene, C_6Cl_6, are formed, showing that carbon can unite directly with chlorine. According to W. G. Mixter, hydraulically-compressed sugar charcoal containing 0·13 per cent. of hydrogen and 0·04 per cent. of ash absorbs 4 per cent. of chlorine at a red heat, and does not give it up in a vacuum at that temp. The chlorine cannot be displaced by nitrogen, but can be removed by hydrogen. At the ordinary temp., little or no chlorine is absorbed. Lampblack absorbs more chlorine, and both charcoal and lampblack lose it at the temp. at which porcelain softens. Chlorine seems to act with most energy on those forms of carbon which are contaminated with hydrogen. The form in which it is combined is uncertain; nothing is extracted from the product by chloroform, benzene, alcohol, or ether. H. Moissan said that dry chlorine does not act on the diamond at 1100°–1200°, and some Cape diamonds changed neither in weight nor colour by the treatment. H. L. F. Melsens took advantage of the great adsorption of chlorine by charcoal to prepare liquid chlorine. The charcoal sat. with adsorbed chlorine is used like the chlorine hydrate in Faraday's experiment (**2**. 17, 10). W. G. Mixter noted that when charcoal, sat. with adsorbed chlorine, is burnt, a carbon chloride is formed. He found that when hydrogen is passed over purified wood charcoal sat. with chlorine, hydrogen chloride is formed and there is a reduction of temp. M. Berthelot and A. Guntz found the adsorption of 35·5 grms. of chlorine by purified charcoal develops 6·78 cals., a quantity double the heat of volatilization of liquid bromine and iodine, but much below the heat of formation of hydrogen chloride. In the formation of hydrogen chloride by passing hydrogen over charcoal sat. with chlorine, about seven times as large a vol. of chlorine is given off unchanged as the vol. of hydrogen chloride produced. R. Lorenz found that when a mixture of steam and chlorine is passed over charcoal at a dull red heat, hydrochloric acid is quantitatively formed, $H_2O+Cl_2+C=2HCl+CO$; but, according to A. Naumann and F. G. Mudford, this is not the primary reaction, for with an excess of steam, the reaction is probably $2H_2O+2Cl_2+C=4HCl+CO_2$, and the carbon dioxide is subsequently reduced to carbon monoxide. C. Willgerodt said that charcoal does not act as a carrier of chlorine to benzene. M. Berthelot found that dry chlorine unites with carbon when an electric arc with carbon electrodes is formed in the gas; and W. von Bolton so produced ethane hexachloride, C_2Cl_6, and hexachlorobenzene, C_6Cl_6. W. G. Mixter said that sugar charcoal and lampblack adsorb less **bromine** than chlorine; and when heated in vacuo, 0·26 to 1·49 per cent. of bromine is retained by the charcoal. The direct union of bromine and carbon has not been recorded. W. G. Mixter found that sugar charcoal and lampblack adsorb **iodine** in the same way as is the case with bromine. H. Davy said that when the electric discharge from carbon electrodes is passed through iodine vapour no chemical change occurs. At first, white fumes appear, and this is attributed to the action of moisture or hydrogen adsorbed by the charcoal; for the fumes soon cease, and when the tube is cooled the iodine appears to be unaltered.

H. Moissan found that the diamond is not attacked by **hydrofluoric acid** at 1100°–1200°. According to A. Bartoli and G. Papasogli, when wood charcoal or gas-retort carbon, after purification by chlorine, is used as the positive electrode in the electrolysis of aq. hydrofluoric acid, it is partly disaggregated, swelling up in the immersed part, and becoming so brittle that after a while it splits up by its own weight into rather large fragments, whereas the carbon at the negative electrode remains quite unaltered. On repeatedly washing the altered carbon until the wash-water is no longer acid, then drying it at 100°, reducing it to impalpable powder, repeatedly boiling it with hydrochloric acid, and once more thoroughly washing it with water, it exhibits the following properties: (i) It dissolves partially, giving a dark red colour, in strong sulphuric acid. (ii) It is attacked by a hot soln. of sodium hypochlorite, yielding sodium fluoride, mellic acid, and the usual derivatives of the latter. (iii) In addition to carbon, hydrogen, and oxygen, it contains fluorine, amounting to about 3 per cent. of the disaggregated carbon, and not due to electrolysis of mineral matter, inasmuch as the carbon used in the experiment did not yield on ignition any perceptible quantity of ash. When graphite is employed as positive electrode in the electrolysis of strong aq. hydrofluoric acid, the immersed portion swells up, becomes pappy, and quickly disintegrates; and the disintegrated portion when purified in the manner above described, forms a black powder, which swells up considerably when heated, is insoluble in all solvents, and contains carbon, oxygen, hydrogen, and fluorine. According to H. Debray and E. Péchard, when **hydrochloric acid** is electrolyzed with carbon electrodes, the gas evolved at the positive pole is a mixture of chlorine, carbon dioxide, and oxygen. The positive electrode is disintegrated and forms a black powder, which, after being washed and dried in vacuo, deflagrates below a red heat, giving off carbon monoxide and dioxide. The amount of oxygen in the product varies with the conc. of the acid. No soluble organic compound is formed. G. Gore said that wood charcoal is not changed by liquid hydrogen fluoride or chloride. W. G. Mixter found that after charcoal has been ignited in hydrogen chloride, it retains 0·26 per cent. of chlorine. M. Berthelot found that neither purified wood charcoal nor graphite is attacked by **hydriodic acid**. According to G. Gore, **silver fluoride** is not affected when heated with carbon, but in the presence of chlorine, silver chloride is formed; similarly, in a graphite containing vessel, silver fluoride is converted into the bromide or iodide when heated in the presence of bromine or iodine—a volatile carbon fluoride is formed. J. L. Gay Lussac and L. J. Thénard found that the fire-resisting **chlorides** mixed with carbon are not decomposed when heated, unless water be present; in that case, mercuric and silver chlorides may form carbon monoxide or dioxide, hydrogen chloride and the metal. F. Feigl found that charcoal exerts an **oxidizing action** when boiled with many soln.—*e.g.* **potassium iodide** is oxidized to iodine, and in alkaline soln. to the iodate. According to W. Skey, any surface of graphite, native or artificial, which has been for some time exposed to the air, liberates iodine from a soln. of **potassium iodide** in dil. sulphuric acid. The graphite, which can thus liberate iodine, loses this property when washed in ammoniacal or other alkaline soln.; also when ignited. This property of liberating iodine is restored to such graphite by a short exposure of it to the air, or by evolving nascent hydrogen against it; also by digesting it for a little while with hydrochloric or dil. sulphuric acid, either at a common temp. or at the b.p. of these acids respectively. Graphite, which thus liberates iodine, also rapidly determines a chemical effect upon mercury, when voltaically paired with it in pure hydrochloric acid, mercurous chloride being formed. Charcoal does not, even freshly prepared, notably liberate iodine; but it can be made to do so by digesting it with an acid, the effect of which is perhaps due to its removing all alkaline matters therefrom, and thus enabling the charcoal to retain the oxidizing agent necessary for effecting the liberation in view. When graphite, which has been exposed to the air, is voltaically connected in sea-water with graphite just recently ignited, electric currents are generated; graphite which has been desulphurized also generates electric currents when connected in this manner with any conducting sulphide in a soln. of an alkaline sulphide.

A. J. Balard found that there is an immediate detonation when charcoal is added to **chlorine monoxide**, Cl_2O, but the gas obtained is a mixture of oxygen and chlorine and contains but little carbon dioxide; and he added, "I believe that the decomposition is effected less by the affinity of carbon for oxygen, than by the heat which is developed by the adsorption of the gas in the pores of the charcoal." P. Schützenberger made some observations on this reaction. A. J. Balard said that charcoal did not appear to exert any action on **hypochlorous acid**. A. Bartoli and G. Papasogli found carbon dioxide among the products of the action of **sodium hypochlorite** on lignite. For the action of mixtures of **alkali chlorates** and acids, *vide infra*. H. Moissan said molten potassium chlorate does not act on the diamond. According to A. Ditte, when **iodine pentoxide** is warmed with charcoal, the reduction is accompanied by detonation; charcoal has no action on a boiling aq. soln. of **iodic acid**. At ordinary press., but in a sealed tube, the different varieties of carbon are attacked at different temp., thus, iodine and carbon dioxide are produced at 160°

with wood charcoal; at 180° with sugar charcoal, gas carbon, coal, and coke; and at 210°, with anthracite. Graphite is attacked with difficulty at 210°; but the diamond is not attacked at 260°. H. Moissan said that graphite separated from a soln. of carbon in platinum is readily attacked by iodic acid, giving off iodine vap. and carbon dioxide. J. L. Gay Lussac said that the **iodates** detonate on red-hot carbon. G. Lemoine also found that the separation of iodine from iodic acid is facilitated in the presence of charcoal.

W. Spring[5] observed no signs of the formation of carbon sulphide by subjecting a mixture of powdered carbon and **sulphur** to great press. F. Clément and J. B. Désormes also found that sulphur could be evaporated from a mixture of the two elements provided a certain temp. be not attained; when sulphur vapour is passed over red-hot carbon, a reaction occurs and carbon disulphide is formed. The reaction was studied by C. Brunner, G. J. Mulder, A. Schrötter, T. Sidot, G. C. Wittstein, etc.—*vide infra*. A. G. Doroshewsky and G. S. Paffoff studied the catalytic effect of carbon on the oxidation of sulphur. According to W. G. Mixter, charcoal adsorbs sulphur when heated to redness in sulphur vapour, or **carbon disulphide.** The sulphur is entirely removed by hydrogen, and is virtually all given up at a red heat. Filter paper soaked in carbon disulphide, and heated in sulphur vap., adsorbs nearly its own weight of the latter, and the product does not give up sulphur to carbon disulphide, or to a boiling aq. soln. of potassium hydroxide. According to H. Moissan, sulphur vapour begins to attack the diamond at about 1000°; while with black diamonds, the attack begins at about 900°. S. Bidwell discussed the influence of temp. on intimate mixtures of sulphur and graphite. B. Rathke, and A. von Bartal made carbon selenide, and M. Shimosé, carbon telluride, respectively by the action of **selenium** and **tellurium** or of their compounds, on carbon. W. A. Lampadius noted that carbon disulphide is formed when a pyritiferous coal is distilled; and F. Clément and J. B. Désormes observed carbon disulphide is produced when carbon is heated with many metal **sulphides.** F. Feigl found a soln. of an **alkali sulphide** is oxidized to sulphate when boiled with a little charcoal and in alkaline soln., the **copper sulphides** are oxidized to sulphate; and **cobalt sulphide** to sulphate. M. Houdard studied the solubility of the diamond in molten **manganese sulphide.**

F. Feigl found that a soln. of **hydrogen sulphide** is oxidized to sulphuric acid when boiled with charcoal. G. Gore found carbon to be insoluble in liquid **sulphur chloride.** Purified charcoal was found by M. Berthelot to react with **sulphur dioxide** at a red heat, forming carbon monoxide, carbonyl sulphide, carbon disulphide, and a little free sulphur. B. Lepsius said that when charcoal is heated electrically to a white heat in this gas, carbon monoxide is formed and also some sulphur; A. Eiboart said that carbon dioxide and sulphur are slowly formed; and A. Scheurer-Kestner represented the reaction by the equation: $2SO_2+3C=2CO+CO_2+2S$. F. Feigl found that **alkali sulphites** are oxidized when boiled with charcoal in alkaline soln. G. Tolomei said that carbon is attacked by **sulphuric acid** only when impurities are present. M. Berthelot stated that purified wood charcoal is not attacked by cold sulphuric acid, but at 100°, small quantities of sulphur and carbon dioxides are formed; purified graphite gives no gas at 100°, but the acid acquires a brown tinge. H. Moissan observed no reaction at the b.p. when sulphuric acid is mixed with graphite which has separated from a soln. of carbon in iron. According to A. Verneuil, when wood charcoal is heated with conc. sulphuric acid, the residue in the flask contains, among other things, *mellitic acid* and *benzene pentacarboxylic acid*:

1400 grms. of ordinary sulphuric acid were heated with 100 grms. of carbon, the process being continued until only from 90 to 100 grms. of residue remained in the flask. The temp. of the reaction was about 280°, but rose towards the end to about 300°, a rapid evolution of gas being maintained in order to ensure that the water formed was expelled with the carbon and sulphur dioxides. When the residue is treated with water, a dark brown soln. is formed, and a black, insoluble coagulum remains, showing no trace of the original structure of the charcoal. It is soluble in alkalies and in conc. sulphuric acid, and is under investigation. The strongly acid soln. is mixed with just sufficient barium chloride to precipitate the sulphuric acid, filtered, and evaporated to dryness, when a brown, amorphous, strongly acid residue is left, equal in weight to about 20 per cent. of the original carbon. When this residue is dissolved in water, sat. with ammonia, filtered and conc., ammonium mellitate separates in quantity equal to about 4 per cent. of the original carbon. The mother liquor is evaporated with a slight excess of barium hydroxide, and the barium salts are dissolved in hydrochloric acid, and fractionally precipitated with barium hydroxide soln. The first fraction carries down most of the colouring matter, whilst the next fraction is crystalline, and consists of barium benzenepentacarboxylate, which can be recrystallized from hydrochloric acid in the form of an acid salt.

E. Philippi and co-workers described the preparation of pyromellitic acid by the action of sulphuric acid on wood charcoal. According to H. Giraud, during the preparation of sulphur dioxide from charcoal and sulphuric acid, a white crystalline sublimate occasionally forms in the neck of the flask, and may be obtained in quantity by using excess of charcoal and carrying on the action until gas ceases to be evolved. After purification and recrystallization from alcohol, this substance forms small, colourless, efflorescent crystals, which, on sublimation, are transformed into a substance crystallizing in long needles and melting at 280°, and which is probably *pyromellitic anhydride.* H. Debray and E. Péchard found that when sulphuric acid is electrolyzed with carbon electrodes, a mixture of carbon dioxide and oxygen is evolved. The positive electrode is disintegrated, and the black powder which is formed, when washed and dried in vacuo, deflagrates at a temp. below red heat, evolving carbon monoxide and dioxide. A. Bartoli and G. Papasogli obtained a mixture of oxygen, carbon monoxide, and dioxide at the anode during the electrolysis of dil. sulphuric acid with graphite electrodes. By suitable alteration in the conc. of the acid, the temp., and the current density, A. Coëhn succeeded in carrying out the electrolysis in such a manner that carbon monoxide and carbon dioxide were almost alone produced at the anode. The gaseous mixture contained 70 per cent. carbon dioxide, about 30 per cent. carbon monoxide, and 1 per cent. of oxygen. At low temp., a disintegration of the anode takes place, and suspended particles of carbon find their way into the acid. At high temp., carbon dissolves in the acid, the soln. being coloured from yellow to reddish-brown. If the soln. thus formed is electrolyzed, using a platinum cathode, a deposit of carbon is obtained, at first as a thin, coloured film and then as a graphitic deposit. The soln. reduces Fehling's soln. and probably contains carbohydrates. In reversal of the above process, a cell was formed by means of a lead peroxide plate and a carbon electrode, in which, working under the conditions previously maintained, the carbon acts as the soluble electrode. This gave 1·03 volts with an external resistance of 100 ohms, and yielded a constant current until the lead peroxide plate was exhausted. F. Vogel said that the electrolytic dissolution of carbon is very improbable, since carbon separates from carbon compounds not as a cation, but rather as an integral part of the cation. K. Heumann and P. Köchlin found that powdered freshly calcined charcoal develops much sulphur and carbon dioxides when heated with **chlorosulphuric acid**, $SO_2.Cl(OH)$, but no carbonyl sulphide is formed.

M. Berthelot studied the reduction of **sulphates** by purified carbon (*vide* 2. 20, 29), and showed that the end-state with **potassium sulphate** can be represented by $K_2SO_4+2C=K_2S+2CO_2$, if the carbon is not present in too great an excess. J. Mactear represented the reactions with **sodium sulphate** and an excess of carbon below a red heat: $Na_2SO_4+4C=Na_2S+4CO$; and at 1150°-1300°: $3Na_2SO_4+6C=Na_2CO_3+Na_2S_2+Na_2S+4CO_2+CO$. He added that potassium sulphate behaves similarly but at a lower temp. A. Scheurer-Kestner represented the reaction in the presence of silica: $3Na_2SO_4+3SiO_2+5C=3S+4CO_2+CO+3Na_2SiO_3$. These equations, it must be observed, involve some guess-work. E. Kunheim studied the action of mixtures of carbon with an **alkaline earth, cerium, thorium, magnesium, aluminium, chromium, or manganese sulphate** in the electric arc furnace. H. Moissan found that molten **potassium sulphate or hydrosulphate** does not attack the diamond; and the subject has been further studied by M. C. Schuyten. H. Moissan found that **calcium sulphate** is not reduced by the diamond at 1000°. O. Boudouard found that a mixture of carbon and **barium sulphate** at 800° gives 82 per cent. of carbon monoxide and 17·1 per cent. of carbon dioxide. J. J. Berzelius found that mixtures of carbon and **selenites** furnish carbon monoxide and dioxide without detonation, and either a selenide or selenium is formed. The alkali selenites, said B. Rathke, give mostly polyselenides and very little monoselenide. E. Mitscherlich found that the **selenates** detonate on red-hot carbon and the smell of selenium can be detected. F. Feigl found that **sodium thiosulphate** in alkaline or neutral soln. is not affected by boiling with charcoal.

According to M. Berthelot,[6] neither the diamond nor graphite is altered when heated in **nitrogen**. He also found that charcoal free from hydrogen does not react with nitrogen either under the influence of an electric spark, or in the electric arc; but if the charcoal is associated with hydrogen, or if hydrogen or water vapour are present, then acetylene is produced, and this reacts with the nitrogen, forming hydrogen cyanide—*vide supra*. If the carbon contains alkalies or alkaline earths, then cyanides are produced. According to W. G. Mixter, nitrogen is not taken up when carbon is heated in nitrogen, but lampblack, sugar charcoal, and blood charcoal may retain nitrogen very tenaciously if they are heated in ammonia or nitrous oxide, and these gases are decomposed. The nitrogen is probably retained by the charcoal in the form of cyanogen, since that substance is adsorbed readily by charcoal at a red heat, and yields a product which, like those obtained by the direct action of nitrogen, furnishes ammonia when heated with steam. No paracyanogen appears to be retained. W. Hempel also found that the simultaneous combustion of nitrogen and oxygen in the presence of carbon furnishes considerable quantities of nitric acid. According to L. Clouet, when carbon is heated with **ammonia**, ammonium cyanide and hydrogen are formed: $2NH_3+C=H_2+NH_4CN$. The reaction was also discussed by M. Bonjour, C. Langlois, and W. G. Mixter. F. Kuhlmann said that some methane is also formed, but this was denied by C. Weltzien. H. Davy investigated the action of heated carbon on **nitrous oxide**; he said that combustion proceeds more vigorously than in air, so that one vol. of nitrous oxide yields one vol. of nitrogen and half a vol. of carbon dioxide. W. G. Mixter made analogous observations. J. Dalton also found that heated carbon burns more vigorously in **nitric oxide** than it does in air, forming half a vol. of nitrogen and half a vol. of carbon dioxide. P. L. Dulong noted that red-hot carbon burns in **nitrogen tetroxide** with a red flame. C. F. Schönbein discussed the action of this gas on carbon. R. Weber reported that **nitrogen pentoxide** has no action on carbon. F. Feigl found that **sodium nitrate** in alkaline soln. is not affected when boiled with charcoal. According to H. Debray and E. Péchard, when **nitrous acid** is electrolyzed with carbon electrodes, the gas evolved at the positive pole is a mixture of nitrogen oxides and carbon dioxide. The positive pole disintegrates, and furnishes a black powder, which, after being washed and dried in vacuo, deflagrates at a temp. below a red heat with the evolution of carbon monoxide and dioxide. The amount of water and oxygen in the product varies with the conc. of the acid. W. G. Mixter said that charcoal adsorbs nitrogen from nitrous and nitric oxides. E. Philippi and co-workers investigated the action of nitric acid on carbon.

According to C. F. Schönbein,[7] red-hot carbon burns vigorously in conc. **nitric acid**, and powdered carbon decomposes the acid in the cold—nitrogen peroxide free from carbon dioxide is evolved. H. Moissan found that amorphous carbon at ordinary temp. and press. is oxidized by nitric acid; and A. Scott showed that nitric acid and wood charcoal give a black substance easily soluble in water, alcohol, and ether. It contains over 30 per cent. of carbon; 2 or 3 per cent. of hydrogen; and some nitrogen; it combines with alkalies, and the soln. gives a precipitate with most metal salts, and with hydrochloric or nitric acid. G. Dickson and T. H. Easter-field found that well-burnt wood charcoal reacts readily with fuming nitric acid, and there is a considerable rise of temp. If wood charcoal be boiled for 24 hrs. with fuming nitric acid, it passes completely into soln., and when diluted with water, a black amorphous substance resembling mellogen is precipitated while mellitic acid and non-crystallizable acids remain in soln. Nitric acid of sp. gr. 1·1 can oxidize well-burnt wood charcoal, and when the mixture is boiled for 7 days, it forms a black mud which is soluble in alkalies. The acid soln. contains mellitic acid, but no oxalic acid. Coal under similar conditions gives a small yield of mellitic acid. F. B. Burls and co-workers noted that when carbon and certain carbon compounds—cane sugar, caramel, etc.—are heated with dil. nitric acid, some hydrogen cyanide is evolved. They suggest that nitrous acid is first formed: $2HNO_3+C=CO_2+2HNO_2$, and it is this which reacts with the carbon: $HNO_2+2C=CO_2+HCN$.

According to R. J. Friswell, when bituminous coal is treated with 49 per cent. nitric acid the mass becomes warm, and dense red fumes are given off. When the deep brown liquid is filtered from the unchanged coal, and acidified with hydrochloric acid, it furnishes a deep brown, flocculent precipitate. The precipitate is colloidal and peptizes as the salts and acids are removed by washing.

When washed and dried at 100°, it forms a black friable mass, showing bright conchoidal fractures. If heated on platinum foil it puffs, swells slightly, and leaves a residue of carbon rather more bulky than its original mass, and almost as brilliantly black. The puffing is very like that of a nitro-compound with a very high carbon ratio; attempts to reduce it with zinc dust and caustic soda and with sodium amalgam have hitherto failed, and so have similar attempts with acid-reducing mixtures. The presence of nitrogen is indicated in the usual manner on heating it with sodium; on submitting it to dry distillation with zinc dust, hydrogen and cyanogen are evolved, and a small aq. distillate, smelling of ammonia and faintly of pyridine, and containing a very large quantity of hydrocyanic acid, is also obtained.

L. Carius oxidized graphite by mixing it with nitric acid, sp. gr. 1·5, and heating it in a sealed tube to 250°–260°, and keeping the temp. at 300°–330° for 1–2 hrs. W. Luzi's and H. Moissan's observations on the action of nitric acid on the different forms of graphite have been previously described. F. C. G. Müller showed that when wood charcoal is heated in the vapour of nitric acid above 1000°, the issuing gases consist of 52·2–57·2 per cent. CO_2; 13·3–14·7 per cent. CO; 3·4–4·6 per cent. H_2; 24·9–26·7 per cent. N_2.

P. Schafhäutl, and later R. F. Marchand, noted the formation of a peculiar substance when graphite is treated with oxidizing agents. This product was then studied by B. C. Brodie, J. Gottschalk, M. Berthelot, etc. B. C. Brodie found that when graphite is heated with a mixture of nitric acid and potassium chlorate, it increases in weight, and what he called **graphitic acid** is formed. To this he assigned the formula, $C_{11}H_4O_5$. He prepared this product in yellow plates by treating an intimate mixture of one part of purified graphite and three parts of potassium chlorate, with sufficient conc. nitric acid to make a liquid mass. The solid residue remaining after the mixture has been heated 3–4 days on a water-bath, is washed with water and dried at 100°. Four or five repetitions of the treatment are needed to ensure the conversion of all the graphite to graphitic acid. H. Moissan's modification of this process has been previously described; and T. Gottschalk stated that five successive treatments were needed to oxidize graphite completely to graphitic acid by the action of fuming nitric acid of sp. gr. 1·525, and potassium chlorate; and he added that the graphite passes through successive stages of oxidation, forming, after three operations, a grass-green substance which is readily oxidized to graphitic acid by heating on a water-bath with a soln. of potassium permanganate and dil. sulphuric acid. L. Staudenmaier claimed that graphitic acid can be prepared in considerable quantity, in a comparatively short time (24 to 48 hrs.), and without danger of explosion by the following process:

Very finely divided graphite (25 grms.) is stirred into a mixture of conc. sulphuric acid (1 litre) and nitric acid of sp. gr. 1·4 (½ litre), and, at intervals, potassium chlorate is added (about 450 grms. in all). The mixture is kept at the ordinary temp., is well stirred after each addition of chlorate, and each portion of chlorate is added only after the gas-evolution from the previous addition has completely ceased. When a sample treated with permanganate and acid becomes of a pure yellow colour, the acids are thoroughly washed with cold water from the powder, which is then oxidized with permanganate. Any excess of permanganate is destroyed by hydrogen peroxide, and the resulting graphitic acid washed successively with dil. nitric acid, alcohol, and ether.

F. S. Hyde also suggested modifications of the process. Ordinary charcoal when similarly treated is converted into a brown mass soluble in water, while the diamond is not attacked. M. Berthelot utilized these facts in devising a method for determining the proportions of amorphous carbon, graphite, and diamonds present in a mixture. G. Charpy found that permanganic or chromic acid oxidizes graphite to graphitic acid, but the reaction readily proceeds too far. V. Kohlschütter and P. Haenni assumed that chlorine dioxide is the oxidizing agent in the mixture of potassium chlorate and nitric acid. A. Lang studied the oxidation of graphite with permanganic acid, and conc. sulphuric acid, fuming nitric acid, and potassium chlorate. According to B. C. Brodie, if lampblack sugar charcoal is heated with a mixture of 4 parts of sulphuric acid, and one of nitric acid, the carbon is rapidly oxidized to a black mass which is soluble in conc. acid, and is reprecipitated by water; it is soluble in dil. acids, in salt soln., in water and in aq. alkali hydroxides. The reaction with graphite under similar conditions has been previously discussed.

F. Gottschalk said that the composition of the end-product varies between $C_{11}H_4O_6$ and $C_{33}H_{12}O_{18}$, according to the duration of the oxidation; L. Balbiano, between $C_{13}H_4O_7$ and $C_{14}H_4O_7$. M. Berthelot, W. Luzi, and H. Moissan found that different varieties of graphite furnish different oxidation products. The yellow flakes of graphitic acid do not possess a crystalline structure; they have no effect on polarized light. The flakes are made up of an indefinitely large number of very thin plates of diameter $10\mu\mu$ to $50\mu\mu$, and of ultra-microscopic thickness. The particles show the Brownian movement. According to P. Gaubert, graphitic acid is crystalline; the optical character is negative; and the index of refraction is 1·93–2·00. V. Kohlschütter and P. Haenni have shown that the apparently crystalline particles of graphitic acid are not crystals, but pseudomorphs of the original graphite particles. After repeated washing with water, graphitic acid passes into a colloidal soln., which can be flocculated by dil. acids, and the precipitated gel is peptized by water. The variously coloured graphitic acids differ merely in their degree of dispersity, the lighter coloured products, obtained by repeated oxidation, being more highly dispersed. It is not true, as was formerly supposed, that the colour of the graphitic acid depends on the sample of graphite from which it is made.

F. A. J. Fitzgerald compared the rapidity of oxidation of E. G. Acheson's graphite with Cingalese graphite when treated by L. Staudenmaier's process under like conditions. The latter variety was all converted into the yellow oxide after five treatments, whereas Acheson's graphite was not all oxidized after seven treatments. This agrees with H. Moissan's observations that the higher the temp. to which the graphite has been heated, the more resistance does it offer to attack by the oxidizing mixture. T. Hübener, and W. Luzi noted that besides graphitic acid, much mellitic acid is produced, and with potassium chlorate and fuming nitric acid, all the graphitic acid can be converted into mellitic acid. Observations have been made by J. C. G. de Marignac, N. Fedoroff, A. Bartoli and G. Papasogli, W. A. Selvig and W. C. Ratliff, M. Berthelot and P. Petit, P. and L. Schützenberger, E. Weinschenk, etc. Graphitic oxide is regarded as an organic compound derived directly from elementary carbon, a link as it were between organic and inorganic chemistry. In contrast with the general stability of graphite, graphitic oxide or acid—as it is variously called—is peculiarly unstable, and B. C. Brodie found that it deflagrates at a temp. just below a red heat, and leaves a black, soot-like residue known as *pyrographitic acid*, $C_{22}H_2O_4$—probably graphite. J. Stingl said that pyrographitic acid has marked decolorizing powers; heating with sulphuric acid converts it into carbon.

According to M. Berthelot, when a mixture of one part of graphitic oxide and 80 parts of hydriodic acid, of sp. gr. 2·0, is heated to 280°, it forms an amorphous, insoluble, brown substance which he called *hydrographitic acid.* It passed back into graphitic oxide when treated with potassium chlorate and nitric acid. V. Kohlschütter and P. Heanni showed that when heated or treated with reducing agents, graphitic acid is reduced to carbon. Heating experiments have shown that the gases evolved are water, carbon monoxide, and carbon dioxide, the ratio CO/CO_2 being greater the more slowly the heat is applied. The temp. at which the decomposition becomes explosive is also lower the slower the heating, and if the heating is very slow the decomposition may go quietly to completion without explosion. The black, voluminous residue consists of 99·7 per cent. carbon. It has all the properties of soot, but can be compressed into a mass very similar to graphite. When the decomposition of the graphitic acid by heat takes place under press., the graphitic character of the residual carbon is more marked. By decomposing the graphitic acid under sulphuric acid at 160°–180°, a residue was obtained having properties intermediate between those of soot and graphite. Treatment of graphitic acid with reducing agents, such as ferrous or stannous salts, gave products with strongly marked graphitic properties, giving graphitic acid again when oxidized. These products, however, were contaminated with adsorbed iron or tin compounds, which were difficult to remove. L. Balbiano found that when graphitic oxide is heated under reduced press. it furnishes carbon monoxide, carbon dioxide, and water; while at higher temp. the water vapour acts upon the carbon, and small amounts of hydrogen and methane are formed. By treating graphitic oxide with a soln. of hydroxylamine in a mixture of alcohol and water, a residue consisting only of graphite and water remains. The general results of the work of S. Porcher, A. Bartoli and G. Papasogli, H. Moissan, J. Wiesner, E. Weinschenk, F. S. Hyde, G. B. Trener, H. le Chatelier and S. Wologdine, and G. Charpy show that the modifications of carbon obtained by B. C. Brodie, W. Luzi, and M. Berthelot are compounds, soln., or mixtures of carbon with other elements. G. A. Hulett and O. A. Nelson found that on removing water from graphitic acid, the vap. press. drops continuously with no suggestion of a break, and concluded that graphitic acid is a colloidal oxide of carbon in which water is adsorbed on relatively large surfaces. The oxide is assumed to be of the order C_3O or $C_{11}O_4$. L. Balbiano considered various graphitic acids to be adsorption products of graphite, water, carbon monoxide, and carbon dioxide. They have no acidic or quinonic functions, and he suggested they be called *hydrocarboxygraphites.* P. Debye and P. Scherrer also said that the X-radiograms of graphitic acid show that it is a mixture and not a homogeneous chemical individual.

H. Debray and E. Péchard found that in the electrolysis of nitric acid with graphite electrodes, similar phenomena were observed as with nitrous acid; and A. Bartoli and G. Papasogli stated that with graphite electrodes, nitrogen-free graphitic acid is formed; some carbon monoxide and dioxide are evolved; and the soln. contains mellitic, pyromellitic, and hydromellitic acids. C. F. Rammelsberg said that some graphites burn in contact with fused **potassium nitrate,** while other varieties are not attacked; H. Moissan found that this treatment has no action on the graphite which separates from a soln. of carbon in molten platinum. A. Vogel said that if potassium nitrate be at a temp. a little above its fusion point, the carbon is oxidized to carbon dioxide, and nitrogen, nitric oxide, and nitrogen trioxide are formed; but if the temp. and the proportions of the constituents are suitable a mixture of potassium nitrite and carbonate is formed; if the nitrate is in excess, only potassium nitrite is formed. H. Moissan said that molten potassium nitrite does not act on the diamond. J. Reiset and N. A. E. Millon said that **ammonium nitrate** detonates on red-hot carbon, and an explosion occurs when a mixture of that salt and carbon is heated to 170°. In the electrolysis of various salt soln. with wood charcoal or retort carbon electrodes, A. Bartoli and G. Papasogli found the anode gradually disintegrates to a black powder of mellitic and hydromellitic acids, less gas than the theoretical amount is evolved, and the soln. acquires a brown colour, and an acidic reaction; with soln. of **nitrates, phosphates, arsenates, and antimonates,** mellogen is formed, and phospho-mellogen or stibio-mellogen. They also found that soln. of **phosphoric, arsenic, and antimonic acids** behave like the soln. of the salts. G. Gore found carbon to be insoluble in liquid **phosphorus trichloride,** or **antimony pentachloride.**

According to H. M. Kahn,[8] fused **alkaline earth carbides** dissolve carbon, some of which separates as graphite on cooling. The amount of carbon dissolved by the fused carbide increases with the intensity of the current employed in the furnace and also with the time of passage of the current when its intensity is kept constant. In an experiment in which a current of 500–600 ampères was passed for six and a half minutes, five per cent. of carbon was taken up by the fused carbide. When the period of heating is further prolonged, the results are complicated by decomposition of the carbide. According to G. Gore, carbon is insoluble in liquefied **cyanogen** and in liquid **carbon dioxide.** M. Berthelot said that carbon reacts with **carbonates,** forming carbon monoxide, etc. H. Moissan found that at 1000° to 1200°, the diamond quickly disappears in contact with fused **potassium or sodium carbonate,** the graphite which separates from a soln. of carbon in platinum is rapidly attacked by this mixture; molten alkali carbonates and the diamond furnish carbon monoxide. V. A. Jaquelain and H. Baumhauer, and L. Colomba suggest that the carbon dioxide is reduced by the diamond, $CO_2+C=2CO$; while C. Doelter believed that the carbon dioxide is dissociated, and that the diamond is attacked by the liberated oxygen. O. Boudouard found that a mixture of carbon and **calcium carbonate** at 650° gives a mixture of 78 per cent. carbon monoxide and 22 per cent. of carbon dioxide; carbon and **barium carbonate** at 800° give a mixture of 95 per cent. of carbon monoxide and 5 per cent. carbon dioxide. K. E. Glasson found that with **iron carbonate** a mixture of carbon monoxide and dioxide is obtained in the proportions 1 : 5. S. Petuchoff heated the carbonates of the alkalies and calcium with carbon and sulphur, and noted that some carbon monoxide is formed. A number of observations has been made on the action of carbon on **organic compounds**—*e.g.* R. Ehrenfeld, G. Lemoine, and J. B. Senderens studied its action on *alcohols*; P. P. Bedson, on *pyridine*; C. A. Parsons, on *benzene, paraffin, sugar, carbon tetrachloride,* and *carbon disulphide*; and J. Stenhouse, and C. C. Stanford, on decaying organic matter. H. L. Dejust found a soln. of *p-phenylenediamine* is rapidly oxidized by air in the presence of graphite. A. W. Hofmann, P. Cazeneuve, R. Doupouy, M. Bodenstein and C. G. Fink, etc., studied the *catalytic action of carbon.* I. von Ostromisslensky found graphite to be insoluble in *tar, phenanthrene, chrysene, pyrene, picene,* and *triphenylene,* but it appears to be soluble in *decacylene,* while the diamond is insoluble in that menstruum. F. Feigl found that *oxalic acid* in aq. soln. is oxidized to carbon dioxide when boiled with charcoal. R. S. Marsden and J. Violle have noted the slow diffusion of carbon into the walls of heated **porcelain** crucibles. A. Daubrée, A. L. du Toit, etc., have studied the action of **fused silicates** on the diamond—*vide* origin of the diamond.

C. R. A. Wright and A. P. Luff[9] found that carbon monoxide begins to reduce ferric oxide and copper oxide at a lower temp. than hydrogen, and hydrogen at a lower temp. than carbon. Carbon from carbon monoxide begins to act at a lower temp. than sugar charcoal; and metal oxides prepared by precipitation are often reduced at a lower temp. than those prepared by the ignition of the metal salts. The reduction of **ferric oxide** with sugar charcoal began at 450°; of **cuprous oxide** at 390°; and of **cupric oxide,** between 390° and 440°. With carbon from carbon monoxide, the reduction of ferric oxide began at 430°; of cuprous oxide at 345°; and of cupric oxide, between 350° and 430°. The carbon reduction of **manganese dioxide** began at 260°; of **pyrolusite** at 390°; of **lead monoxide** at 415° to 435°; of **red lead** at 330°; of **lead dioxide,** 250° to 270°; **cobalt monoxide,** 450°; **cobalt sesquioxide,** 260°; **nickel monoxide,** 450°; and **nickel sesquioxide,** 145°; A. Guntz obtained carbon monoxide and metal by heating a mixture of carbon with ferrous oxide or manganous oxide to a high temp. R. Schenck and

W. Heller measured the equilibrium press. between iron, ferrous oxide, carbon, and the two oxides of carbon approached from both sides of the equation. They also used different forms of carbon—sugar charcoal, carbon from carbon monoxide, graphite, and the diamond. They found

Sugar Charcoal .		408°	465°	560°	590°	627°	649°
	Press. mm.	5·6	10·4	161·7	314·5	546·8	750·1
Carbon from CO .		468°	600°	669°	719°	778°	780°
	Press. mm.	10·3	65·0	169·2	395·8	750·0	780·0
Graphite .		500°	550°	609°	640°	700°	755°
	Press. mm.	12·3	36·8	77·5	111·0	287·3	574·2
Diamonds .		480°	530°	563°	585°	641°	675°
	Press mm.	8·2	54·1	134·7	228·5	521·3	725·1

From which it appears that the diamond reduces more energetically than graphite. They also made similar measurements with manganous oxide where the press. were less than for ferrous oxide, since at 1200° the press. was 10 mm., and at 1229°, 15·3 mm. The application to the blast furnace was also discussed by R. Schenck, A. Smits, B. Osann, E. Baur, etc. H. C. Greenwood gave for the reduction temp. of **chromium sesquioxide** with carbon, 1185°; **manganous oxide,** 1105°; **uranium dioxide,** 1490°; **silica,** 1460°; **zirconia,** 1400°; and **thoria,** 1600°. H. Moissan found that not the smallest trace of calcium carbide was formed when **calcium oxide** was heated with sugar charcoal at the fusion temp. of platinum (over 1755°). H. Moissan said that fused **alumina** is not reduced by carbon, but the vapours of alumina and carbon readily react to form aluminium carbide. E. Berger and L. Delmas examined the behaviour of different forms of carbon when mixed with metal oxides.

N. A. E. Millon[10] found that at 320° wood charcoal in contact with **alkali hydroxide,** and exposed to air, is transformed into a substance with some acidic properties; it is analogous to humus, it is soluble in aq. ammonia, and alkali-lye; but insoluble in water. P. Degener and J. Lach wetted animal charcoal with alkali-lye, and exposed it to air and light; they noted that an alkali peroxide was formed. Similar results were obtained with **alkaline earth hydroxides.** According to F. Haber and L. Bruner, carbon and sodium hydroxide interact to furnish hydrogen. Sodium formate and sodium hydroxide, when fused together, give off pure hydrogen, the reaction begins at about 205° and is quite complete at 350°; it is represented by the equation $HCO_2Na+NaOH=H_2+Na_2CO_3$. No oxalate is formed. A mixture of sodium oxalate and sodium hydroxide begins to decompose at 270°–280°, evolving pure hydrogen and forming carbonate only. If the potential of the carbon electrode in sodium hydroxide were due to the presence of either formate or oxalate, it should be higher than the hydrogen potential, because both formate and oxalate break up spontaneously, yielding hydrogen. Measurements of the potential of carbon in sodium hydroxide to which sodium formate or oxalate had been added, and from which hydrogen was being evolved owing to their decomposition, always gave the hydrogen potential—1·5 volts. The action of carbon monoxide on sodium hydroxide at 350° was found to be $2NaOH+CO=Na_2CO_3+H_2$. Hence, as previously indicated, it was inferred that the carbon electrode is really a hydrogen electrode.

Carbon exerts a **reducing action** on many salts. Carbon is one of the most important and useful of reducing agents for abstracting oxygen from the metal oxides. It is used in blowpipe reactions on charcoal; in the manufacture of iron and steel; and by its aid, directly or indirectly, the metals copper, zinc, lead, and tin are extracted; and even the metals of the alkalies obtained. It is used likewise in the poling of copper. In the case of animal charcoal, said W. Heintz,[11] the reducing action may be due largely to adsorbed hydrogen. C. F. Schönbein noted that soln. of **ferric salts** are reduced to the ferrous state, and D. Tommasi noted that in the electrolysis of soln. of ferric chloride, the carbon electrodes are strongly attacked and chlorine is given off. According to C. Moride, if a purified carbon rod be placed in an acidic soln. of **cupric sulphate**, it gradually becomes covered with copper. The reduction does not proceed so well in neutral or alkaline soln., and it goes better with soln. acidified with sulphuric acid than with nitric or hydrochloric acid; and worse in the presence of organic acids. A. F. Fol observed the effect with different kinds of carbon. C. F. Schönbein reported the reduction of **mercuric chloride** soln. to mercurous chloride, but A. E. Esprit said that there is really no reduction, the mercuric chloride is merely withdrawn from the soln. by absorption; and F. Feigl showed that when mercurous salts are boiled with blood charcoal, mercurous chloride is oxidized to mercuric chloride. C. Moride, and A. F. Fol noted the ready reduction of neutral or acid soln. of **silver nitrate,** or ammoniacal soln. of **silver chloride** to the metal. D. Avery noted the reduction of a soln. of **auric chloride,** $4AuCl_3+6H_2O+3C=4Au+12HCl+3CO_2$; but G. A. König said that the action is more physical than chemical. S. Brussoff made observations on the precipitation of gold from soln. of auric chloride by animal and wood charcoal, coke, and graphite. The gold is retained by the carbon, and the chlorine remains in soln. M. Lazowsky found that soln. of copper, silver, gold, mercury, platinum and palladium salts are reduced by this agent and the metal is deposited on the charcoal. W. Heintz noted the precipitation of platinum from soln. of **platinum chloride.**

F. Fiegl showed that when a soln. of **potassium chromite** is boiled with blood charcoal potassium chromate is formed, and he studied the oxidization of tervalent chromium to chromates. M. Berthelot [12] observed that at ordinary temp. charcoal is oxidized by a soln. of **chromic acid** and a little oxalic acid is formed. H. Moissan also found that amorphous carbon is readily oxidized by a mixture of chromic and sulphuric acids; the resistance to the attack is increased when the carbon has been preheated to a high temp. Molten chromic acid has very little action on graphite prepared from a soln. of carbon in melted platinum. R. E. and W. B. Rogers stated that diamonds are attacked at 180° to 230° by a mixture of **potassium dichromate** and sulphuric acid. G. Charpy found that a mixture of chromic acid and sulphuric acid oxidizes graphitic oxide or graphite to carbon dioxide more quickly than a mixture of conc. sulphuric acid and **potassium permanganate.** The former gives as much carbon dioxide at 45° as the latter does at 100°. A mixture of nitric acid and potassium chlorate was found to be less effective than the conc. sulphuric acid and potassium permanganate. The oxidizing action of some of these soln. is utilized in wet processes for the determination of carbon.[13] L. J. Simon found that a mixture of silver dichromate and sulphuric acid oxidizes Canadian graphite completely, but the diamond, wood charcoal, coke, sugar charcoal, anthracite, and natural coke are only partially oxidized. The action of mixtures of sulphuric or nitric acid and potassium chlorate has been previously discussed.

The uses of carbon.[14]—The diamond is used as a gem-stone; for bearings, etc., in watches, electric meters, and scientific instruments; for testing the scratching hardness of minerals, etc.; for cutting glass; drilling glass and pottery; and, as a powder, in cutting diamonds, drilling rocks,—for which purpose carbonado is preferred because it has no tendency to cleavage, etc. Graphite is used in making refractory goods—*e.g.* bricks, crucibles—when the crystalline or flaky variety is preferred. A mixture of plastic clay with 50 to 75 per cent. of Cingalese graphite is moulded, dried, and fired in muffles in a reducing atm. It is used as a resistor in electric furnaces—*e.g. kryptol* is a mixture of graphite, carborundum, and clay so compounded as to give a granular mass; but graphite alone gives as good or even better results. Graphite is used in the manufacture of lead pencils. A mixture of graphite and clay, very carefully graded and washed, is moulded by expression, fired, and fitted into the wooden casing. Graphite—particularly the colloidal form (*q.v.*)—is used as a lubricant with or without tallow, grease, palm oil, etc. Graphite is used in the foundry as a facing for moulds; in making paints, particularly for coating iron surfaces; in electrotyping; for commutator brushes; in making battery plates; as a polishing medium—*e.g.* for gunpowder—in making stove polish; as a preventive of boiler scale; etc. Amorphous graphite, and charcoal are used for decolorizing sugar, fats, glycerol, etc.; in the filtration and disinfection of liquids; for the separation and recovery of gases and vapours; the purification of gases; the storage of gases; as a catalyst in many reactions; in the production of high vacua; as an absorbent in gas masks for noxious gases, and in the removal of industrial stenches. The charcoal mask was recommended by J. Stenhouse in 1854. Charcoal is used as a constituent of some explosives; as a depilatory in the tannery; in making crucibles; battery plates; in the manufacture of indian ink, printers' ink, black paints; etc. The manufacture of carbon electrodes for electric furnaces and arc lighting is one of the most important branches of the carbon industry, and is growing rapidly as electric furnaces are increasingly applied in the metallurgical industries. As experience in the manufacture of carbon electrodes grows, the specifications as to purity, electrical resistance, hardness, and density become more and more stringent. Carbon electrodes were used by H. Davy[15] about 1806. Carbon filaments are employed in incandescent electric lamps. The light emitted by a hot body increases rapidly with rise of temp. A platinum wire heated by the electric current gives a good light, but this metal melts at too low a temp. to render it satisfactory. Carbon filaments were then tried and they gave better results, but they had a comparatively short life. Improvements in the manufacture of the filaments considerably increased the length of their practical life. The useful life of a carbon filament lamp depends more on the vaporization than on the m.p. of the carbon. Different kinds of carbon have different vap. press. The graphitized filaments have the longer life.

The carbons are made by squirting a soln. of cellulose through a die which hardens the liquid into dense fibres; these are carbonized out of contact with air at as high a temp. as possible in a gas-fired oven. The filaments are afterwards heated electrically in an atm. of hydrocarbon gas and the decomposition of the hydrocarbon produces a smooth dense deposit of graphite. The filament is afterwards heated in an electric furnace at over 3000° for a few moments, and the result is known as the *metallized filament* because the temp. coeff. of its resistance is now similar to that of the metals. While the simple carbon filament has a practical life of about 100 hrs. at 3 watts per candle, the graphitized filament burns about 500 hrs., and the metallized filament 1500 hrs. under the same conditions.

Filaments made from osmium, tantalum, and tungsten are superior to carbon. Tungsten withstands the highest temp. without melting or vaporizing, and it gives the highest luminous efficiency.

The compounds of carbon with the other elements are bewildering in number and complexity. Over two hundred thousand have been isolated and analyzed, and more are synthesized every year. Hence, the study of the compounds of carbon, with the exception, conventionally, of a very small proportion, is relegated to a special division called Organic Chemistry.

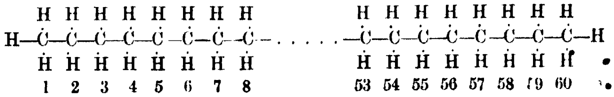
§ 12. The Constitution, Valency, and Atomic Weight of Carbon

In his paper: *Ueber die Constitution des Knallquecksilbers*, F. A. Kekulé[1] showed that the C_2-group was *quadrivalent* in methane, methyl chloride, chloroform, chloropicrin, acetonitrile, mercuric fulminate, etc. F. A. Kekulé understood by C_2 what A. W. Williamson, and C. F. Gerhardt represented by C, the atom of carbon of at. wt. 12; and later, in his *Ueber die gepaarten Verbindungen und die Theorie der mehratomigen Radicale*, stated:

> Die Kohlenstoff ist, wie sich leicht zeigne lässt und worauf ich später ausführlicher eingehen werde, vierbasisch oder vieratomig; d.h. 1 Atom Kohlenstoff $=C=$ 12 ist äquivalent 4 At. H. Die einfachste Verbindung des C mit einem Element der ersten Gruppe, mit Wasserstoff oder Chlor, ist daher: CH_4 und CCl_4.

The subject has been discussed in the first volume (**1.** 5, 16), where it is shown that E. Frankland, and H. W. Kolbe anticipated F. A. Kekulé a little in demonstrating the quadrivalency of carbon. The position of carbon in the middle of the periodic table corresponds with its forming compounds with nearly all the other elements irrespective of their electrochemical nature. According to A. Stock, the chemistry of carbon is a composite of the chemical properties of boron, nitrogen, and silicon, the elements nearest to carbon in the periodic system. It resembles silicon in respect of its quadrivalence, and the formation of compounds of similar formulæ; it resembles boron in respect of the large number of compounds which it forms, and the tendency to form long chains of atoms; it resembles nitrogen in its tendency to form volatile compounds of low mol. wt.; it resembles silicon and boron in its tendency to form non-volatile compounds of high mol. wt.; and it possesses in a greater degree than nitrogen or silicon the tendency to form molecules with both negative and positive groups. Carbon atoms have a great tendency to unite amongst themselves, to form complex atomic systems. In tetracetylenedicarboxylic acid, there are ten carbon atoms in juxtaposition $HO.OC-C\equiv C-C\equiv C-C\equiv C-C\equiv C-CO.OH$; and in dimyricyl, $CH_3(CH_2)_{58}CH_3$, there is a long continuous chain of sixty carbon atoms:



$$\begin{array}{cccccccccccccccccccc} & H & H & H & H & H & H & H & H & & H & H & H & H & H & H & H & H & \\ H- & C- & C- & C- & C- & C- & C- & C- & C- & \cdots\cdots & -C- & C- & C- & C- & C- & C- & C- & C & -H \\ & H & H & H & H & H & H & H & H & & H & H & H & H & H & H & H & H & \\ & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & & 53 & 54 & 55 & 56 & 57 & 58 & 59 & 60 & \end{array}$$

This was illustrated by G. Martin by collecting the thermal data of the combinations of carbon with other elements and erecting perpendiculars from the positions of these elements on the periodic table. The lengths of the perpendiculars are proportional to the thermal data, or what he calls the affinities of the elements. The loci of the upper ends of the perpendiculars are supposed to form a surface—*affinity surface.* The affinity surface for carbon shows a steep peak over carbon itself, and it indicates that carbon has a greater affinity for itself than is the case with any other element. Carbon appears to be unique in the number and variety of such compounds which it readily forms.

The greater part of the theory of the constitution of organic compounds is built up on the assumptions that (i) the valency of carbon is four; (ii) the four valencies are eq. each to each; and (iii) the valencies are distributed in three dimensions acting in the direction of the axes of a tetrahedron, and, added H. E. Armstrong, nothing is more surprising than the completeness with which the vast array of facts included in organic chemistry may be ordered by reference to the tetrahedron model.

Attempts have been made to prove that the four valencies of the carbon atom are of equal value. The argument is negative rather than positive. A. Popoff showed that the two unsaturated valencies of carbon monoxide are of equal value; and A. Geuther, and L. Henry then attempted to demonstrate the equality of all four carbon valencies in so far as compounds with the same radicles introduced in different positions are identical in their properties. The argument is not conclusive since it can also be interpreted to mean that there is only one orientation for stable equilibrium when the compound is prepared in the different ways. According to J. U. Nef, the two bromopropionic acids

$${}^{Br}_{H}\!>\!C\!<\!{}^{CH_3}_{COOH}$$

$${}^{H}_{Br}\!>\!C\!<\!{}^{CH_3}_{COOH}$$

behave differently towards polarized light being respectively dextro- and lævotropic. When heated, hydrogen bromide is given off, and the residual ethylidene carboxylic acid absorbs ammonia, $H.NH_2$, water, H.OH, etc., furnishing products which ought to be the same if all the carbon valencies are alike, but two derivatives are obtained from the *d*- and *l*-acids. Hence, argued J. U. Nef, the four carbon valencies are not alike each to each, but are eq. in pairs as illustrated by $\pm C \mp$, so that the products of decomposition would be represented

$$\pm\!>\!C\!<\!{}^{CH_3}_{COOH}$$

$$\mp\!>\!C\!<\!{}^{CH_3}_{COOH}$$

P. Walden found that the *d*- and *l*-monobromosuccinic acids change on standing 2 to 5 years at ordinary temp. so as to form a mixture of equal amounts of the two acids; and a similar change occurs with the *d*- and *l*-lactic acids in 2 or 3 days at 140°.

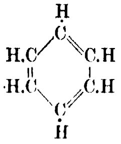
The disposition of the four valencies of the carbon atom has been the subject of much discussion. J. H. van't Hoff's view that the carbon atom is a material point at the centre of a tetrahedron with its valencies directed towards the four apices has been previously outlined (**1.** 5, 15). J. A. le Bel has modified this hypothesis. E. Knoevenagel suggested that the valencies of the tetrahedral carbon atom are directed, not to the corners, but to the middle of the sides; and F. W. Hinrichsen showed that the so-called double bonds can then be regarded as expressing the union of two carbon atoms along a common edge. J. Thiele assumed that the carbon atom has a *residual* or *partial valency* over and above its quadrivalency; and that the partial valencies of adjacent carbon atoms are conjugated.

Carbon in triphenyl methyl, $C(C_6H_5)_3$, prepared by M. Gomberg, may be *tervalent*. The compound has been studied by F. Kehrmann and F. Wentzel, J. F. Norris and L. R. Culver, W. Loeb, J. Piccard, W. Schlenk and co-workers, J. Schmidlin, A. E. Tschitschibabin, etc. It appears probable that the white solid is hexaphenylethane, $(C_6H_5)_3C.C(C_6H_5)_3$, which slowly dissociates in organic solvents, forming a yellow soln. which contains free triphenylmethyl, $(C_6H_5)_3C.C(C_6H_5)_3 \rightleftharpoons 2C(C_6H_5)_3$. The case appears to be analogous to that of cuprous chloride, $Cu_2Cl_2 \rightleftharpoons 2CuCl$. A. E. Tschitschibabin, and F. W. Hinrichsen hold that in ethylene, C_2H_4, carbon is tervalent and not quadrivalent with a double bond, because the mol. vol. is greater in bodies with the so-called double bond than it is in those with single linkages. This is not what would be anticipated, for atoms with a double bond should be nearer together than if bonded with single linkages. This argument is not conclusive. J. U. Nef, L. Gattermann, R. Scholl, etc., hold that in hydrocyanic acid, C:NH. the isonitriles, C:N.R; and fulminic acid, HO.N:C, carbon is truly *bivalent*. A. E. Tschitschibabin, and F. W. Hinrichsen hold that in acetylene, C_2H_2, carbon is bivalent because with quadrivalent carbon and a triple bond, acetylene is not likely to be so stable as it really is. A. Gillet also discussed the bivalency of carbon. The bivalency of carbon in carbon monoxide has been previously discussed (**1.** 5, 13). If carbon here be quadrivalent, J. W. Brühl said that the calculated and observed values for the mol. refraction are in agreement, but not if the carbon be bivalent, C : O. F. Landolph suggested that in acetone dihydrofluoride, $C_3H_6O.2HF$, the carbon is *sexivalent*, but, as F. W. Hinrichsen has shown, there is no need for this assumption; among other possible formulæ, carbon quadrivalent, there is $(CH_3)_2C(OH)F$. Similarly, in J. Thiele and W. Peter's methyl iododichloride, CH_3ICl_2, carbon appears to be sexivalent, and in M. Gomberg's triphenylbromomethane tetraiodide, $\{(C_6H_5)_3CBr\}I_4$, carbon appears to be *octovalent*. In these cases the carbon is quadrivalent when the halogens are assumed tervalent.

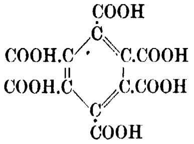
The carbon molecule.—D. Aufhaüser [2] argued that from its position in the periodic table, and the character of its compounds, carbon ought to be a very reactive gas. That it is not is taken as evidence that solid carbon is highly polymerized. The number of atoms contained in the carbon molecule is unknown. The non-volatility of carbon, except at very high temp., has led to the view that the molecule is very complex. According to H. F. Jüptner von Jonstorff, and W. C. Roberts-Austen, the presence of 0·5 per cent. of carbon in iron lowers the m.p. about 70°; and with this datum the number of atoms per mol. of carbon in molten iron is two; it is also estimated that at 850°, the mol. is triatomic; and at lower temp., still more complex. Here, the assumption is made that the carbon does not form a complex with the iron. From cryoscopic observations on soln. of carbon in iron and cobalt, A. Jouniaux also estimated that the graphite mol. above 1500° is monatomic when in soln. in these metals. H. F. Jüptner, H. W. B. Roozeboom, etc., have shown that the carbon is probably present as a carbide between 1650° and 1250°. P. J. van Kerckhoff assumed that the molecule of amorphous carbon is C_2, of graphite, C_3, and of the diamond, C_4, so as to make the observed sp. hts. fit the mol. ht. 6·4; C. E. Carbonelli likewise assumed that the diamond has a molecule C_5. H. W. Kolbe suggested that graphite has mols. of bivalent carbon, that amorphous carbon has mols. of tervalent carbon, and that the diamond has a mol. C_3, consisting of two atoms of bivalent carbon and one atom of quadrivalent carbon, C : C : C. E. Donath supposed that the diamond mol. is diatomic; and that amorphous carbon is polyatomic. According to W. Vaubel, calculations based on the difference between the heats of combustion of carbon and carbon monoxide lead to the conclusion that the mol. of carbon at its b.p. contains 24 atoms. The heat of dissociation of this complex carbon mol. is taken as 32,300 cals., and hence it is deduced that acetylene, carbon disulphide, and other compounds which have commonly negative heats of formation assigned to them, have really positive heats of formation. All this, however, is merely guessing, and furnishes no precise information. W. Nernst's observations on the sp. ht. of the diamond fit formulæ deduced on the assumption that the mol. of the solid is monatomic; while the sp. ht. of graphite fits better the assumption that the mol. is polyatomic, C_n, where n is greater than unity.

The heat of combustion of carbon is the joint effect of an absorption of heat owing to the degradation of the complex mol. into atoms, and the heat of oxidation of the carbon to its oxide, CO_2. M. Copisaroff assumes that the cause of the progressive increase in the heat of combustion of carbon in passing from the diamond to charcoal is due to the varying stability of the carbon mol. in the cases, and that this in turn depends upon the mode of linking of the units inside the mol.; that the mols. with atoms free to rotate will be the least stable, while mols. with rigid atoms will be the most stable; and in the intermediate case, some atoms will be rigid and some free. The greater the rigidity, the larger the heat of combustion. In amorphous carbon, added M. Copisaroff, the atoms are mobile and not rigid; in the diamond all the atoms are rigid; and in graphite, some atoms are rigid, and some are mobile. This is also thought to explain the regular gradation in any selected physical property in passing from amorphous carbon to the diamond—*vide supra*, action of nitric acid on carbon.

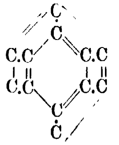
The intermediate products of the moist oxidation of carbon led V. Meyer to the view that the carbon mol. is polyatomic; similar views have been advocated by many chemists—J. Dewar, F. A. Kekulé, W. Barlow and W. J. Pope, H. S. Redgrove and J. C. Thomlinson, etc. According to H. Meyer, the diamond resists oxidation by wet processes, while graphite furnishes no mellitic acid, $C_6(COOH)_6$, if oxidized directly, but if it be first converted into graphitic acid, the latter does give some mellitic acid; coal gives very little of this acid, but charcoal gives a relatively large proportion of mellitic acid which occurs combined with aluminium in nature as *honeystone*. This acid has been studied by H. Meyer and K. Steiner, and by W. J. Jarrad. In the presence of osmium tetroxide, as catalytic agent, amorphous carbon can be oxidized to carbon dioxide, mellitic acid, etc., by potassium chlorate at 100°. This curious acid is assumed to have the structural relationship with benzene indicated in the subjoined graphic formulæ, and it is further suggested that mellitic acid and carbon have an analogous structure:



Benzene, C_6H_6



Mellitic acid, $C_6(COOH)_6$



Carbon (imaginary), C_{12}

During the wet oxidation of carbon, there is formed a yellow hygroscopic mass with an acid reaction, which is soluble in alcohol and ether, and which becomes black with alkalies. There is evidence that the yellow mass probably contains an acid derivative of a hydrocarbon with a five carbon ring, and O. Dimroth and B. Kerkovius hence believe that the carbon mol. consists of atoms arranged pentagonally as well as hexagonally. O. Aschan considers that the concentric hexagonal arrangement of the carbon atoms in J. Dewar's mol. would leave the atoms so strained that charcoal would be an explosive substance like acetylene. The very great stability of charcoal makes him believe that the mol. has a web-like structure formed of atoms arranged as illustrated in Fig. 19, where the dots represent quadrivalent carbon atoms. He considers that the hydrogen invariably associated with wood charcoal is really united with the carbon atoms at the outer boundary; and the nitrogen (1 per cent.) invariably found with bone charcoal replaces some of the boundary CH-group. This means that wood and bone charcoals are complex organic compounds and not forms of elementary carbon. Modifications of this hypothesis were used by T. F. E. Rhead and R. V. Wheeler, and I. Langmuir to explain the oxygenation of carbon, etc. The term molecule used in this sense has a different connotation to that regularly employed in chemistry. The X-radiogram revelations of the structure of the diamond and graphite have been discussed in a previous section —Figs. 10 to 12. L. F. Hawley and S. S. Aiyar have discussed the presence of a small proportion of methoxy-groups in wood charcoal.

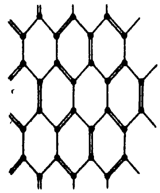


Fig. 19.—O. Aschan's Carbon Molecule.

The atomic weight of carbon.—The at. wt. of carbon was first deduced from the analysis and density of carbon dioxide. A. L. Lavoisier[3] found that gas contained 24 to 28 per cent. of carbon; F. Clément and J. B. Désormes, 27 to 28 per cent.; N. T. de Saussure, 27·04 to 27·38 per cent.; S. Tennant, 27 to 27·8 per cent.; W. Allen and W. H. Pepys, 28·60 to 28·67 per cent.; and J. L. Gay Lussac, 27·38 per cent. The last-named also obtained 42·99 per cent. of carbon in carbon monoxide, and he later inferred that the at. wt. of carbon is 6, when that of oxygen is 16; and he represented the formula of carbon dioxide by C_2O_2, and that of carbon monoxide by C_2O, analogous to water H_2O.

According to H. E. Roscoe and A. Harden,[4] in his first table of at. wt., J. Dalton gave 4·5 for the at. wt. of carbon, and in 1808, he changed this to 5. W. Prout, in 1815, gave 6 for the at. wt. (O=8); in 1817, J. J. G. Meinecke, and L. Gmelin gave 6 (O=8); in 1826, L. J. Thénard gave C=12·25 (H=1); in 1834, P. T. Meissner gave 4·24 (H=1); and in 1837, O. B. Kühn gave C=6·1 (H=1). This confusion in the at. wt. was not clarified until A. Avogadro's hypothesis had been used as the touchstone. Never less than 12 parts by weight of carbon are present in a molecular proportion of the volatile compounds of carbon (**1.** 5, 5). This makes the hydrogen eq. of carbon in carbon monoxide to be 6, and in carbon dioxide 3. In cases where the laws are applicable to soln, the same conclusion is obtained with soln. of carbon compounds. There is a vacancy in the periodic table for an element between boron, 11·0, and nitrogen, 14; and carbon fits very well in this place as a member of the family of quadrivalent elements.

The atomic heat of carbon deviates from the normal value 6·4 if 12 be the at. wt. of carbon. H. V. Regnault accordingly proposed 24 for the at. wt. of carbon; and B. C. Brodie, 33 for the at. wt. of graphitic carbon which he called *graphon*. Neither suggestion was of any particular value. This law of isomorphism (**1.** 11, 10) has not been of much assistance in fixing the at. wt. of carbon, since it shows few crystallographic analogies with the other members of the same family of elements. Indeed, P. Groth said:

> The profound chemical differences exhibited by carbon and silicon are reflected in the fact that except for the agreement between the cubic crystalline forms of the two iodides, CI_4 and SiI_4, there is no isomorphism between analogously constituted compounds of the two elements—between the carbonates and silicates, for example—and also in the fact that the two elements unite to form a very stable compound, carborundum, CSi, whose crystalline form exhibits no relation to that of either of its constituent elements.

The various methods which have been employed for obtaining the at. wt. of carbon can be arranged in two groups—chemical and physical. The chemical methods can be subdivided: (i) The combustion of carbon to carbon dioxide; (ii) the combustion of carbon monoxide or other compounds of carbon to carbon dioxide; and (iii) the analysis of the carbonates or organic salts of the metals—lead, silver, and beryllium. In 1838, J. B. A. Dumas [5] analyzed naphthalene, and concluded that the at. wt. of carbon, 12·24, obtained by J. J. Berzelius and P. L. Dulong in 1819, by a physical method, was too high. In 1839, J. J. Berzelius analyzed lead oxalate and carbonate, and obtained 12·242, which confirmed his former result.

The determination of the atomic weight of carbon by the combustion of carbon or carbonaceous compounds.—J. B. A. Dumas and J. S. Stas, in their *Recherches sur le véritable poids atomique du carbone*, determined the ratio C : CO_2 by burning diamond, and natural and artificial graphite in oxygen. They thus obtained 11·9975 for the at. wt. of carbon. O. L. Erdmann and R. F. Marchand made a similar investigation and obtained 12·0093; H. E. Roscoe likewise obtained 12·0029; C. Friedel, 12·0112; and J. D. van der Plaats, 12·0031. J. B. A. Dumas and J. S. Stas tested the corrections for the change in volume of the soln. of potassium hydroxide produced by the absorption of carbon dioxide, and by some inexplicable error, they concluded that

> En tenant compte dans la pesée du diamant du poids de l'air qu'il déplace et dans celle de l'acide carbonique condensé de l'air qu'il déplace aussi ces rapports ne sont pas altérés

A. Scott showed that the magnitude of the correction is quite serious, lowering the values:

	J. B. A. Dumas and J. S. Stas	O. L. Erdmann and R. F. Marchand	H. E. Roscoe	C. Friedel	J. D. van der Plaats
Uncorrected . .	11·9975	12·0093	12·0029	12·0112	12·0031
Corrected . .	11·9938	12·0054	11·9973	12·0056	12·0018

B. Brauner also checked these calculations. J. S. Stas, in his *Recherches nouvelles sur le véritable poids atomique du carbone*, described experiments in which carbon monoxide was passed over heated copper oxide. He determined the loss in weight of the copper oxide, and the weight of carbon dioxide formed. From the ratio (CuO less Cu) : CO_2, he obtained the at. wt. 12·0046. J. S. Stas' results were criticized by A. Scott, and J. D. van der Plaats. A. Scott also analyzed naphthalene and cinnamic acid by combustion, and obtained, respectively, 11·999 and 12·002 for the at. wt. of carbon.

The determination of the atomic weight of carbon by the analysis of metal salts containing carbon.—In 1811, and in 1814, J. J. Berzelius analyzed lead carbonate, and combining the results with J. L. Gay Lussac's observations on the $C : O_2$ ratio in carbon dioxide, and from the ratio $CO_2 : PbO$, obtained results corresponding with the at. wt. 12·026; while in 1839, from the ratios $PbCO_3 : PbO$, and $PbC_2O_4 : PbO$, obtained 12·242; and in 1841, from analysis of the lead salts of organic acids, he obtained 12·118. J. von Liebig and J. Redtenbacher analysed silver acetate, and from the ratio $AgC_2H_3O_2 : Ag$ obtained 12·039; with silver tartrate, $Ag_2C_4H_4O_6 : Ag$, 12·044; with silver racemate, $Ag_2C_4H_4O_6 : Ag$, 12·049; and with silver malate, $Ag_2C_4H_4O_5 : Ag$, 12·050. A. Strecker recalculated these values by the method of least squares. J. C. G. de Marignac obtained with silver acetate, $AgC_2H_3O_2 : Ag$, 12·036; E. J. Maumené with silver acetate, and oxalate and the respective ratios $AgC_2H_3O_2 : Ag : CO_2$, and $Ag_2C_2O_4 : Ag : 2CO_2$, obtained 11·934 and 11·928. The general tendency is for these results to be a little high owing to the slight volatilization of silver during the ignition. W. L. Hardin electrolyzed silver acetate and benzoate dissolved in a soln. of potassium cyanide, and from the ratio $AgC_2H_3O_2 : Ag$ obtained 11·9999; and from the ratio $AgC_7H_5O_2 : Ag$, 12·0011. C. L. Parsons analyzed beryllium acetylacetonate and basic acetate, and from the respective ratios $Be(C_5H_7O_2)_2 : BeO$, and $Be_4O(C_2H_3O_2)_6 : 4BeO$, obtained 12·007 when the at. wt. of beryllium is 9·112. A. Scott titrated tetramethylammonium bromide and tetraethylammonium bromide with a standard soln. of silver and obtained 12·017 and 12·019 respectively. These determinations were discussed by T. E. Thorpe from the point of view of P. A. Guye and N. Zachariades' observations on the tendency of finely divided substances to absorb air. T. W. Richards and C. R. Roover evaluated the ratio $Na_2CO_3 : 2Ag = 29·4351 : 59·91676$, and hence computed 12·003 for the at. wt. of silver; E. Moles argued that if another value were adopted for sodium, these results agree with the at. wt. 12·000 for carbon.

The determination of the atomic weight of carbon by physical methods.—In 1814, W. H. Wollaston[6] calculated the at. wt. of carbon from the density determinations of oxygen and carbon dioxide by J. B. Biot and F. J. Arago. It was assumed that no change in volume occurs when the oxygen is converted into carbon dioxide. W. H. Wollaston obtained 12·063 for the at. wt. of carbon, oxygen 16. J. J. Berzelius and P. L. Dulong obtained 12·24 in a similar manner. The latter value was accepted for some years, although, in 1836, T. Thomson obtained 12·000 from density determinations. F. J. Wrede showed that, owing to the greater compressibility of carbon dioxide, oxygen yields rather less than its own vol. of carbon dioxide, the density of which is correspondingly high. After making an allowance for this, he obtained 12·023 from the ratio $CO_2 : CO$; 12·021 from the ratio $CO : O$; and 12·022 from the ratio $CO_2 : O$. P. A. Guye and T. Batuecas obtained 11·998 by this method. D. Berthelot by his method of limiting densities (1. 5, 8), and the density determinations of A. Leduc, and Lord Rayleigh, obtained numbers ranging from 12·000 to 12·007—probable mean 12·005—for the at. wt. of carbon; with G. Baume and F. L. Perrot's value for the density of methane, the value 12·0085 was obtained; and for ethane, 12·036. Lord Rayleigh's value for the density and compressibility of carbon monoxide gave 12·003. A. Jacquerod and F. L. Perrot measured the expansion of carbon monoxide and dioxide up to 1067·4°, and from the mean densities obtained the respective at. wt. 12·009 and 11·992. G. Baume calculated from the density of methyl ether, $(CH_3)_2O$, the at. wt. 11·9919 ± 0·0010; and A. Leduc's value for the density of toluene gave 12·003. A. Leduc's method of limiting densities (1. 13, 4) with carbon monoxide and dioxide, and with acetylene, gave 12·005. P. A. Guye's method of critical constants (1. 13, 4) with carbon monoxide and methane, with Lord Rayleigh's and A. Leduc's data for carbon monoxide, gave 12·003; and, with G. Baume and F. L. Perrot's value for methane, 12·004.

Observations or summaries have been made by P. A. Guye, N. Delaunay.

A. Leano, J. A. Wanklyn, etc. G. D. Hinrichs, and E. Moles advocated the whole number 12 for the at. wt. J. A. Groshans discussed the relation of W. Prout's hypothesis to the at. wt. of carbon. B. Brauner summarized the various determinations of the at. wt. of carbon prior to 1909, and obtained 12·002 with an uncertainty of one unit in the third decimal place; F. W. Clarke obtained 12·0000 ±0·00029. The International Table of atomic weights for 1922 gave **12·005** as the best representative value. E. Rutherford and J. Chadwick found no evidence of the **disintegration of the carbon atom** when bombarded by α-rays. The **atomic number** of carbon is 6. F. W. Aston found no **isotopes.**

L. Bell and P. R. Bassett found helium lines in the spectrum of the negative tongue in the carbon arc of at least 100 amp They assume this shows that some carbon atoms have dissociated into helium; but other more probable interpretations are possible. Some hydrogen lines are attributed to adsorbed water vapour.

§ 13. The Carbides—The Alkali Carbides

H. Moissan begründete die Chemie der Karbide.—O. Hönigschmid (1914).

The binary compounds of carbon with most of the elements are called **carbides**; a few compounds of carbon with the metalloids—*e.g.* oxygen, the halogens, and sulphur—are not usually regarded as carbides. The existence of the metal carbides was recognized by C. A. Vandermonde, C. L. Berthollet, and G. Monge,[1] in their *Mémoire sur le fer considéré dans ses différens états métalliques*, but no definite compound was recognized. It was observed that relatively small proportions of carbon greatly modified the malleability and ductility of the metal, but the low proportion of carbon seemed to exclude the idea that a definite compound was formed. A few years later, A. F. de Fourcroy, in L. B. G. de Morveau's *Encyclopédie*, stated:

> Le carbone est susceptible de se combiner directement et entièrement aux métaux. . . . Ce nom *carbure* répond à celui de *sulfure* et de *phosphure* qui appartient à des combinaisons analogues entre le soufre et le phosphore et les différents corps; comme on distingue les sulfures alcalins, alcalino-terreux et métalliques, il est vraisemblable qu'il existe des carbures alcalins, alcalino terreux, et métalliques.

The nomenclature was here in advance of the facts. C. J. B. Karsten expressed the idea that in steel the carbon is not distributed uniformly throughout the mass of metal as carbon but rather as the carbide, FeC_3. J. J. Berzelius thought that he had made a series of definite carbides by heating the cyanides of some of the metals; similarly with the ferrocyanides, but here the product is a mixture of the carbides of iron, and the other metal. J. B. A. Dumas then argued that the products obtained by J. J. Berzelius are not really carbides, but are mixtures of the metal with carbon. Other carbides were reported by E. Davy, F. Wöhler, L. Troost and P. Hautefeuille, L. Maquenne, H. Moissan, etc. In his investigation: *Sur une nouvelle classe de radicaux métalliques composés*, M. Berthelot described sodium and potassium carbides; and he, and M. Keiser, showed their relation to acetylene, a gas which these carbides produce on treatment with water. The carbides of copper, silver, and mercury produced by the action of acetylene on metal salt soln. very readily decompose, maybe explosively, when heated. The other carbides are produced by the direct action of the metal on carbon at a high temp., and, within certain limits of temp., are stable. K. Nischk studied the relative affinities of carbon and oxygen for the metals.

The carbides are made (i) By the direct union of carbon and metal; (ii) By the action of carbon on the oxides or oxysalts of the metals; (iii) By the action of carbon on the hydrides or nitrides of the metals; (iv) By the action of metals on the oxides of carbon; (v) By heating the metallic oxides with calcium carbide in place of carbon; (vi) By the simultaneous action of carbon and of a very oxidizable metal on an oxide of the metal; (vii) By the action of metals on the hydrocarbon gases; (viii) By the action of acetylene on metal salt soln.; (ix) By passing acetylene into a soln. of the metal in liquid ammonia—probably, said H. Moissan, the acetylene-carbide is first formed and the liberated hydrogen converts some acetylene into ethylene: $3C_2H_2+2NaNH_3=C_2Na_2.C_2H_2+2NH_3+C_2H_4$; and (x) By decomposing some organic compounds by heat, as in the case of the thiocyanates of silver, copper, zinc, bismuth, iron, manganese, lead, or tin. F. Haber arranged the carbides in groups according to the periodic classification, as extended in Table XVI. The carbides of the elements in the left division of the different groups are usually stable at a high temp. and are non-volatile solids; while those in the right division are either easily decomposed at a high temp. (metal carbides) or are readily volatile (carbides of the metalloids). Carbon fluoride and carbon dioxide are gaseous but very stable; and paracyanogen is a stable solid. Aluminium and silicon carbides in the division on the right are exceptional.

TABLE XVI.—PERIODIC CLASSIFICATION OF THE CARBIDES.

Group I.	Group II.	Group III.	Group IV.	Group V.	Group VI	Group VII.	Group VIII.
Li_2C_2	BeC_2	BC	C	$(NC)_n$	O_2C	F_4C	—
Na_2C_2	MgC_2	Al_4C_3	SiC	P	S_2C	Cl_4C	—
K_2C_2	CaC_2	Sc	TiC	YC	Cr_2C_3	Mn_3C	$(Fe,Co,Ni)_3C$
CuC_2	Zn	Ga	Ge	As	Se	Br_4C	—
Rb_2C_2	SrC_2	YC_2	ZrC	CbC	Mo_2C	—	$(Ru,Rh,Pd)C_n$
Ag_2C_2	Cd	In	SnC	Sb	Te	I_4C	—
Cs_2C_2	BaC_2	LaC_2	CeC_2	Di	—	—	—
—	—	—	—	—	—	—	—
—	—	Yb	—	Ta	W_2C	—	$(Os,Ir,Pt)C_n$
AuC_n	HgC_2	Tl	PbC	BiC_n	—	—	—
—	—	—	ThC_2	—	U_2C_3	—	—

The metal carbides can be roughly classified according to their action on water or dil. acids. (i) The **acetylides** are derivatives of acetylene, because they furnish that gas when treated by these agents—*e.g.* alkali metals; copper; silver; alkaline earth metals; magnesium; and mercury. They are constituted:

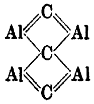
Sodium carbide, Na_2C_2

Calcium carbide, CaC_2

(ii) **Methanides** are derivatives of methane because they furnish that gas when treated with water or dil. acid—*e.g.* beryllium, aluminium, and manganese. They are constituted:

$$Be = C = Be$$

Beryllium carbide, Be_2C



Aluminium carbide, Al_4C_3

There are of course other possibilities—*e.g.* Al ⋮ C.Al ⋮ C : Al.C ⋮ Al. (iii) *Mixed carbides* supposed to be partly acetylides and partly methanides in that they furnish both acetylene and methane when treated with dil. acids or by water—*e.g.* lanthanum, cerium, yttrium, and thorium carbides. Uranium carbide has been represented

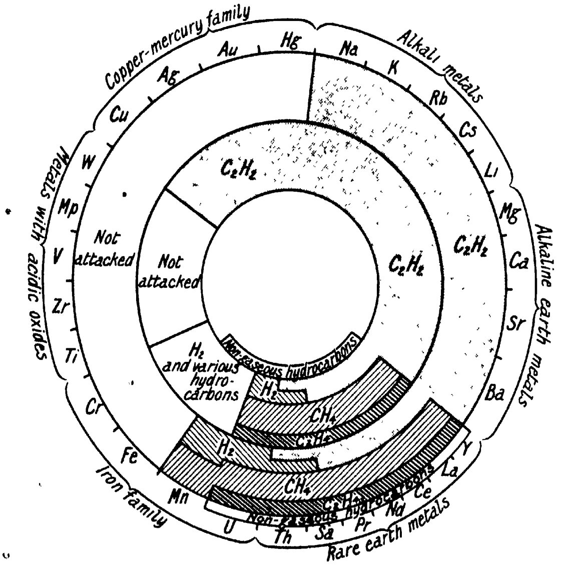


FIG. 20.—Graphic Representation of the Action of Water and Dilute Acids on the Metal Carbides.

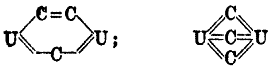

Uranium carbide, U_2C_3

(iv) The other carbides which are decomposed by water or dil. acids furnish different hydrocarbons—ethylene, etc. (v) The carbides not decomposed by water or dil. acids.

M. Delépine arranged the carbides of the metals about three concentric circles as indicated in Fig. 20. The products with water are indicated in the outer ring,

and the products with dil. hydrochloric acid in the inner ring. Beryllium and aluminium carbides have been omitted from the scheme; they give methane with both liquids.

The following monographs, etc. deal with the carbides: M. Delépine, *Carbures métalliques*, Paris, 1904; O. Hönigschmid, *Karbide und Silizide*, Halle a. S., 1914; F. B. Ahrens, *Die Metallkarbide und ihre Anwendung*, Stuttgart, 1896; A. Frank, *Zeit. Elektrochem.*, 3. 427, 1897; *Journ. Gasbeleucht.*, 41. 682, 1898; O. Sandmann, *Zeit. angew. Chem.*, 14. 673, 1901; J. H. Vogel, *Handbuch der Acetylen*, Braunschweig, 1904.

H. Moissan prepared a series of complex **acetylene carbides**: $Na_2C_2.C_2H_2$, $K_2C_2.C_2H_2$, $Li_2C_2.C_2H_2.2NH_3$, and $CaC_2.C_2H_2.4NH_3$, by passing acetylene into a soln. of the corresponding metal in liquid ammonia. All these complexes furnish the simple carbides when heated.

The alkali carbides.—H. Moissan obtained **lithium carbide,** Li_2C_2, by warming lithium acetylenediammoniocarbide in vacuo; he also made lithium carbide by heating lithium in a stream of acetylene. A. Guntz represented the reaction with acetylene: $C_2H_2+4Li=2LiH+C_2Li_2$; and he obtained a similar result with ethylene: $C_2H_4+6Li=4LiH+C_2Li_2$; and with carbon monoxide or dioxide at a dull red heat; at a higher temp., only a little carbide is formed. H. Moissan also obtained lithium carbide by heating four gram-atoms of carbon with a mol of lithium carbonate in an electric furnace. A. Guntz made lithium carbide by heating a mixture of equal parts of amorphous carbon and lithium at a dull red heat, in vacuo, for half an hour. Diamonds react in the same way as amorphous carbon. The carbide was also made by heating lithium with an electric arc using carbon electrodes in vacuo. According to E. Vigouroux,[2] sodium has no perceptible action on carbon. S. Opolsky found that where an excess of sodium is used in the preparation of the homologues of thiophene, a brown, explosive **sodium carbide** is formed. M. Berthelot made *sodium acetylene carbide*, $Na_2C_2.C_2H_2$, by warming sodium in a stream of acetylene gas; when heated to a dull red heat, sodium carbide, Na_2C_2, is formed; allylene also furnishes sodium acetylene carbide mixed with carbon when the gas is passed over heated sodium. R. de Forcrand prepared the carbide in a similar manner. H. Moissan made it by the dissociation of sodium acetylene carbide in vacuo; and C. Matignon made it of a high degree of purity by heating sodium acetylene carbide in a stream of hydrogen at 220°–230°. C. E. Parsons made it by heating borax and carbon over 1000°.

H. Davy noted that if charcoal, graphite, or the diamond be heated to redness with potassium at a temp. at which the metal is volatile, the carbon "seemed gradually to combine with the potassium," and the product, when treated with water, gave off a gas which burnt like hydrogen. According to J. J. Berzelius, the black mass obtained in the preparation of potassium by the reduction of the carbonate with carbon, is a *Kohlenstoffkalium*. In 1836, E. Davy also prepared what he called a peculiar compound of carbon and potassium, or *carburet of potassium;* it gave acetylene when treated with water, and was undoubtedly impure potassium carbide. H. Moissan made **potassium carbide,** K_2C_2, by the dissociation of potassium acetylene carbide in vacuo. M. Berthelot found that molten potassium inflames in acetylene, and the mixture then explodes—there is a separation of carbon, and potassium carbide is formed. At a dull red heat, ethylene also converts potassium partially into carbide. H. Moissan made **rubidium carbide**, Rb_2C_2, by rapidly heating rubidium acetylene carbide in vacuo to 300°, and **cæsium carbide,** Cs_2C_2, was prepared in a similar way.

These carbides appear to be white powders or white masses with a crystalline fracture; if carbon is present as an impurity, the carbide may be grey or black. The sp. gr. of lithium carbide, according to H. Moissan, is 1·65 at 18°; and sodium carbide, according to C. Matignon, has a sp. gr. of 1·575. H. Moissan said lithium carbide easily breaks and is not hard enough to scratch glass; and C. Matignon said that sodium carbide is not sensitive to percussion or friction. C. Matignon said that **hydrogen** is without action on sodium carbide. According to H. Moissan, lithium carbide at a dull red heat burns vigorously in **oxygen** ; sodium carbide was found by C. Matignon to be stable in air or oxygen at ordinary temp., but when heated, combustion occurs, and sodium carbonate is formed; H. Moissan said rubidium carbide is not attacked in the cold by oxygen. A. Guntz said that lithium carbide does not dissociate when heated ; on the other hand, at a dull red heat, in vacuo, said H. Moissan, rubidium or cæsium carbide gives amorphous carbon and the metal. R. de Forcrand, and C. Matignon gave for the heat of formation $C_2H_{2gas}+2Na=C_2Na_{2solid}+H_2+49{\cdot}3$ Cals. ; and $2C_{diamond}+2Na_{solid}=C_2Na_2-8{\cdot}8$ Cals. H. Moissan said that lithium carbide is decomposed by cold **water,** giving off acetylene only—a kilogram of lithium carbide gives 587 litres of acetylene. A similar reaction was found by C. Matignon to occur with water, but with a large excess of sodium carbide an explosion may occur and carbon be separated. In spite of the apparent irreversibility of the reaction, J. Billitzer considers that the slight increase in the solubility of acetylene in water brought about by the addition of small quantities of salts, indicates the possibility that acetylides may exist in soln. The thermal value of the reaction with sodium carbide, given by C. Matignon, and R. de Forcrand, is: $C_2Na_2+2H_2O=C_2H_{2gas}+2NaOHaq.+37{\cdot}6$ Cals. The other alkali carbides are also decomposed by water, and acetylene is evolved.

H. Moissan found that cold lithium carbide burns with great brilliancy in **fluorine** or **chlorine,** but it must be warmed a little before combustion occurs in **bromine** or **iodine.** According to C. Matignon, sodium carbide burns in chlorine with the separation of carbon ; in bromine, carbon and brominated hydrocarbons are formed ; and with iodine, ethylene tetraiodide, C_2I_4, is formed. H. Moissan found rubidium or cæsium carbide burns in fluorine, chlorine, bromine, or iodine. Conc. acids, said H. Moissan, attack lithium carbide very slowly : C. Matignon gave for the action of **hydrochloric acid** on sodium carbide: $C_2Na_2+2HCl=2NaCl+2C+H_2$; but if the carbide is suspended in ether, acetylene is formed : $C_2Na_2+2HCl=2NaCl+C_2H_2$. H. Moissan found that rubidium or cæsium carbide inflames in contact with hydrochloric acid—unless the acid be dil. H. Moissan found that lithium carbide burns in the vap. of **sulphur** or **selenium** ; rubidium carbide behaves similarly. C. Matignon found that in contact with sodium carbide at 150°, hydrogen sulphide, acetylene and sodium hydrosulphide are formed. He also observed a separation of carbon when sodium carbide is heated with **sulphur dioxide** ; and H. Moissan said that sulphur dioxide in the cold does not attack rubidium carbide, but inflammation occurs when heat is supplied. C. Matignon found that **carbon monoxide** does not attack sodium carbide below 250°, and that the reaction with **carbon dioxide** resembles that with sulphur dioxide ; H. Moissan also found the same to be true with respect to rubidium carbide. Rubidium and cæsium carbides react vigorously when heated with **silicon** or with **boron.** The action of **nitric oxide** with rubidium carbide resembles that with sulphur dioxide. C. Matignon said that sodium carbide reacts with **nitrogen pentoxide** at 150° with incandescence and the separation of carbon. H. Moissan said that an explosion occurs when rubidium or cæsium carbide is brought in contact with **nitric acid.** Lithium carbide burns vigorously in **phosphorus** vap., forming the alkali phosphide which gives phosphine with water. C. Matignon observed a similar result with sodium carbide ; and with phosphorus. H. Moissan observed that at a red heat lithium carbide is decomposed by **arsenic,** and a mixture of rubidium carbide and arsenic inflames when heated. C. Matignon observed that carbon is liberated when sodium carbide is triturated in a mortar with **mercury, aluminium, lead,** or **iron** ; the reaction may be very vigorous. H. Moissan found that when a mixture of **calcium** and rubidium carbide is heated, in vacuo, rubidium distills off. H. Moissan found that molten **potassium hydroxide** decomposes lithium carbide with the development of much heat. The carbides are powerful reducing agents, and when mixed with oxidizing agents, explosive mixtures may be formed. H. Moissan noted that at 400°, **ferric oxide** or **chromic oxide** is reduced by rubidium carbide with the development of much heat; ferric oxide is reduced with incandescence when gently heated with cæsium carbide; at 200°, **lead monoxide** is explosively reduced by rubidium carbide, and lithium carbide is reduced with great vigour and with incandescence. A. Guntz noted that lithium carbide reduces molten **lithium chloride** to the subchloride, Li_2Cl. C. Matignon found that when sodium carbide is rubbed in a mortar with certain **chlorides** or **iodides,** the mixture may become incandescent, and explode; the **sulphates** are reduced when triturated with sodium carbide.

When a soln. of lithium in liquid ammonia is treated with acetylene, H. Moissan found that fine crystals of **lithium acetylenediamminocarbide,** $C_2Li_2.C_2H_2.2NH_3$, or $C_2HLi.NH_3$, are formed, which, under a lens, appear to resemble the crystals of Iceland spar. The compound readily decomposes into lithium carbide, etc., when heated in air or hydrogen; it burns in contact with water, or chlorine, and also in sulphur dioxide or carbon dioxide. C. Matignon prepared **sodium acetylenecarbide,** $C_2Na_2.C_2H_2$, by passing purified and dry acetylene, warmed to the m.p. of sodium, over sodium heated by an oil-bath. The last particles of sodium are transformed but slowly. H. Moissan made the same compound by passing acetylene over sodium hydride—hydrogen is evolved; the reaction proceeds at −80°; he also made this compound by passing acetylene into a soln. of sodium in liquid ammonia cooled to −40°; the blue liquid becomes colourless, and ethylene is evolved. To obtain crystals of the compound, the soln. is cooled to −60° or the ammonia is allowed to evaporate. According to M. Skossarewsky, the mol. electrical conductivity of sodium acetylide, $NaHC_2$ (more likely $Na_2C_2.C_2H_2$), in liquid ammonia is of the same order as that of sodium acetate. H. Moissan made **potassium acetylenecarbide,** $C_2K_2.C_2H_2$; **rubidium acetylenecarbide,** $C_2Rb_2.C_2H_2$; and **cæsium acetylenecarbide,** $C_2Cs_2.C_2H_2$, in a similar manner.

The alkali acetylene carbides all form microscopic, white, rhombic plates resembling boric acid; the crystals are deliquescent. They decompose into the simple carbide when heated in vacuo, or in a stream of hydrogen. The rubidium and cæsium compounds begin to melt with decomposition below 300°. C. Matignon gave for the heat of formation $2C_{diamond}+H+Na=C_2HNa-29\cdot2$ Cals. Dry **air** has no action on rubidium acetylenecarbide, which, when heated in **oxygen,** inflames. The compounds are readily decomposed by **water** giving the alkali hydroxide and acetylene; for the sodium compound, C. Matignon gave $C_2NaH+H_2O=NaOH+C_2H_{2gas}+14\cdot5$ Cals. Boiling **ether** has no action on sodium acetylene carbide; **alcohol** decomposes it energetically with the formation of sodium ethoxide: and it sinks in **ligroïn,** sp. gr. 0·899, without showing any chemical action. H. Moissan found that cæsium acetylenecarbide sinks in **benzene** and **carbon tetrachloride** without chemical action. C. Matignon found sodium acetylene carbide inflames at ordinary temp. in **chlorine** or **bromine;** and if suspended in ligroïn, and **iodine** be added, the acetylene is attacked and sodium carbide remains. H. Moissan observed that potassium acetylene carbide inflames in chlorine, forming hydrogen chloride and carbon; the rubidium compound inflames at ordinary temp. in **fluorine,** chlorine, bromine, or iodine vap.; so also does the cæsium compound inflame in fluorine and chlorine, but it must be warmed a little before it inflames in bromine or iodine vap. Cæsium acetylenecarbide takes fire in **hydrogen chloride.** The rubidium compound inflames in contact with **hydrochloric acid,** and it also takes fire in contact with molten **sulphur.** The potassium compound reacts with **sulphur dioxide** at ordinary temp. and it becomes incandescent; likewise with the cæsium compound. The rubidium compound decomposes in contact with monohydrated **sulphuric acid,** and burns with a pale flame; likewise also the cæsium compound. C. Matignon found the sodium compound can be recrystallized from liquid **ammonia** without change. H. Moissan found that the cæsium compound ignites at about 100° in **nitrogen peroxide.** The cæsium compound burns vigorously in contact with monohydrated **nitric acid.** The rubidium and cæsium compounds become incandescent when warmed in contact with **phosphorus** or **arsenic.** When the potassium compound is warmed with **carbon dioxide** the mass becomes incandescent. The rubidium compound does not react in the cold, but it does so vigorously when warmed. Amorphous **silicon** and **boron** at about 350° are not attacked by the rubidium compound, while at this temp., **lead dioxide** is reduced explosively, and **cupric oxide** and **manganese dioxide** are vigorously reduced with incandescence. Cupric oxide and lead-dioxide are also reduced explosively by the cæsium compound at a dull red heat.

A. Lagermark[3] prepared **sodium allylenide,** C_3H_3Na, by the prolonged action of allylene on sodium.

§ 14. The Carbides of the Copper Family of Elements

The direct action of carbon on copper has been discussed in connection with the last-named element (**3.** 21, 6). K. Nischk[1] studied the relative affinities of copper for carbon and oxygen. P. Rucktäschel, and W. Hempel made an alloy with 0·3 per cent. of carbon, but no combination between the two elements was observed. E. Briner and R. Senglet found that an endothermic copper carbide is formed from the elements at a high temp. and the product decomposes at 1600°. O. Ruff and B. Bergdahl found the solubility of carbon in copper to be small. As previously cited, J. J. Berzelius' copper carbide was probably a mixture. There are two carbides of copper—cuprous and cupric. Anhydrous cupric carbide has not been prepared. In 1858, before the nature of acetylene had been established, J. A. Quet prepared what was probably **cuprous carbide,** or *cuprous acetylide*, Cu_2C_2, by passing the gas obtained by sparking alcohol vap. through an ammoniacal soln. of cuprous chloride; and in the same year, R. Böttger obtained it by passing coal gas through an ammoniacal soln. of cuprous chloride or sulphite, a soln. obtained by shaking copper oxide with conc. aq. ammonia, or a soln. of sodium cuprous thiosulphate. M. Berthelot showed that the gas obtained by the incomplete combustion of coal gas gives a good yield, which, according to A. Römer, is still further improved by bubbling the gas through ether before it is burnt. M. Berthelot prepared a similar compound by passing acetylene into an aq. or ammoniacal soln. of cuprous salt. R. Blochmann recommended washing the product with aq. ammonia, and drying first in air and then over calcium chloride. E. H. Keiser passed acetylene into water carrying cuprous hydroxide in suspension, or into water with finely divided copper in suspension. M. Kuntzmann said that the intermediate formation of ammoniacal cuprous chloride is not necessary, and the washing with ammonia can be eliminated by aspirating the gases containing acetylene through liquor-ammonia, and then through a cylinder containing copper turnings and ammonia. The red carbide forms on the turnings and remains suspended in the liquid, which itself becomes blue. The formation of cuprous carbide on the cupriferous parts of acetylene generators, and in cupriferous conducting tubes has been discussed by J. Torrey, A. Crova, J. Nicklès, etc. If the copper is in contact with a sacrificial metal like zinc, W. Melentjeff found that the copper carbide is not formed. Cuprous carbide can also be made by treating with acetylene a soln. of a cupric salt in contact with a reducing agent. Thus, E. Péchard, H. Erdmann and O. A. W. Makowka, and J. Scheiber passed acetylene through a soln. of cupric sulphate and hydroxylamine at 50°, but there is no action if the soln. is cold. O. A. W. Makowka found that in place of hydroxylamine, hydrazine, hydroquinone, pyrogallol, potassium iodide, arsenious oxide, or sulphur dioxide can be used. H. G. Söderbaum, and A. Schierl used a soln. of sulphur dioxide and ammoniacal cupric sulphate on a water-bath. The acetylene is freed from phosphine by soln. of lead acetate and mercuric chloride. G. S. Johnson treated a soln. of glucose and cupric sulphate with acetylene. E. Reboul made cuprous carbide by the action of acetylene monobromide on an ammoniacal soln. of cuprous chloride; P. Cazeneuve, by the action of bromoform and zinc dust on an ammoniacal soln. of cuprous chloride; and J. F. Durand, by the action of calcium carbide on a soln. of a cuprous salt.

F. Küspert made **colloidal cuprous carbide,** by adding an ammoniacal soln. of cuprous chloride to an aq. soln. of acetylene, when red colloidal copper carbide is formed. This soln. cannot be filtered, but if 0·2 per cent. of gelatine is added, a stable colloidal soln. is obtained.

There have been some differences of opinion as to the composition of the product. This may be due to the difficulties involved in preparing cuprous carbide of a high degree of purity. E. H. Keiser found that when copper carbide is made by passing acetylene into an ammoniacal soln. of cuprous chloride or oxide, or into water with finely divided cuprous chloride in suspension, free carbon is present. He said:

> All attempts to make copper acetylide free from carbon have failed. It appears that when acetylene is passed into a cuprous soln., and air or oxygen is present in small quantity, the cuprous compound is oxidized to the cupric condition, and there is formed some red cuprous acetylide, but at the same time, some of the hydrogen of acetylene or the copper of the precipitate is oxidized, and carbon remains behind. In its preparation, too, owing to its colloidal nature, it is liable to carry down any cuprous and cupric salts which may be present.

M. Berthelot represented the composition of the product dried over calcium chloride by $(C_2HCu_2)_2O$—*cuproacetyloxide*, and if still further dried, $C_2HCu_2.nCu_2O$; A. Schierl found after drying in vacuo over sulphuric acid, or for a month over phosphorus pentoxide, $C_2HCu.CuOH$; J. Scheiber gave HC : C.Cu.Cu.OH; E. Reboul, C_2HCu; R. Blochmann, $C_2H_2Cu_2O$; O. A. W. Makowka, $CHCu_2.COH$; and E. H. Keiser found that the purest specimens, made by the action of acetylene upon cuprous hydroxide suspended in water, and making an allowance for the free carbon present, had a composition corresponding with C_2Cu_2.

The voluminous precipitate has a red or reddish-brown colour, and when dried, it may be brown. N. Ljubawin said that it decomposes when kept for some time, forming a substance resembling humus, which M. Berthelot said is insoluble in hydrochloric acid. H. Erdmann and O. A. W. Makowka found that cuprous carbide can be kept unchanged in a sat. aq. soln. of acetylene, but when exposed to air, it gradually forms cupric acetate and oxide, but O. A. W. Makowka could detect no cupric acetate. J. A. Quet, and R. Böttger found that cuprous carbide is explosive; and it detonates by percussion, or when heated over 100°. M. Berthelot said that copper, carbon, water, and carbon dioxide and monoxide are formed during the explosion. W. S. Mai said that it can be heated at 60° in air without explosion; and, as observed by

M. Freund and W. S. Mai, if warmed in air or oxygen for some hours it explodes when brought in contact with acetylene. It is suggested that $Cu_2O.C_2H_2$ is formed which, in contact with acetylene, loses water and then decomposes explosively. R. Blochmann said that the red carbide is insoluble in **water**. O. A. W. Makowka found that when the thoroughly washed carbide is treated in the cold with 30 per cent. **hydrogen dioxide,** some cupric dioxide is formed, oxygen is given off, and an aldehyde derivative, $Cu_2CH.COH$, is produced; but in alkaline soln. no cupric dioxide is produced, and the filtrate, when neutralized with sulphuric acid, yields a volatile organic compound. M. Berthelot found cuprous carbide inflames spontaneously in **chlorine** and carbon separates. It behaves similarly with **bromine** vap. and finely-divided **iodine.**

E. Reboul noted a crystalline substance is formed when acetylene is passed into bromine, and A. Sabanéeff ascribed to it the formula $C_4H_2Br_6$, hexabromotetramethylene. A. A. Noyes and C. W. Tucker say that the compound is not formed with acetylene from calcium carbide, but it is formed when acetylene is obtained from an ammoniacal soln. of cuprous chloride sat. with acetylene. The gas in the latter case is contaminated with diacetylene $CH \vdots C.C \vdots CH$ derived from the oxidation of acetylene or cuprous carbide with the intermediate formation of *cuprous diacetylide,* $Cu.C \vdots C.C \vdots C.Cu$; thus, $2C_2Cu_2+2CuCl_2=C_4Cu_2+4CuCl$; and $C_4Cu_2+2HCl=CH \vdots C.C \vdots CH+2CuCl$.

E. Carstanjen and A. Schertel found that cuprous carbide and **ethylene iodide** furnish cuprous iodide, a gas, and an iodiferous crystalline product. R. Chavastelon observed that no evolution of gas occurs when the carbide is treated with cold **hydrochloric acid,** but gas is evolved when the mixture is heated; and, added N. Caro, some diacetylene, ethylidene chloride, and a solid hydrocarbon resembling cuprene, C_7H_6, is formed. M. Berthelot found cuprous carbide is soluble in very dil. hydrochloric acid without the development of gas, and a greenish, almost colourless, liquid is formed which when nearly neutralized with potassium hydroxide, precipitates the carbide unchanged; with hydrochloric acid of sp. gr. 1·1, at ordinary temp., only a little gas is developed, but when warmed there is a turbulent evolution of acetylene, and cuprous chloride is formed. R. Blochmann said that conc. hydrochloric acid transforms the freshly prepared carbide into cuprous chloride, acetylene, and a little ethylidene chloride. A. Römer found that with hydrochloric acid on a water-bath, acetylene is slowly and regularly evolved. A. Römer, and A. A. Noyes and C. W. Tucker found some diacetylene to be produced by the action of hydrochloric acid on cuprous carbide; S. Zeisel, some vinyl chloride; J. Scheiber, no acetaldehyde; and M. Berthelot, an amorphous black powder. A. Schierl noted that cuprous carbide is decomposed by **hydrogen sulphide.** M. Berthelot found that the carbide is slowly attacked when heated with dil. **sulphurous acid.** M. Berthelot said that it is soluble in **sulphuric acid,** and the 1 : 1 acid slowly attacks the carbide. R. Böttger, and A. Römer found that dil. sulphuric acid has no action, but a more conc. acid, on the water-bath, develops acetylene, etc. H. Erdmann and O. A. W. Makowka found that an explosion occurs with the conc. acid. They also say that cuprous carbide is soluble in aq. ammonia only in the presence of air. R. Böttger also made observations on this subject. M. Berthelot found that ethylene is formed when the carbide is treated with zinc in the presence of aq. ammonia. A. Schierl said the carbide is soluble in soln. of **ammonium salts;** and M. Berthelot, that it is decomposed when boiled with a solution of **ammonium chloride** and ammonia is evolved. A. Schierl found that the carbide dissolves in cold dil. **nitric acid**; H. Erdmann and O. A. W. Makowka, that it is decomposed slowly by nitric acid, sp. gr. 1·15, when heated on a water-bath; and M. Berthelot, that the moist carbide is oxidized by nitric acid, but the dried carbide explodes with the separation of carbon. E. H. Keiser also found the carbide is decomposed by nitric acid. M. Berthelot, H. Erdmann and O. A. W. Makowka, and H. C. Jones and C. R. Allen noted the formation of acetylene when cuprous carbide is heated with a soln. of **potassium cyanide.** M. Berthelot found the carbide is slowly attacked by **acetic acid**; H. Erdmann and O. A. W. Makowka say that acetic acid and **oxalic acid** have no action; and A. Schierl said that it is decomposed by acetic and other organic acids. R. Böttger, and H. Erdmann and O. A. W. Makowka say that cuprous carbide is insoluble in aq. soln. of **alkali hydroxides.** Cuprous acetylide gives an explosive mixture of silver and silver acetylide when treated with a soln. of **silver nitrate**; and a mixture of mercury and mercurous acetylide when treated with a soln. of **mercurous nitrate.** Cuprous carbide forms a number of complex salts, thus, M. Berthelot, R. Chavastelon, and K. A. Hofmann and F. Küspert made **cuprous chlorocarbide,** $C_2H_2.CuCl_2$, or $C_2HCu_2Cl+HCl$, or $(C_2H_2Cu)Cl.CuCl$; **cuprous oxychlorocarbide,** $C_2H_2.Cu_2Cl_2.Cu_2O$; **potassium cuprous chlorocarbide,** $C_2H_2(Cu_2Cl_2)_2KCl$; and $C_2H_2[(Cu_2Cl_2)_2KCl]_2$; and M. Berthelot and M. Delépine made **cuprous iodocarbide,** $C_2Cu_2.2CuI$. M. Berthelot prepared **cuprous allylenide,** possibly C_3H_3Cu.

According to A. A. Noyes and C. W. Tucker, **cupric carbide,** or **cupric acetylide,** CuC_2, is formed as an intermediate product when cuprous carbide is heated with cupric chloride and water. J. F. Durand obtained it as a precipitate by adding calcium carbide to an aq. soln. of cupric chloride. F. C. Phillips made the impure carbide by passing acetylene into an ammoniacal soln. of cupric chloride. The deep red precipitate contains hydrogen and oxygen; the pure carbide has not been made. The product becomes brownish-black when exposed to air; it is soluble in hydrochloric acid, but not if it has been long exposed to air; and when boiled, the soln. gives off acetylene. Cupric acetylide with a soln. of mercurous nitrate gives mercurous acetylide; and with silver nitrate, silver acetylide.

According to H. G. Söderbaum, on passing a stream of the purified acetylene into an ammoniacal soln. of either cupric sulphate or nitrate, a black, flocculent precipitate is slowly produced. This substance, after being dried over sulphuric acid, gave various results on analysis, a fact which was found to be due to the absorption of oxygen from the air during the process of drying; in an exhausted desiccator, however, the substance ceased to increase in weight after two days, and the analysis corresponded with the formula $(C_{17}Cu_8H_4O_3)_n$. This *copper acetylide* is a black, amorphous powder insoluble in water and organic solvents; it explodes between 70° and 80° when heated, and decomposes quickly on heating with hydrogen chloride with formation of the halogen salt of copper, and a carbonaceous residue of the formula $(C_{12}H_4O_3)_n$. On passing acetylene into a neutral or faintly acid soln. of copper acetate, a precipitate is formed corresponding in composition with the formula $C_4Cu_4O+(H_2O)_n$, and differing from the compound above mentioned in being stable in the air and non-explosive. It seems, therefore, that a large number of copper acetylides are capable of existence. The composition of the precipitate produced by acetylene in a dil. ammoniacal soln. of cupric sulphate varies with the temp. at which the precipitation is effected. At 5°, the compound, after drying over phosphorus pentoxide, has the composition $C_{24}H_2Cu_{12}O$ $=(12C_2Cu+H_2O)$, and is a black powder, which explodes at 50° when quickly heated, and is dissolved by potassium cyanide and dil. sulphuric and hydrochloric acids, a small amount of a carbonaceous residue being invariably left. At 15°, the acetylide contains less copper, whilst the amount of carbon remains practically unaltered. The atomic ratio of carbon to copper, therefore, is at this temp. greater than 2 : 1.

A number of copper hydrocarbides of indefinite composition have been reported. H. Erdmann and P. Köthner obtained what they regarded as a *Kupferacetylen* approximating to $Cu_3C_{44}H_{64}$, by the action of dry acetylene on copper powder at 230° to 250°. P. Sabatier and J. B. Senderens say that cuprene, C_7H_6, is a gaseous product under these conditions. H. Alexander said that the copper of H. Erdmann and P. Köthner's product is retained mechanically by a hydrocarbon; F. A. Gooch and D. F. Baldwin also agree that the product is only a hydrocarbon or hydrocarbons mixed with copper or copper oxide.

The direct action of carbon on silver has been discussed in connection with the last-named element (3. 22, 7). O. Ruff and B. Bergdahl observed that carbon is slightly soluble in molten silver. W. Hempel and P. Rucktäschel made an alloy with 0·4 per cent. of carbon. J. L. Gay Lussac's observation [2] that there is a three per cent. increase in weight when silver is heated with lampblack has been taken as evidence that a *silver tetritacarbide*, Ag_4C, is formed; but, as J. Percy emphasized, the sulphur impurities in the lampblack probably accounted for the increase in weight, and the evidence for the existence of this compound is of no value. The carbonaceous residues obtained when certain organic salts of silver are ignited have been supposed to contain a definite carbide because a prolonged calcination did not burn off all the carbon.

C. F. Gerhardt and A. Cahours heated to redness in an open vessel silver cumate, and obtained a dull yellow earthy residue with the composition *silver hemicarbide*, Ag_2C. Dil. nitric acid extracted the silver and left behind carbon. J. von Liebig and J. Redtenbacher heated silver cyanide until at a certain stage there was incandescence, nitrogen was evolved, and a dull white fused silver carbide remained. They stated that when the carbide was heated with access of air, carbon burnt at the surface, and a layer of silver protected the underlying carbide from further oxidation. When treated with nitric acid, silver dissolved and a network of carbon remained. No analyses were made. J. J. Berzelius heated silver pyroracemate, and obtained a grey powder which acquired a metallic lustre when burnished. When boiled with a soln. of potassium carbonate, washed with water, and ignited in air, the composition corresponded with *silver carbide*, AgC; and in another experiment the composition was represented by Ag_4C_3. H. V. Regnault heated silver malate to 150°, when a slight explosion occurred, and a dark grey, homogeneous, metallic mass remained. The oily matters were removed by washing with a soln. of potassium hydroxide; then with dil. hydrochloric acid; and with aq. ammonia to remove silver chloride. The dark grey substance so obtained, said H. V. Regnault, can be nothing else than silver carbide, and analyses agree with the formula AgC. Nitric acid dissolved it with the separation of black flakes of charcoal.

Before the nature of acetylene had been established, J. A. Quet, A. Vogel and C. Reischauer, and R. Böttger observed that an explosive compound of silver is formed during the action of pyrogenetic gases on an ammoniacal soln. of silver chloride or nitrate, as in the parallel case of cuprous carbide. The relation of the explosive compound to acetylene was established by M. Berthelot about 1860. The compound was made by M. Miasnikoff, M. Behrend, M. Berthelot, and E. Reboul by passing acetylene into an ammoniacal soln. of silver nitrate: $C_2H_2+2Ag(NH_3)_2NO_3=C_2Ag_2+2NH_4NO_3+2NH_3$. E. H. Keiser thus described the process:

Purified acetylene was passed into an ammoniacal soln. of silver nitrate. The precipitate was washed by decantation first with water to which ammonia had been added, afterwards with water, and finally with alcohol and ether. The precipitate was drained on a funnel by means of a filter-pump and quickly transferred to a sulphuric acid desiccator and dried in vacuo. The desiccator should be protected from light, and when dry the colour of the product is snow-white.

R. T. Plimpton said that the precipitate from dil. soln. is pale yellow, and that from conc. soln., yellow; and G. Arth said that the precipitate from ammoniacal soln. is at first yellow, and then becomes white. If a neutral soln. of silver nitrate is used, R. Chavastelon said that the precipitate first formed is a complex silver nitratocarbide which passes into the carbide when the action of the acetylene is continued. R. Kremann and H. Hönel dropped a soln. of acetylene in acetone into a 5 per cent. alcoholic soln. of silver nitrate, and the mixture was allowed to stand in a well-closed vessel and shaken repeatedly. If an aq. soln. of silver nitrate be used, the precipitation is not so sharp.

The composition of the silver compound was represented by the formula $C_2H_2Ag_2$, by M. Miasnikoff; by $(C_2HAg)_2.Ag_2O$, by E. Reboul, and M. Berend; by $(C_2HAg_2)_2O$, by M. Berthelot; by $C_2H_2Ag_2O$, by R. Blochmann, and W. Lossen; by $C_2Ag_2.nH_2O$, by R. T. Plimpton; and by C_2Ag_2, by E. H. Keiser, R. Chavastelon, F. Brandstätter, L. Knorr and H. Mathes, and M. Berthelot and M. Delépine. Silver carbide is a snow-white amorphous powder. M. Berthelot and M. Delépine found the heat of formation to be $C_2H_{2\text{soln.}}+2Ag(NH_3)_2NO_{3\text{soln.}}=C_2Ag_2+2NH_4NO_{3\text{soln.}}+2NH_{3\text{soln.}}+15{\cdot}55$ Cals.; or $C_2H_2+Ag_2O=C_2Ag_2+H_2O+22{\cdot}25$ Cals. with gaseous acetylene and water, and 32·95 Cals. with acetylene in soln. and liquid water. Hence, with diamond carbon: $2C+2Ag=C_2Ag_2-87{\cdot}15$ Cals. The explosiveness of silver carbide is thus connected with its endothermal formation. The carbide readily explodes when dry, and R. Blochmann found it to be as explosive as cuprous carbide; that it decomposes in contact with hydrochloric acid, forming acetylene and silver chloride; and it gradually becomes grey when exposed to light. C. W. B. Normand and A. C. Cumming found that about 2 gram-atoms of iodine are consumed per gram-atom of silver, and silver iodide, $C_4H_2I_2$, etc., are formed. The reaction has been studied by M. Berend, and A. Bäyer. G. Arth found that it dissolves in an aq. soln. of potassium cyanide with the evolution of acetylene. J. F. Durand obtained explosive silver nitratocarbide, $Ag_2C_2.AgNO_3$, by adding calcium carbide to silver nitrate soln. Mercurous acetylide precipitates silver acetylide from aq. soln. of silver nitrate. Silver acetylide has no action on aq. soln. of cupric, mercurous, or mercuric nitrates.

Silver carbide forms complexes with other silver salts, *e.g.* J. A. Nieuwland and J. A. Maguire prepared **silver fluocarbide**; M. Berthelot, and C. Willgerodt, **silver chlorocarbide,** $C_2Ag_2.AgCl$, and $2C_2Ag_2.AgCl$; M. Berthelot, **silver iodocarbide,** $Ag_2C_2.2AgI$; J. A. Nieuwland and J. A. Maguire, **silver perchloratocarbide;** and **silver bromatocarbide;** M. Berthelot, and R. T. Plimpton, **silver sulphatocarbide,** $2Ag_2C_2.Ag_2SO_4$; G. Arth, R. Chavastelon, A. Vogel and C. Reischauer, E. H. Keiser, and R. T. Plimpton, **silver nitratocarbide,** $Ag_2C_2.AgNO_3$; C. Willgerodt, **silver nitratohydrocarbide,** $AgHC_2.AgNO_3$; R. Cavastelon and R. T. Plimpton, **silver dinitratocarbide,** $Ag_2C_2.2AgNO_3$; J. A. Nieuwland and J. A. Maguire, **silver phosphatocarbide;** A. E. Edwards and W. R. Hodgkinson, **silver chromatocarbide,** $C_2Ag_2.AgCrO_4.H_2O$. C. Liebermann made **silver allylenide,** C_3H_3Ag.

The direct action of carbon on gold has been discussed in connection with that metal (**3**. 23, 6). O. Ruff and B. Bergdahl[3] observed the slight solubility of carbon in gold. W. Hempel and P. Rucktäschel prepared an alloy with 0·31 per cent. of carbon. R. Böttger obtained an explosive compound by the action of pyrogenetic gases on soln. of auric chloride. F. C. Phillips said that auric chloride soln. are reduced to gold by acetylene, but, added J. A. Mathews and L. L. Watters, no precipitate is produced if the soln. be made alkaline with potassium hydroxide; nor does any precipitation occur with soln. of potassium cyanoaurate. According to M. Berthelot, if acetylene be passed through a soln. of aurous thiosulphate, a yellow explosive compound is formed; and J. A. Mathews and L. L. Watters found that the product obtained by passing acetylene into a soln. of sodium aurous thiosulphate is **aurous carbide,** Au_2C_2. Aurous carbide forms yellow flakes which are highly explosive by percussion, brushing with a camel's-hair brush, or by rapid heating. If heated very slowly, it can be decomposed without explosion. Aurous carbide is decomposed by hydrochloric acid, giving off acetylene, and leaving a black residue of aurous chloride. Cold water has no action, but when boiled with water, aurous carbide is decomposed into its constituents without forming acetylene. Soln. of cuprous sulphate and neutral ferric chloride do not decompose it in the cold, but if boiled, decomposition without explosion occurs.

§ 15. The Carbides of the Alkaline Earths

After E. Davy[1] had prepared his carburet of potassium, R. Hare, in 1839, experimented on the preparation of calcium by heating an organic salt of calcium —*e.g.* calcium acetate—or a mixture of calcium oxide and sugar charcoal; he found that when mercuric cyanide is heated with lime, a black mass containing carbon is produced. When these mixtures were heated in the electric arc, there was formed a grey mass containing some free carbon, which oxidized in air, and when treated with water gave a gas with an unpleasant smell. The product must have been an impure calcium or mercury carbide. H. Debray and H. St. C. Deville also seem to have prepared a similar product by melting lime and coal in the oxy-hydrogen furnace. In 1862, F. Wöhler prepared what he called *Kohlenstoffcalcium* by heating an alloy of calcium and zinc with carbon, and he identified the gas which was evolved as acetylene. T. S. Hunt stated in 1886 that in the electric furnace the oxides, not only of the alkali metals, but also those of calcium, magnesium, aluminium, silicon, and boron, in the presence of carbon can be reduced to form carbides. W. Borchers in 1891 concluded that "all the oxides are capable of being reduced by carbon heated by electricity," and although he does not mention calcium carbide, yet, after the commercial importance of this carbide had been established, he claimed that he had obtained **calcium carbide,** CaC_2, but drew no attention to it since he was seeking for the metals. This claim for priority has no bearing on the history of our knowledge of calcium carbide. L. K. Boehm said that he had made calcium carbide in 1891, by heating carbon and the alkaline earth by means of an electric current. It is evident from all this that calcium carbide had been made in electric furnaces more or less as an accidental product, but it was then of no commercial importance.

T. L. Willson first made calcium carbide and grasped the importance of this compound as a means of preparing acetylene so as to bring it within the range of commercial utility. The general history of calcium carbide has been described by D. Korda, F. Liedbetanz, V. B. Lewes, J. H. Vogel, R. Pitival, etc. Early in 1892, T. L. Willson attempted to reduce magnesium and calcium oxides to the metallic state in the electric furnace, in order to utilize these metals in the reduction of alumina.

In attempting to reduce lime by carbon, he obtained a fused bath which caused a short-circuiting of the current, and to prevent which he added a layer of carbon which prevented the splashing of the bubbling liquid against the sides of the electrodes. He produced in this way calcium carbide as a hard crystalline mass which disintegrated and crumbled on exposure to the air, and gave rise to a violent evolution of gas when brought in contact with water. The gas burnt with a very smoky flame.

The publication by A. C. Frazer of the correspondence with Lord Kelvin, and a report by F. P. Venable show that the carbide was made by electric smelting about the middle of 1892, but the issue of a patent in Feb. 21st, 1893, was the first public announcement of this work. Meanwhile, L. Maquenné studied the observations of C. Winkler (i) on the reduction of the alkaline earth carbonate by magnesium, $CaCO_3+3Mg=3MgO+C+Ca$, and (ii) the residue when treated with water gave off hydrogen with a disagreeable smell. L. Maquenné prepared barium carbide by the action of magnesium on a mixture of barium carbonate and retort carbon: $BaCO_3+3Mg+C=BaC_2+3MgO$; and stated that the reaction is successful only with barium carbonate; for the others, particularly calcium carbonate, are only partially attacked, and give on treatment with water a mixture of hydrogen and a little acetylene. At the end of 1892, H. Moissan published an account of the formation in the electric furnace of a fusible calcium carbide. He said:

If the temp. reaches 3000°, calcium oxide is rapidly reduced by carbon, and the metal is set free in large quantities; it combines readily with the carbon of the electrodes, forming a calcium carbide which is liquid at a red heat, and so is easily collected.

Later, he added that at the high temp. of the electric furnace, only a single compound of carbon and calcium can exist; this compound is crystalline, and its analysis corresponds with CaC_2. L. M. Bullier applied for a patent for the preparation of the carbides of the alkaline earths based on H. Moissan's researches. H. Moissan's experiments were made in an arc furnace resembling Figs. 4 and 5. H. Moissan thus describes the preparation of the carbide:

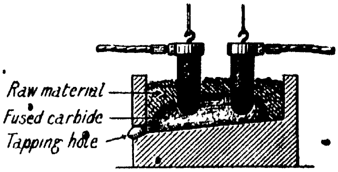

FIG. 21.—Calcium Carbide Furnace (Diagrammatic).

An intimate mixture of 120 grms. of calcium oxide made from marble and 70 grms. of sugar charcoal is heated in the crucible of the electric arc furnace. A slight excess of lime is purposely allowed since the crucible supplies some of the carbon required for the carbide; if an excess of lime is used, calcium is the chief product. Calcium carbonate can be substituted for the lime, but not with advantage, because of the large vol. of the substance employed. The yield is 120–150 grms. A lime containing magnesia yields carbide only with difficulty because magnesium carbide is not readily made, and the magnesia then retards the fusion.

E. Botolfsen has studied the direct combination of carbon and calcium. No combination could be detected by heating the two elements in vacuo at 700°—*i.e.* below the m.p. of the metal—during 50 hrs. Carbide was formed when fused calcium was heated in contact with carbon, but, owing to the distillation of the calcium, only traces were produced. If heated to 850° in an atm. of argon at normal press., no increase in the yield of carbide was observed. If, however, carbon be heated with an excess of calcium to 850°–870° in contact with calcium vapour, only 17 per cent. of the carbon remains uncombined; and at 925°–975°, all the carbon had combined in 45 hrs. No trace of a *calcium subcarbide* was observed. H. Moissan made calcium carbide by the action of calcium-ammonium on acetylene. L. Hackspill and E. Botolfsen found the product is impure.

The electric current, said F. Krüger, plays no part in the production of calcium carbide other than as a means of obtaining a high temp. H. Moissan found the carbide is decomposed if the temp. be too high. H. J. Krause and J. Y. Yee said that the reduction of the calcium oxide and the evolution of carbon monoxide begins at about 1200°. V. Rothmund said that the reaction begins at 1620° when the partial press. of the carbon monoxide is one-fifth (M. de K. Thompson says that this should be one-third) of an atm.; at temp. below 1620° in the presence of carbon monoxide, some carbide is decomposed. The temp. of formation may be reduced by decreasing the partial press. of the carbon monoxide. C. Diesler said that good yields can be obtained at 1600° by working at high press. E. Rudolfi gave 1800°–1819° for the temp. of formation with the partial press. of carbon monoxide one-fifth of an atm. A. Lampen said that below 1700° he could detect no carbide formation with certainty; at 1725°, there were traces of carbide formed; and at 1800°, the mass fused and much acetylene was evolved when the product was treated with water. W. Borchers said that "the reactions taking place in the production of calcium carbide are $CaO+C=Ca+CO$, and $Ca+2C=CaC_2$. The second reaction was discovered by F. Wöhler." The carbons are corroded badly about 6 ins. below the surface of the mixture when the carbons were immersed about a foot in the mixture. G. Gin suggests that free oxygen is found in the gases produced in the hottest portions of a calcium carbide furnace, whilst calcium vap. is found in cooler portions of the furnace. It was suggested that these substances may be formed by the reactions $2CaO+4C=2CaC_2+O_2$ and $CaC_2+2CaO=3Ca+2CO$, the temp. in the hottest zones of the furnace being higher than the dissociation temp. of carbon monoxide. According to C. Bingham, the corrosion of the carbons has been attributed to the action of air on the carbons owing to the latter being raised to a high temp. by the heat (i) produced by the combustion of carbon monoxide on the surface of the charge; (ii) produced by ohmic resistance; and (iii) carried by conduction from the hot zone by the carbons themselves. R. S. Hutton and J. E. Petavel showed that if the carbon is completely burned in the raw material, and the furnace made completely gas-tight so that no air can enter, there is very little consumption of carbon. The subject has also been discussed by O. Ruff and O. Geocke; and the power consumption by H. Furusaki. J. Leede recommended making the charge by coking a mixture of lime with a hydrocarbon—pitch, asphaltum, etc. H. L. Hartenstein, and L. Landin used a similar process, and also recommended adding a little calcium chloride or fluoride to make the product more fusible. T. L. Willson previously said that he obtained "the best results by infusing the lime in tar, and then subjecting the mixture to the electric arc." One type of furnace employed on a large scale is illustrated diagrammatically by Fig. 20. The general manufacture has been described by J. Baumann, J. H. Reid, F. L. Slocum, F. E. Norton, O. Ruff and E. Förster, C. Bingham, V. B. Lewes, J. H. Vogel, F. Liedbetanz, B. Waeser, P. Schläpfer, P. Wangemann, etc. J. H. Reid degasified a mixture of pulverized calcium carbonate and coal, and passed it on, while still hot, to an electric furnace, where it yielded calcium carbide and carbon monoxide. If required, the carbide was run into water, and the gaseous products passed through the furnace chamber so as to collect hydrocarbons like methane, ethylacetylene, methylallene, etc.

A great many varieties of furnace and a great many modifications in the details of manufacture have been proposed. Many of these proposals are still-born—*e.g.* R. P. Pictet heated the mixture in a shaft furnace by a ring of tuyères burning water-gas mixed with air, and below that, the mixture was heated in the electric arc at 3000°; the resulting calcium carbide flowed to the bottom of the furnace. F. Sebald added a little lead or tin to make the furnace charge conduct better.

Instead of using calcium oxide or carbonate, E. Jacobsen, and C. M. J. Limb used a mixture of calcium sulphate or sulphide and carbon; R. C. Baker used calcium borate or pandermite and obtained calcium carbide and boride; and H. Hilbert and A. Frank used calcium phosphate: $Ca_3(PO_4)_2+14C=3CaC_2+2P+8CO$. M. W. Travers prepared calcium carbide without electric heating by melting sodium with an intimate mixture of calcium chloride and retort carbon in an iron crucible for half an hour; and P. Wolff inflamed a mixture of calcium oxide, carbon, and aluminium as in the thermite process.

The product obtained in the earlier stages of the industry was very impure until it was recognized that special care must be taken in the choice of raw materials. The lime may contain silicates, phosphates, and sulphates, and these may appear in the carbide as silicides, sulphides, and phosphides, which are decomposable by water, yielding acetylene contaminated with hydrogen, hydrogen sulphide and phosphide. Nitrides, which contaminate the gas with ammonia, may also be formed. The impurities in the carbide have been discussed by C. Willgerodt,[2] J. de Brévans, E. Hubou, H. Giraud, N. Caro, F. B. Ahrens, L. M. Bullier and M. Perrodil, E. Chuard, A. Bergé and A. Reychler, etc. Commercial calcium carbide contains as accessory constituents some cyanamide, unconverted carbon, crystallized alumina (corundum), and calcium oxide. J. H. Vogel gave analyses of some of the earlier commercial carbides. The following are selected from his list:

CaC_2	C	$CaO(CO_2)$	Si	P	S	N	Fe_2O_3	MgO	Al_2O_3
83·23	6·12	6·62	0·32	0·006	0·020	2·020	2·31	0·32	0·28
90·12	2·36	4·42	1·32	0·005	0·032	0·01	1·03	0·005	0·26

Some of the more recent products have over 95 per cent. CaC_2. *Silicon* is present as calcium or iron silicide (H. le Chatelier, F. Wöhler, H. Moissan, F. B. Ahrens, O. Hackl); silicon (R. S. Marsden); silica crystals (H. Moissan); carborundum (H. Moissan); and ferrosilicon—*vide* iron; *sulphur*, as calcium or aluminium sulphide (H. Moissan, G. Döllner and E. Jacobsen, A. Mourlot); *iron*, as silicide, phosphide, or carbosilicide or ferrosilicon (H. Moissan, G. Hanekop); *phosphorus*, as calcium or iron phosphide (H. Moissan, A. P. Lidoff); *calcium*, as free oxide, sulphide, phosphide, etc. (J. H. Vogel); *aluminium*, as sulphide; *arsenic* (J. H. Vogel); *cyanides* and *nitrides* (A. Rossel, L. Franck, H. Bamberger, N. Caro); and *carbon* is found as graphite. H. Giraud reported minute crystals in the insoluble residue remaining after the carbide had been treated with water, but H. Moissan could find no diamonds. Several methods have been proposed—by H. L. Hartenstein,[3] C. J. Lundström, J. von Orlowsky, W. Rathenau, E. Zühl and R. Eisemann, etc.—for eliminating impurities as slags.

K. Nischk[4] studied the formation of the carbides of calcium, strontium, and barium. In 1892, L. Maquenné made an impure **barium carbide,** BaC_2, by fusing together barium carbonate (26 grms.), powdered magnesium (10·5 grms.), and retort carbon (4 grms.), when an intense reaction occurred, $BaCO_3+3Mg+C=3MgO+BaC_2$. The mixture of magnesia and barium carbide gave acetylene when treated with water. He also made it by heating barium amalgam with powdered carbon in an atm. of hydrogen; the reaction begins at a red heat. He also made the carbide by heating barium nitride with carbon. H. Moissan, and L. M. Bullier made barium carbide by heating a mixture of sugar charcoal and barium oxide or carbonate in an electric arc furnace. H. Moissan made **strontium carbide,** SrC_2, in a similar manner. C. M. J. Limb made barium carbonate by heating native barium manganate, *i.e.* psilomelane, at a high temp. with carbon.

H. Moissan established the composition of the three alkaline earth carbides by analysis. Arguments [5] as to whether calcium carbide is or is not a *fine chemical* are futile until the disputants have agreed as to the definition of a fine chemical. Similarly, it is a waste of time to discuss whether calcium carbide is or is not an organic compound until it is decided what is an *organic compound. E.g.* if organic chemistry be the chemistry of carbon compounds, then the carbonates, carbides, cancrinite (silicate), cast iron, etc., would belong to that department of chemistry. When the definition is settled, there will probably be no need for argument. Without sharp-cut definitions the opponents in this type of disputation cross rapiers without touching one another. Each fights his own shadow.

The properties of calcium, strontium, and barium carbides.—The prevailing colours of commercial calcium carbide are black, reddish-black, or reddish-brown, and less commonly yellowish-red or brown. These colours are attributed by H. Moissan [6] to the presence of iron. E. Wedekind, and H. Moissan said that a mere trace suffices to produce both the coloration and a lustrous iridescent sheen. There may be a bluish or purplish iridescence on the surface. The carbide with streaks of a darker colour than the remaining mass owes its colour to the overheating of the furnace which has caused the separation of amorphous carbon, and volatilization of calcium. According to H. Moissan, and E. Botolfsen, if quite free from iron, calcium carbide is white, and as transparent as sodium chloride. The mass cleaves readily and has a crystalline fracture. The carbide which has been cooled slowly is coarsely crystalline; and that which has quickly chilled has a steel-like fracture, with a fine, almost invisible, grain. The **crystals** do not belong to the cubic system. According to C. H. Warren, the **cleavages** are cubic, being nearly equal and parallel to three directions at right angles to one another. The fresh cleavage surfaces may show striations, which indicate that the crystals are built up from a series of thin plates. The thin sections in transmitted light may appear colourless, greenish-yellow, purplish-red, or lilac-yellow. There is a slight pleochroism. The complex polysynthetic twinning is parallel to the diagonals approximately at 45° to the pinacoids. The dodecahedral twinning appears to be mimetic, so that, geometrically, the crystals are pseudo-cubic. The double refraction, rectangular cleavage, and parallel extinction correspond with either the tetragonal or rhombic system—probably the latter. The **index of refraction** exceeds 1·75; and the double refraction is strong, being nearly 6·050. The optical extinction is generally parallel to the rectangular cleavages, but with a yellowish carbide, the extinction may be inclined 12° to 24° with the rectangular cleavages. The interference figures resemble the so-called uniaxial figures. According to H. Moissan, the **specific gravity** of calcium carbide is 2·22 at 18°; that of strontium carbide, 3·19; and that of barium carbide, 3·75. H. Moissan said that platinum may be melted in contact with the solid carbide. H. M. Kahn found barium carbide fused at a lower temp. than the other alkaline earth carbides. As indicated above, there is evidence that the carbide decomposes at a high temp., but no change occurs at the temp. of molten platinum. E. Botolfsen found that calcium carbide dissociated when heated to 1050° for 3 hrs., and a deposit of finely divided metallic calcium was obtained; the carbon united with the iron containing vessel, forming iron tritacarbide. M. de K. Thompson said that the decomposition of calcium carbide into its elements is appreciable a little above 1475°. E. Tiede and E. Birnbrauer gave 800° for the **dissociation temperature.** V. Ehrlich, and G. Erlwein and co-workers concluded that calcium carbide, when heated, dissociates into *calcium subcarbide,* CaC, and carbon; E. Briner and A. Kurhne found no evidence of a subcarbide, and concluded that the carbide dissociates into its elements; G. Bredig could identify neither a subcarbide nor calcium as a product of the decomposition; E. Botolfsen identified volatilized calcium; O. Ruff and E. Förster obtained no evidence of the existence of a subcarbide; and H. J. Krase and J. Y. Yee showed that above 1100°, there is an appreciable vap.

press. of calcium, and that assuming the reaction is $CaC_2 \rightleftharpoons Ca + 2C$, they found data in agreement with

	1000°	1100°	1200°	1300°
C liberated . . .	0·00	3·68	1·12	22·32

G. Gin and M. Leloux observed a similar decomposition of the other alkaline earth carbides. The decomposition of barium carbide occurs at a lower temp. than the volatilization temp. of carbon. The carbides themselves are non-volatile. The **specific heat** has not been determined, but B. Carlson calculated from the additive rule:

	0°	1000°	1500°	2000°	2500°	3000°	3500°
Sp. ht. .	0·247	0·271	0·296	0·325	0·344	0·363	0·381
Mol. ht. .	15·92	18·36	19·58	20·80	22·02	23·24	24·42

O. Ruff and E. Förster gave 2300° for the **melting point** of calcium carbide, and they found that, owing to the dissociation $CaC_2 \rightleftharpoons Ca_{vapour} + C_{graphite}$, the **vapour pressure,** p mm., in an atm. of the calcium vapour is

	2025°	2200°	2255°	2325°	2405°	2425°	2460°	2500°
p .	12	26	128	228	541	631	756	780

so that the dissoc. press. of calcium carbide is 760 mm. at 2500° ± 50°, and 1 mm. at 1825° ± 50°. A. Guntz and H. Basset gave for the **heat of formation** from diamond carbon and solid calcium: $Ca + 2C = CaC_2 + 13{\cdot}15$ Cals. R. de Forcrand gave $-7{\cdot}25$ Cals., and with amorphous carbon $-0{\cdot}65$ Cal. for calcium carbide, and $-7{\cdot}25$ Cals. and $-0{\cdot}65$ Cal. respectively for barium carbide. For the heat of formation of the latter from its gaseous elements he gave 76·65 Cals. O. Ruff and E. Förster gave $CaO + C \rightleftharpoons Ca + CO - 120$ Cals., $Ca + 2C \rightleftharpoons CaC_2 + 13{\cdot}15$ Cals.; $CaO + 3C \rightleftharpoons CaC_2 + CO - 97$ Cals.; and $2CaO + CaC_2 \rightleftharpoons 3Ca + 2CO + 143$ Cals. The temp. of formation has been already discussed. According to G. Hanckop, the **electrical conductivity** of the molten carbide is from $\frac{1}{450}$th to $\frac{1}{600}$th of that of mercury, and that of the solid carbide is still smaller.

Neither F. P. Venable and T. Clarke, nor H. Moissan observed any reaction between dry **hydrogen** on cold, or on heated, calcium carbide; and they found that dry **oxygen** reacts with the heated carbide at a dull red heat with incandescence, forming calcium carbonate and carbon dioxide; but O. Ruff and E. Förster found that an appreciable quantity of acetylene, $CaC_2 + H_2 \rightleftharpoons Ca + C_2H_2$, is formed at 2200°. Calcium carbide disintegrates and crumbles on exposure to ordinary **air,** but not to dried air; hence it is preserved by immersion in oil—say kerosine—or in air-tight tins. Like sodium and potassium, it gives rise to a violent evolution of gas when in contact with **water.** H. Moissan showed that if a fragment of this carbide be passed into a eudiometer tube filled with mercury, and then a few cubic centimeters of water introduced, a violent evolution of gas is produced, which only ceases when all the carbide is decomposed, calcium hydroxide remaining suspended in the liquid. The gas evolved is pure acetylene, completely absorbed by ammoniacal cuprous chloride, and leaving an almost imperceptible trace of impurity at the top of the tube. This decomposition by water takes place with evolution of heat, but without ever reaching the point of incandescence. It is nevertheless as vigorous as the reaction between sodium and water. From the weight of the carbide taken in the experiment and the vol. of the gas produced, the reaction appears to be represented by $CaC_2 + 2H_2O = C_2H_2 + Ca(OH)_2$. O. Ruff and E. Förster found that at 250° water vapour forms acetylene and calcium oxide, but at dull redness, calcium oxide, carbon, and hydrogen: $CaC_2 + H_2O \rightleftharpoons CaO + 2C + H_2$.

C. H. Warren thus describes the slow decomposition of the carbide by water as it appears under the microscope using thin rectangular cleavage fragments, immersed in a mixture of glycerol and water so that the decomposition may be slow enough to prevent effervescence. With crossed nicols, the margins of the grains appear gradually to lose their strong interference colours, and a rim of feebly birefringent material begins to develop. The corners change more quickly than the sides, so that the unchanged carbide assumes a circular or elliptical outline which constantly diminishes in size until the entire grain has changed to feebly refracting calcium hydroxide. During this change, the structural appearance of the grain does not alter, and the cleavage cracks and twinning lines remain. If enough water is present, the calcium hydroxide may finally dissolve. The change seems to involve the passage of one crystalline substance into another without immediately breaking down the essential crystal structure, so that OH-groups take the place of the carbon atoms. This phenomenon recalls the preservation of the crystalline structure of some zeolites during dehydration.

According to H. Moissan, at room temp. the alkaline earth carbide takes fire in **fluorine** gas, forming calcium and carbon fluorides. F. P. Venable and T. Clarke found that calcium carbide is not attacked by **chlorine** in the cold, but at 245°, the carbide becomes incandescent, forming calcium and carbon chlorides. A. Frank stated that when calcium, barium, and strontium carbides are heated in a stream of chlorine, graphite carbon separates out, but the yield is much less than the theoretical. According to H. Moissan, and F. P. Venable and T. Clarke, **bromine** reacts at 350°, and **iodine** decomposes the carbide at 305°, with incandescence. H. Moissan compared the temp. of incandescence of the three alkaline earth carbides with the dried halogens.

	Chlorine	Bromine	Iodine
Calcium carbide .	245°	350°	305°
Strontium carbide .	197°	174°	182°
Barium carbide .	140°	130°	122°

E. Barnes found liquid bromine acts slowly on calcium carbide at ordinary temp., forming carbon hexabromide and calcium bromide, but dry chlorine had no action at ordinary temp. on two months' exposure. In a sealed tube at 100°, bromine and calcium carbide form carbon and calcium bromide. According to H. Moissan, barium carbide combines with iodine at a lower temp. than that at which it is attacked by chlorine or bromine; this is the reverse of what occurs with calcium carbide. H. Moissan showed that with dil. or conc. acids, the alkaline earth carbides decompose with the evolution of acetylene; the carbides become incandescent when warmed in **hydrogen chloride,** and much hydrogen is formed. Calcium and strontium carbides become incandescent in **sulphur** vap. at about 500°, barium carbide at 150°, and the alkaline earth sulphide and disulphide are formed. Similar results were obtained with **selenium** vap. Fuming **sulphuric acid** slowly attacks the alkaline earth carbides. Fused calcium carbide dissolves **carbon** and gives it up as graphite on cooling; H. M. Kahn's observations have been indicated in connection with carbon, and he obtained similar results with the other carbides of the alkaline earths. A. Frank found that when calcium, strontium, or barium carbide is heated in a current of **carbon monoxide or dioxide,** carbon separates in the form of graphite: $CaC_2+CO\rightleftharpoons CaO+3C$; the reaction is reversible and progresses from right to left above 1600°, and at lower temp. it goes from left to right. O. Ruff and E. Förster represented the reaction at about 1700°, $CaC_2+CO\rightarrow CaO+3C$. V. Rothmund, and C. A. Hansen also studied this reaction. M. de K. Thompson found the partial press. of carbon monoxide in the reversible reaction: $CaO+3C\rightleftharpoons CaC_2+CO$, at 1445° and 1475°—below 1445° the partial press. is too small to measure conveniently, and above 1475° the carbide dissociates $CaC_2\rightleftharpoons Ca+2C$. The partial press. at 1445° is 0·44 mm. and at 1475°, $0{\cdot}82\pm0{\cdot}02$ mm. From the equation $\log(p_2/p_1)=Q(T_1^{-1}-T_2^{-1})$, at room temp., $Q=121{,}000$, and the negative temp. coeff. of 3·3 cals. per degree gives for $\theta°$ above the room temp., $Q=121{,}000-3{\cdot}3\theta$; at 1460°, $Q=116{,}000$ Cals. The heat-change is negative in passing from left to right of the given equation. The free energy of the reaction at 1475° is +23,700 cals., and it decreases as the temp. rises to 1920°; above that temp. there is an increase. Assuming the mean values of Q, the equilibrium press., p, of the carbon monoxide calculated for different temp. is

	1475°	1575°	1675°	1775°	1875°	1975°
p . .	0·08	0·50	2·53	10·7	10·5	133·0 mm.

The results are graphed in Fig. 22. H. Moissan found that when a mixture of calcium carbide and **alcohol** is heated in a sealed tube, calcium ethoxide and acetylene are formed: $CaC_2+2C_2H_5OH=(C_2H_5O)_2Ca+C_2H_2$. He also said that the carbide is insoluble in the reagents—**carbon disulphide, petroleum,** or **benzene.** P. Lefebure found the primary reaction of calcium carbide on **amyl chloride** is: $2C_5H_{11}Cl+CaC_2 \rightarrow C_2H_2+2C_5H_{10}+CaCl_2$, but a complex series of changes follows on. D. Sandmann found that **potassium thiocyanate** reacted with calcium carbide: $CaC_2+5KSCy=CaS_5+5KCy+2C$. H. Moissan detected no signs of a reaction between the alkaline earth carbides and **silicon** or boron at a white heat; **silica** yields silicon carbide. H. C. Geemuyden found that **boron trioxide** is reduced by calcium carbide in an electric furnace, and calcium boride is formed.

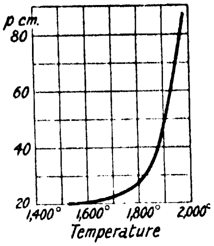

FIG. 22.—Equilibrium Pressure of Carbon Monoxide, $CaO+3C \rightleftharpoons CaC_2+CO$.

H. Moissan observed no reaction between the alkaline earth carbides and **nitrogen** at 1200°, but A. Frank, and N. Caro showed that at 700°-800°, dry nitrogen changes barium carbide into barium cyanide and cyanamide in the proportions 30:70; the reactions are represented: $BaC_2+N_2=Ba(CN)_2$; and $Ba(CN)_2=BaN_2C+C$. The reaction is utilized in the preparation of cyanides. Calcium carbide forms the cyanamide at 1100°-1200°, and when the resulting calcium cyanamide, CaN_2C, is fused with alkali salts, in the presence of carbon, alkali cyanide is formed. According to N. Caro, at atm. press., the reaction $CaC_2+N_2=C+CaN_2C$, is reversed at about 1360°, but if free lime is present, the reversal occurs at a lower temp. Thus, M. le Blanc and M. Eschmann found that with a 75 per cent. calcium carbide, the reversal occurs at 1150°. O. Ruff and E. Förster investigated the reaction between nitrogen and calcium cyanamide. The cyanamide formed above 1100° begins to decompose at 1200°. A. Remelé and B. Rassow studied the nature of the carbon formed in this reaction. M. de K. Thompson and R. H. Lombard, V. Ehrlich, and H. J. Krase and J. Y. Yee studied the equilibrium conditions with different press. of nitrogen; there is a disturbance owing to the volatilization of the cyanamide at 1050°. Owing to the reversibility of the reaction, nitrogen is not taken up by fused calcium carbide as it leaves the furnace since the cyanamide cannot exist at the temp. of the fused carbide. As the carbide cools, it becomes impermeable to gases, and absorption occurs only on a thin surface film. H. Moissan passed acetylene into a soln. of calcium in liquid ammonia, and obtained **calcium tetrammino-acetylenecarbide,** $CaC_2.C_2H_2.4NH_3$. E. Botolfsen also prepared the same compound, and found that when heated to 150°, or even to 700°, the solid residue contains calcium carbide, hydride, cyanide, nitride, and cyanamide. R. Salvadori found that at about 650°, calcium carbide and **ammonia** begin to react according to the equation $CaC_2+4NH_3=CaCN_2+NH_4CN+4H_2$. The reaction takes place in two stages, in the first of which the calcium carbide and the nitrogen formed by the decomposition of the ammonia interact forming calcium cyanamide: $CaC_2+N_2=CaCN_2+C$. The carbon thus liberated then acts on the ammonia, giving ammonium cyanide and hydrogen; he also found that the reaction with **ammonium chloride** and the formation of cyanides or cyanamides (*q.v.*) by the reaction of the carbides with **nitrogen,** is, as stated by F. Fichter and C. Schölly, confined to the carbides of the alkalies or alkaline earths. According to H. Moissan, fuming **nitric acid** does not react in the cold with the alkaline earth carbides, and when heated the reaction is slow. H. Moissan found that **phosphorus** vap. converts the alkaline earth carbides into the phosphides without incandescence; with **arsenic** vap. there is a considerable evolution of heat as the alkaline earth carbide is converted into the arsenide. A. Frank showed that some graphite is formed, but less than the theoretical amount, when the carbides of the alkaline earths are heated in a current of phosphorus or arsenic vap. H. Moissan found that at a red-heat, **antimony** and calcium carbide give an alloy of antimony and calcium.

H. Moissan stated that calcium carbide is not decomposed by **sodium** or **magnesium** at the softening temp. of glass; there is no reaction with **iron** at a red heat, but at a higher temp., a carburetted alloy of calcium and iron is formed; **tin** has no perceptible action at a red heat; and **aluminium** forms a carbide. A. Rossel found that when calcium carbide mixed with powdered magnesium, **zinc,** aluminium, iron, or **copper,** is heated in air, a flame appears, and a nitride is formed, $CaC_2+3Mg+2N+5O=CaO+Mg_3N_2+2CO_2$. F. P. Venable and T. Clarke noted that soln. of **alkali hydroxides** give acetylene with calcium carbide. O. Ruff and E. Förster gave for the fusibility of mixtures of calcium carbide and **calcium oxide,**

CaO . . .	4	14	25	29	35	42 per cent.
m.p. . . .	2200°	2000°	1715°	1645°	1715°	1815°

which yields a V-shaped curve with a simple eutectic at 1640° and 30 per cent. CaO. H. Moissan noted the energetic reducing action of calcium carbide on **metal oxides.** The metal may separate as in the case of lead, tin, and bismuth, or the metal may combine with other substances present, thus, the oxides of barium, strontium, aluminium, chromium, molybdenum, manganese, tungsten, and titanium furnish the carbides of these metals. H. N. Warren said that the oxides of tin, copper, lead, manganese, iron, nickel, cobalt, chromium, molybdenum, and tungsten give alloys with calcium. According to J. N. Pring, lead oxide dropped into molten calcium carbide reacts violently, some lead is volatilized and an alloy of lead and calcium is formed. N. Tarugi found that the reaction with cupric oxide begins at 432°, but is completed near 1408°. B. Neumann, and F. von Kügelgen added a chloride to the mixture of calcium carbide and metal oxide. The former argued in favour of the reaction, $2M_2O+2MCl+CaC_2=6M+CaCl_2+2CO$; and the latter, $4M_2O+2MCl+CaC_2=10M+CaCl_2+2CO_2$. B. Wedding did not see any application of calcium carbide as a deoxidizing and carburetting agent in the cast-iron industry. L. M. Bullier, O. Fröhlich, B. Neumann, and H. C. Geemuyden recommended reducing the **chlorides** of copper, silver, manganese, cobalt, zinc, nickel, lead, etc., with calcium carbide accompanied by an alkali chloride, calcium fluoride, or water-glass as a flux. The **carbonates** behave like the oxides; the **sulphates** are not reduced so readily as the chlorides; many natural minerals—**sulphides,** and **silicates,** gave good results. H. C. Geemuyden found that in the electric furnace, the sulphides of magnesium, antimony, lead, and iron are reduced, and the metals volatilized except in the case of iron; aluminium sulphide was not reduced, and N. Tarugi examined the action of many **metal salts**; he found cupric sulphite and carbonate behave like the oxide; the reaction with lead salts is completed at 400°; lead chromate furnishes free chromium and a lead-calcium alloy; salts of mercury and arsenic give the metal free from calcium; salts of silver, gold, zinc, cadmium, antimony, bismuth, tin, nickel, cobalt, and platinum give alloys with calcium. J. F. Durand found that impure acetylides are precipitated when aq. soln. of cupric, mercuric, silver, lead, ferrous, nickel, cobalt, and manganese salts are heated with calcium carbide. F. P. Venable and T. Clarke found **chromosulphuric acid** oxidizes calcium carbide; and H. Moissan found that calcium carbide and molten **chromic acid** develop carbon dioxide, but a soln. of chromic acid gives acetylene. Molten **potassium chlorate,** or **potassium nitrate,** at a red-heat, forms carbonates; **lead fluoride** at ordinary temp. becomes incandescent.

§ 16. The Carbides of the Magnesium-Zinc Family

According to P. Lebeau,[1] when beryllium oxide is mixed with half its weight of sugar charcoal and a small quantity of oil, and heated to a high temp. in the electric tube furnace for 5–10 minutes, **beryllium carbide** is formed. If the temp. is too low, beryllium nitride, or a mixture of nitride and carbide, is produced. The same compound was made by H. Moissan. F. Fichter and E. Brunner found the reaction between beryllia and carbon begins at about 1900°. From the analogy of beryllium and aluminium carbides, P. Lebeau assigned to beryllium carbide the formula Be_4C_3(Be, 13·8), but, added L. Henry, it does not follow that because beryllium carbide is similar in its properties to aluminium carbide, it must be analogous in composition. Magnesia and silica are both in many respects similar to alumina. The analyses of the carbide quoted by P. Lebeau agree closely with the formula Be_2C, and the apparent analogy between this compound and aluminium carbide cannot be allowed to override the great weight of the other experimental evidence in fixing the valency of beryllium. P. Lebeau showed that beryllium carbide forms transparent yellow-brown, microscopic crystals, similar to those of aluminium carbide. The crystals scratch quartz easily; sp. gr.=1·9 at 15°. The carbide is readily attacked by chlorine at a dull red heat, with formation of beryllium chloride and a residue of amorphous carbon and graphite. Bromine behaves similarly at a somewhat higher temp., but iodine has no action even at 800°. Oxygen produces superficial oxidation at a dull red heat, sulphur vap. attacks it below 1000°, but phosphorus and nitrogen have no appreciable action at dull redness. Dry hydrogen fluoride attacks the carbide with incandescence below a red heat, with formation of fluoride and liberation of carbon; hydrogen chloride behaves similarly, but with less energy. In contact with water or dil. acids, the carbide is slowly decomposed, with liberation of methane, the change occurring rapidly and completely in contact with a hot conc. sodium or potassium hydroxide soln. It reduces conc. boiling sulphuric acid, but is only slowly attacked by conc. nitric or hydrochloric acid, although hot hydrofluoric acid dissolves it rapidly. Fused potassium hydroxide decomposes it with incandescence, potassium nitrate and chlorate are without action, but potassium permanganate and lead peroxide oxidize it readily. F. Fichter and E. Brunner found that ammonia reacts with beryllium carbide at 1000°, forming beryllium nitride with the separation of carbon. H. Moissan found that in the electric furnace beryllium carbide readily dissolves carbon, and on treatment of the cold mass with hydrochloric acid, graphite is obtained. According to P. Lebeau, when a mixture of beryllia (75 parts) and boron (45 parts) is moistened with a little alcohol, compressed, and then heated in a carbon crucible in an electric furnace for 7–8 minutes, brilliant crystals of **beryllium borocarbide**, $Be_6B_6C_4$, are formed. They have a metallic lustre, a sp. gr. 2·4, and are readily soluble in acids. The compound is not altered by exposure to air at ordinary temp., but it is superficially oxidized at a red heat; it burns in chlorine at about 450°, producing boron and beryllium chlorides, and amorphous carbon. K. Nischk studied the formation of beryllium carbide.

Only impure **magnesium carbide** has hitherto been obtained. J. Parkinson[2] showed that when heated in a stream of benzene vap. the metal suffers a marked change; it becomes black and brittle; decomposes water; and leaves a residue of carbon when treated with hydrochloric acid. Methane does not act to any great extent on the red-hot metal; but with coal gas there is an increase in weight. C. Winkler stated that magnesium carbide and carbon are produced in the reduction of carbon dioxide by heated magnesium, for the product, when treated with hydrochloric acid, gives a hydrocarbon gas which burns with a luminous flame. The direct union of carbon with the magnesium is only superficial. J. T. Nance obtained similar results, and he noted that some carbide is formed when a mixture of magnesium powder and wood charcoal is gently ignited. M. Berthelot, H. Moissan, and W. Eidmann heated magnesium powder in a stream of acetylene, and obtained an impure magnesium carbide mixed with carbon; it developed acetylene when treated with water.

There are a number of patents for preparing magnesium carbide or magnesium calcium carbide. C. Whitehead heated a mixture of coal with lime and magnesia or dolomite; H. Auziès and A. Ségoffin heated magnesite or dolomite with carbon in an electric furnace; C. J. Wollaston heated briquettes made of calcium sulphate, kieselguhr, and powdered dolomite; and H. S. Blackmore used a mixture of magnesium fluoride and calcium carbide with alkali fluoride as flux: $MgF_2+CaC_2=MgC_2+CaF_2$.

H. Moissan heated M. Berthelot's carbide in a graphite crucible in an electric furnace. Not the slightest evolution of gas occurred when the cold product was placed in water. Hence, he added that magnesium carbide is completely decomposed at a high temp., and this explains why magnesia can be fired and kept liquid in a carbon crucible without being reduced; magnesium carbide cannot exist at the fusion point of magnesia. W. Borchers claimed to have reduced magnesia by carbon in the electric furnace. P. Lebeau heated a mixture of magnesia and carbon in an electric furnace, and inferred that a carbide is formed because the magnesia volatilizes 3 to 4 times as quickly as it does in the absence of the carbon. The gases in the furnace atm. probably react with the carbide, reproducing magnesia and carbon. He believed that the reaction between magnesia and carbon occurs only between the vap. of these substances at the temp. of the electric arc. O. P. Watts mentioned that carbon can be volatilized from a bed of magnesia, and his sublimate contained magnesia and carbon. R. E. Slade proved that magnesia is reduced by carbon at as low a temp. as 1700° as well as in the electric arc. He was able to collect some of the magnesium produced, and he found it to be always associated with some carbide. There is evidence of the reoxidation of the magnesium by the carbon monoxide in the furnace, $CO+Mg=MgO+C$. K. Nischk studied the formation of magnesium carbide. B. Oddo made **magnesium bromocarbide**, $HC:C.MgBr$; and G. I. Iotsitch and D. Gauthier, **magnesium dibromocarbide**, $MgBr.C:C.MgBr$. G. I. Iotsitch made **magnesium bromoallylenide**, C_3H_3MgBr.

No carbides of zinc or cadmium have been prepared. Much commercial zinc (*q.v.*) contains free carbon. O. Ruff and B. Bergdahl[3] found that only traces of carbon dissolve in zinc, cadmium, or mercury. J. J. Berzelius reported that he had prepared *zinc carbide* by the action of heat on zinc cyanide, but J. B. A. Dumas showed that these products are probably only mixtures. R. T. Plimpton[4] prepared an explosive compound—probably *mercurous carbide*—by the action of acetylene on mercurous acetate suspended in water. E. Burkard and M. W. Travers showed that to ensure the completion of the reaction, the soln. should be frequently agitated, and the current of gas continued for 30 hrs. in darkness: $2HgC_2H_3O_2+H_2O+C_2H_2=2CH_3COOH+C_2Hg_2.H_2O$. The precipitate was washed with water, and then with alcohol, and dried over sulphuric acid. Its composition corresponds with mercurous carbide, $Hg_2C_2.H_2O$. The product is white, and if a little free mercury is present, grey. The elements of water cannot be removed; when dried at 100°, the carbide decomposes. When treated with iodine it furnishes mercurous iodide and ethylene tetraiodide; and with hydrochloric acid, acetylene is evolved.

H. Bassett [5] passed coal gas through Nessler's reagent, and obtained a yellow precipitate which exploded slightly when heated; and he obtained a purer pale yellow precipitate by using the products of the incomplete combustion of coal gas. The precipitate exploded rather more violently than the former product. Analyses corresponded with $C_2HHgI.HgO$. E. H. Keiser made **mercuric carbide** free from iodine, and with the composition corresponding with C_2Hg, by passing purified acetylene into a soln. of mercuric and potassium iodides containing a little potassium hydroxide. The white flocculent precipitate was washed with distilled water, and dried over sulphuric acid. The water was eliminated only by prolonged heating on a water-bath. The compound begins to decompose at about 100°. If gradually heated, the substance becomes dark and a vap. is evolved which has a smell resembling that of phosphine. If heated rapidly, the compound explodes with extreme violence, forming finely divided carbon and mercury. It dissolves readily in hydrochloric acid, forming a soln. of mercuric chloride, and giving off acetylene. It unites slowly with iodine at ordinary temp., more rapidly when heated, forming diiodoacetylene, C_2I_2, which gradually decomposes, $2C_2I_2 \rightarrow C_2I_4+2C$, when kept for some time.

J. F. Durand obtained mercuric carbide by the action of calcium carbide, or of cupric acetylide on a soln. of mercuric nitrate. R. T. Plimpton and M. W. Travers found that freshly precipitated mercuric oxide, suspended in water, is slowly converted into mercuric carbide when treated with acetylene. Ammoniacal soln. of mercuric salts are only partially precipitated by acetylene, but if the mercuric salt be mixed with cupric sulphate or zinc chloride and ammonia, precipitation is complete. They recommend the following method of preparation:

> Freshly precipitated mercuric oxide is dissolved in conc. ammonia, and powdered ammonium carbonate added. The filtered soln. is moderately dil. and sat. with acetylene, preferably in a bottle fitted with a cork and glass stopcock and previously exhausted. The absorption takes place rapidly on shaking, fresh acetylene being admitted from time to time until precipitation is complete. The carbide separates as a heavy, white powder, which is washed by decantation, and finally on a filter until free from ammonia. It may be kept an indefinite time under water without changing, and on account of its highly explosive character is conveniently stored in this condition.

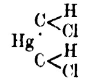
The composition of the white powder is $C_2Hg.\frac{1}{3}H_2O$; its sp. gr. is 5·3 at 16°/16°. When gradually heated, it begins to decompose at about 110° into mercury and carbon; when rapidly heated it decomposes with a violent explosion. When dropped on a heated cylinder explosion occurred at all temp. above 230°; it explodes when struck smartly, but it can be handled with safety. It is insoluble in water, alcohol, and ether. A soln. of ammonium acetate dissolves the fresh precipitate; and a soln. of potassium cyanide readily dissolves the dried compound. When allowed to stand in contact with an alcoholic soln. of mercuric chloride, or when boiled with an aq. soln. of that salt, a non-explosive white substance is formed. Chlorine and bromine cause the compound to explode; a soln. of chlorine in chloroform produces mercuric chloride and what is probably ethane hexachloride. Bromine water yields tetrabromoethylene. The first product of the action of a soln. of iodine in potassium iodide is di-iodoacetylene, and then tetraiodoethylene. Hydrochloric acid in the cold has very little action; when heated, mercuric chloride and acetylene are formed, and some is hydrolyzed to acetaldehyde. It is readily soluble in nitric acid; dil. sulphuric acid has but a slight action; while the conc. acid causes the carbide to explode. J. F. Durand found that mercuric carbide gives a precipitate of silver acetylide with a soln. of silver nitrate, but no precipitate with cupric chloride or nitrate.

According to R. T. Plimpton and M. W. Travers, if acetylene be passed into a soln. of mercuric acetate, in darkness, a white precipitate is formed which gradually becomes grey. In about 2 hrs. the reaction is complete, and the product after washing, and drying in vacuo over sulphuric acid, has the composition $2HgO.3HgC_2.2H_2O$, or $2Hg(OH)_2.3HgC_2$—**mercuric hydroxycarbide.** The precipitate is non-explosive, but it decomposes at ordinary temp. At 100°, water is given off and carbon separates. With iodine, it forms di-iodoacetylene, and ethylene tetraiodide. When heated with hydrochloric acid in the presence of mercuric salts, aldehyde is formed, but little or no acetylene appears. In 1881, M. Kutscheroff showed that hydrocarbons of the acetylene series unite with water in the presence of mercury salts, forming aldehydes and ketones, *e.g.* with acetylene $HC\vdots CH+H_2O=CH_3.CO.H$, and with allylene $CH_3.C\vdots CH+H_2O=CH_3.CO.CH_3$. The reaction is employed industrially for making acetaldehyde which is subsequently oxidized to acetic acid. The mechanism of the reaction has been studied by a number of investigators. E. H. Keiser assigned the formula $ClHg.C\vdots C.HgCl$ to the white precipitate which is formed when acetylene is passed into a soln. of mercuric chloride; K. A. Hofmann considered that the first product of the reaction is a substance with the formula:

$$Hg<\begin{matrix}CCl_2\\ \cdot\\ C(HgCl)_2\end{matrix}$$

and that this is immediately converted by hydrolysis and intermolecular change to trichloromercuriacetaldehyde, $(ClHg)_3.C.COH$. H. Biltz and O. Mumm agreed that the white precipitate is probably trichloromercuriacetaldehyde, but they doubted if K. A. Hofmann's intermediate compound is formed. A. Bergé and A. Reychler said that acetylene has no action on a soln. of mercuric chloride in dil. hydrochloric acid, and they recommended this soln. as a liquid for purifying acetylene; but P. Biginelli, J. S. S. Brame, and D. L. Chapman and W. J. Jenkins have shown that *chloromercurichloracetylene*, or *mercuricdichloracetylene*,

$$\begin{matrix}H\\Cl\end{matrix}\!>C:C<\begin{matrix}H\\HgCl\end{matrix}$$



$$Hg\begin{matrix}C<\begin{matrix}H\\Cl\end{matrix}\\ \cdot\\ C<\begin{matrix}H\\Cl\end{matrix}\end{matrix}$$

respectively are produced in dil. hydrochloric acid soln. D. L. Chapman and W. J. Jenkins prepared this compound in long, colourless, needle-shaped crystals by circulating acetylene through a sat. soln. of mercuric chloride in absolute alcohol through which a current of hydrogen chloride had been passed for 5 minutes. In 16 hrs. the soln. deposited the crystals with the empirical composition $C_2H_2.HgCl_2$. The crystals melt with decomposition near 113°; they are soluble in ether and benzene. The compound is not formed in an ethereal soln. of mercuric chloride in which hydrogen chloride is dissolved. M. Kutscheroff made **mercuric allylenide,** $(C_3H_3)_2Hg$. J. F. Durand made **mercurous carbide or acetylide** by the action of calcium carbide, mercuric acetylide or cupric acetylide, on a soln. of mercurous nitrate.

§ 17. The Carbides of Aluminium and the Rare Earth Metals

The *boron carbides* have been discussed as carbon borides in connection with boron (**5**. 32, 4). H. St. C. Deville[1] was unable to make carbon unite with aluminium; even when carbon tetrachloride is decomposed by aluminium, carbon is produced and the excess of aluminium remains unchanged. J. W. Mallet could detect no sign of the formation of a definite carbide when sodium carbonate is reduced by aluminium. The carbon taken up by the excess of metal was mostly, if not altogether, in a state of mere admixture, and produced no marked effect on the physical properties of the metal. He also observed no carbide formation when carbon monoxide is reduced by aluminium; alumina, and carbon with small yellow crystals, said to be aluminium nitride, were obtained—the nitrogen presumably was derived from the contamination of the carbon monoxide, etc., with air. T. S. Hunt, in 1885, exhibited yellow crystals of what he regarded as an alloy of aluminium and carbon which were found in an electric furnace, reducing a mixture of alumina and carbon. The work of H. Moissan, ten years later, showed that T. S. Hunt's crystals were most probably **aluminium carbide,** Al_4C_3. H. Moissan obtained crystals of this compound in the following way:

Small boats of carbon were filled with aluminium, put into a carbon tube through which a current of hydrogen was passed, and heated in the electric furnace. After cooling, the aluminium was of a grey colour, and on breaking it was seen to be strewn with brilliant fine-yellow crystals. To separate these out, the aluminium is dissolved by conc. hydrochloric acid, surrounding the vessel with ice to keep the temp. low. The residue is washed with ice-cold water, then with alcohol, and finally with ether. This whole operation must be conducted as quickly as possible, since the carbide is attacked by water.

P. W. Askenasy and co-workers used a similar process. According to J. N. Pring, the reaction proceeds from left to right: $6Al+3CO \rightleftharpoons Al_4C_3+Al_2O_3$, but at higher temp. the direction is reversed, and aluminium is re-formed. H. Moissan also made the carbide by heating the metal in a carbon crucible in an electric furnace—when the product is contaminated with nitride; by treating a mixture of china clay and carbon in the electric furnace; and by heating aluminium and calcium carbide in the electric arc. S. A. Tucker and H. R. Moody obtained aluminium carbide by reducing alumina with calcium carbide. O. Ohmann ignited a mixture of aluminium filings with a small proportion of a mixture of potassium chlorate and iron, in an atm. of carbon dioxide. The ignition is started by touching the chlorate and iron filings with a glowing wire, and allowing a stream of carbon dioxide to play on the aluminium powder. The product, Al_4C_3, was used for the preparation of methane. L. Franck, and C. Matignon, made aluminium carbide by heating aluminium and lampblack to a high temp. M. Barnett and L. Burgess heated, in the electric arc-furnace, an intimate mixture of alumina and carbon. F. E. Weston and H. R. Ellis ignited mixtures of powdered aluminium with wood charcoal, sugar charcoal, and graphite, by a fuse of magnesium and barium peroxide. The product contained aluminium nitride, carbide, and oxide, and the free elements. Methane was the only gas produced by the action of water, and hence it was inferred that the only carbide formed was C_3Al_4. It was not easy to initiate the combination in vacuo; and it was assumed that the first action is the oxidation of the carbon to monoxide and dioxide, the heat given out starts the oxidation of the aluminium, and, finally, that the latter reaction raises the temp. sufficiently to bring about combination of the aluminium with carbon and nitrogen. Some mixtures heated to dull redness in a closed crucible reacted vigorously on exposure to air. At 550°, E. Briner and R. Senglet observed no reaction between carbon and aluminium, but at 750° small amounts of carbide were formed. J. N. Pring found that the reaction between carbon and aluminium begins at 650°, and proceeds rapidly at 1400°. C. Matignon made aluminium carbide by heating aluminium in carbon tetrachloride vap. E. Dufau, by heating in the electric furnace, calcium aluminate with carbon—calcium carbide is formed at the same time; A. H. Cowles, by the reduction of sodium aluminate with carbon; L. M. Bullier, by heating sodium chloroaluminate with calcium carbide; and H. Hilbert and A. Frank, by heating aluminium phosphate and carbon: $4AlPO_4+19C=Al_4C_3+4P+16CO$—the phosphorus distils off. L. Franck represented the reaction at 1200°-1300° with carbon monoxide by $2Al+3CO_2=2AlO_3+3C$; and with carbon dioxide by $4Al+3CO_2=2Al_2O_3+3C$. At lower temp., A. Guntz and A. Masson obtained $6Al+3CO=Al_4C_3+Al_2O_3$; and likewise also with carbon dioxide. P. W. Askenasy and A. Lebedeff found that aluminium and aluminium carbide are formed when alumina and wood charcoal are heated side by side in the electric furnace. They assumed that the carbide is first formed: $2Al_2O_3+9C=6CO+Al_4C_3$, and that at a higher temp., say 2100°, the carbide dissociates or reacts with alumina, forming aluminium which remains dissolved in the carbide, otherwise it would boil away; on cooling, the aluminium separates from the soln. M. Barnett and L. Burgess have described a furnace for the production of the carbide. K. Nischk made some observations on the formation of aluminium carbide.

According to H. Moissan, aluminium carbide forms transparent, yellow crystals sometimes 6 mm. long, and in the form of regular hexagons. According to M. L. Huggins, the rhombohedral crystals have a lattice in which each aluminium atom is surrounded by three carbon atoms, and each carbon atom by four aluminium atoms all at the corners of a tetrahedron; and the axial ratio is estimated to be $a:c=1:1{\cdot}225$. The sp. gr. is 2·36. The carbide is stable up to 1400°, but is decomposed at the highest temp. of the electric arc. P. W. Askenasy and co-workers believe that the dissociation of the carbide $Al_4C_3=4Al+3C$ proceeds at a much lower temp. than H. Moissan supposed. P. W. Askenasy and A. Lebedeff say that aluminium carbide is not changed by heating in vacuo between 400° and 1400°. O. Ruff found that aluminium carbide sublimes at temp. up to 2200° without melting, and with some decomposition which is independent of temp. The vap. press. was measured up to 2300°; and at 2200°, aluminium carbide is in equilibrium with graphite and aluminium sat. with graphite and vap. under a press. of 400 mm. E. Briner and R. Senglet said that the reaction $Al_4C_3\rightleftharpoons4Al+3C$ is reversible; dissociation begins below 540°, and, as indicated above, combination begins between 550° and 750°. M. Berthelot gave for the heat of formation: $4Al+3C_{diamond}=Al_4C_3+244{\cdot}9$ Cals. less about 26 Cals. H. Moissan found that the carbide is attacked superficially by oxygen at a dull red heat. M. Berthelot gave for the heat of oxidation $Al_4C_3+6O_2=3CO_2+2Al_2O_3+834$ Cals. H. Moissan noted that when the carbide remains in contact with water at ordinary temp., decomposition takes place very slowly, and methane and aluminium hydroxide are formed. M. Berthelot gave for the heat of decomposition $Al_4C_3+12H_2O=3CH_4+4Al(OH)_3+183{\cdot}8$ Cals. plus about 26 Cals.; the change is accelerated by heat, but is not influenced by light. According to H. Moissan, chlorine attacks it at a dull red heat, with incandescence, aluminium chloride volatilizing, and a residue of amorphous carbon, without any trace of graphite, being left; bromine has no action at the ordinary temp., but attacks the carbide, with incandescence, at about 700°; iodine seems to have no action, even at a bright red heat. At a dull red heat, sulphur attacks the carbide readily, with great development of heat, and formation of aluminium sulphide and traces of carbon bisulphide, although the greater part of the carbon remains in the form of thin lamellæ. Nitrogen and phosphorus have no action on the carbide at a dull red heat, but certain oxidizing agents attack it readily. When slightly heated with dry potassium permanganate, it is oxidized with vivid incandescence; potassium dichromate and chromic anhydride oxidize it slowly at dull redness. The carbide reduces lead peroxide and the red oxide with incandescence, but it is not attacked by potassium chlorate or nitrate. A soln. of an alkali dichromate, acidified with sulphuric acid, attacks it slowly in the cold, or when boiled; fuming nitric acid is without action, even on heating, but on the addition of water the carbide is rapidly attacked; conc. hydrochloric acid attacks it very slowly, but the dil. acid dissolves it in a few hours; boiling conc. sulphuric acid is reduced, with formation of sulphur dioxide, and the dil. acid reacts at about 100°. Fused potassium hydroxide attacks the carbide with great energy at about 300°, but alkali carbonates, even at a bright red heat, produce only incomplete decomposition. J. N. Pring found that with calcium at a high temp., there is a reversible reaction, $2Al_4C_3+3Ca \rightleftharpoons 3CaC_2+8Al$. He added that, up to about 1400°, the carbide behaves as a strong reducing agent, but both aluminium and carbon are simultaneously oxidized, even when the carbide is in excess. Thus, under these conditions, no separation of aluminium or of carbon can be detected. For instance, aluminium carbide interacting with copper oxide produces metallic copper and carbon dioxide, together with small quantities of carbon monoxide. A similar behaviour is noticed when the reactions are brought about in the mass of a flux so as to facilitate the agglomeration of the reduced metal. At higher temp., however, selective reduction begins to be apparent, the reduction being more and more brought about by the carbon of the carbide, with a result that alloys of aluminium and the reduced metal are obtained, the per cent. of aluminium increasing the higher the temp. of reaction. In the case of copper, the per cent. of aluminium in the alloy seems to be limited by the volatilization of aluminium. Copper alloys were obtained containing up to 28 per cent. of aluminium, whereas the equation: $3CuO+Al_4C_3=4Al,3Cu+3CO$, demands an alloy containing 36 per cent. of aluminium. In the case of iron, an alloy was obtained containing 46·7 per cent. of aluminium, or, subtracting the amount of free carbon, 49·6 per cent. of aluminium. This corresponds to the equation: $Fe_2O_3+Al_4C_3=2Fe,4Al+3CO$, which demands an alloy containing 49·2 per cent. of aluminium. Any excess of oxide used in the reaction resulted in oxidation of the aluminium of the alloy. When the reaction between aluminium carbide and iron oxide was brought about in presence of a bath of molten iron at a high temp., alloys were also obtained in which more than 90 per cent. of the aluminium of the carbide used had been set free and taken up by the iron. Aluminium carbide reacts with copper at a temp. below the m.p. of platinum, and with iron just above this temp., to form an aluminium alloy with liberation of free carbon. At higher temp., the reaction takes place with violence and is complete.

W. Hampe[2] showed that the yellow crystals of what F. Wöhler and H. St. C. Deville in 1857 regarded as diamond boron is really **aluminium borocarbide**, $Al_3B_{48}C_2$, or $C_2B_{12}.3AlB_{12}$. The crystals are made by heating aluminium with boron trioxide in graphite crucibles to the highest temp. of a wind furnace, and allowing the fused mass to cool slowly. The reaction was examined by A. Joly, and he expressed the opinion that the alleged borocarbide is not a chemical individual, but gives no evidence either way. The crystals, said W. Hampe, belong to the tetragonal system; octahedra are most common, but long prisms are also formed. According to Q. Sella, the axial ratio of the ditetragonal bipyramidal crystals is $a : c=1 : 0·5762$; W. Sartorius von Waltershausen gave 1 : 0·5736. The colour of the strongly refracting crystals may be pale yellowish-brown, almost colourless, honey-yellow, hyacinth-red, dark brown, or almost black. The sp. gr., according to W. Hampe, is 2·615. The crystals are easily broken, and have a conchoidal fracture. They are harder than corundum, but softer than the diamond. Their properties closely resemble those of aluminium boride. The compound can be heated in oxygen without burning. The crystals become matt in hot conc. hydrochloric or sulphuric acid, and are slowly attacked; hot conc. nitric acid gradually dissolves them. A boiling conc. soln. of potassium hydroxide, or molten potassium nitrate, does not attack the crystals, but they are attacked by fused potassium hydroxide or lead chromate. They are slowly oxidized by potassium pyrosulphate at a red heat. They are readily alloyed by fusion with platinum.

Early in the last century, J. G. Children,[3] 1815, made an electric arc between the surfaces of cerium oxide and carbon, and obtained a product which gave an unpleasant odour when treated with water, and which later work has shown to have been impure **cerium carbide,** CeC_2. G. Mosander claimed to have made cerium carbides by calcining cerous oxalate or tartrate at a high temp., but some of his statements of the properties of the products do not agree with those now known to be characteristic of cerium carbide. H. Moissan prepared cerium carbide by heating an intimate mixture of sugar charcoal (48 grms.) with ceric oxide (192 grms.) in a carbon-tube electric furnace. The oxide fuses, and ebullition commences owing to the evolution of carbon monoxide: $CeO_2+4C=CeC_2+2CO$. In a few minutes, when the mass is in a state of quiet fusion, the reaction is complete. F. Fichter and C. Schölly used a similar method. J. Sterba supposed that *cerium oxycarbide,* $CeC_2.2CeO_2$, is formed by the reduction of ceric oxide with insufficient carbon for complete reduction, but A. Damiens denied this. He believed that the reduction occurs in stages: $2CeO_2+C=Ce_2O_3+CO$; and $Ce_2O_3+9C=2CeC_3+3CO$; and $CeC_3=CeC_2+C$. The red crystals of the intermediate carbide, CeC_3, can be isolated. P. R. Bassett discussed the formation of cerium carbide in the high intensity arc using a positive electrode of carbon with a core of cerium fluoride. W. Muthmann and co-workers prepared cerium carbide by the electrolysis of ceric oxide in the presence of carbon. O. Petterson, and H. Moissan prepared **lanthanum carbide,** LaC_2, by a method similar to that employed for cerium carbide; and H. Moissan likewise made **neodymium carbide,** NdC_2; **praseodymium carbide,** PrC_2; and **samarium carbide,** SaC_2. O. Petterson, and H. Moissan and A. Étard made **yttrium carbide,** YC_2; and O. Petterson, **ytterbium carbide,** YbC_2; and **holmium carbide,** HoC_2, in a similar way.

It will be observed that the rare earth carbides appear to be of the same type as calcium carbide, CaC_2, and that they are not analogous to aluminium carbide, Al_4C_3. Cerium carbide appears as a homogeneous mass with a crystalline fracture, and it readily breaks up in the presence of air. When the fragments are examined under the microscope, some appear as well-marked hexagons of a reddish-yellow colour; lanthanum carbide is rather lighter in colour than cerium carbide. O. Petterson gave 4·71 for the sp. gr. of lanthanum carbide; H. Moissan's values at 20°, are

	LaC_2	CeC_2	PrC_2	NdC_2	SaC_2	YC_2
Sp. gr. .	5·02	5·23	5·10	5·15	5·86	4·13

W. R. Mott gave 4600° for the b.p. of yttrium carbide. At a red heat, **hydrogen** has no appreciable action on neodymium and praseodymium carbides; and at 1000°, no action on samarium carbide; **oxygen** readily unites with yttrium carbide; and at a red heat lanthanum and cerium carbides become incandescent, while praseodymium, neodymium, and samarium carbides become incandescent at 400°. The action of **water** on the rare earth carbides is particularly interesting. The principal gas is acetylene. H. Moissan's analyses are summarized in Table XVII. Both acetylene and methane are accompanied by small amounts of their homologues. A. Damiens assumes that the primary reaction is $MC_2+3H_2O=M(OH)_3+H_2+C_2H_2$, and part of the acetylene is then hydrogenated to form ethylene and ethane. He found that with cerium, lanthanum, neodymium, praseodymium, and samarium

TABLE XVII.—COMPOSITION OF GASES EVOLVED BY THE ACTION OF WATER ON THE RARE EARTH CARBIDES.

carbides, the gas evolved in every case consisted of a mixture of hydrogen, sat. hydrocarbons, ethylenic and acetylenic hydrocarbons. The proportion of hydrogen was, in all cases, high. Unlike H. Moissan, he said that in no case was any methane found, the sat. hydrocarbons consisting of ethane, propane, and isobutane. The ethylenic hydrocarbons consisted of ethylene and its homologues. The different constituents of the mixture were invariably present, but their relative proportions varied according to the velocity of the reaction, which was dependent on the physical state of the carbide. The metallic hydroxides produced were always those of the sesquioxides. O. Petterson assumed that the constitution is of the mixed type, so that

$$\begin{matrix}C-M=C\\ \vdots \\ C-M=C\end{matrix}+6H_2O=C_2H_2+C_2H_4+2M(OH)_3,$$

but there is little to support this hypothesis.

All these carbides are readily attacked by **fluorine** with incandescence—yttrium carbide in the cold, the others when warmed; **chlorine** attacks yttrium carbide below a dull red heat; lanthanum carbide at 250°, cerium carbide at 230°; neodymium and praseodymium carbides, above a red heat; and samarium carbide when heated—all with incandescence; **bromine** attacks yttrium carbide below a dull red heat; lanthanum carbide at 255°, cerium carbide above 230°; and praseodymium, neodymium, and samarium carbides at a dull red heat—all with incandescence; and **iodine** attacks yttrium, lanthanum, cerium, and samarium carbides below a dull red heat with incandescence, while praseodymium and neodymium carbides are attacked at a dull red heat without incandescence. Cerium carbide is attacked by **hydrogen chloride** at 650° with incandescence, and neodymium, praseodymium, and samarium carbides at a dull red heat with incandescence; **hydrogen iodide** attacks cerium carbide at a dull red heat with incandescence. Dil. **acids** easily attack all these carbides with the evolution of gases as in the case of water. The vap. of **sulphur** attacks yttrium and lanthanum carbides; with cerium carbide, the attack is accompanied with incandescence, with neodymium and praseodymium carbides the attack begins at 1000°, and with samarium carbide, above 400°. Yttrium and cerium carbides are attacked by **selenium** vap. at a dull red heat, and lanthanum carbide is attacked more vigorously than with sulphur. Cerium, praseodymium, neodymium, and samarium carbides are attacked when heated with **hydrogen sulphide.** All these carbides are attacked by **sulphuric acid** in the cold, with the evolution of sulphur dioxide. Lanthanum carbide is attacked at 800° by **nitrogen**, forming a nitride; cerium carbide is not attacked at the softening temp. of glass, and neodymium and praseodymium carbides are attacked superficially at 1200°. F. Fichter and C. Schölly found that at 1250°, cerium carbide forms the nitride, not the cyanide or cyanamide. According to H. Moissan, at a red heat lanthanum carbide is attacked with incandescence by **ammonia**; cerium carbide is not attacked at 600°; while praseodymium and neodymium carbides at a red heat form nitrides; and at 1250°, according to F. Fichter and C. Schölly, cerium carbide forms nitride, but rather more slowly than in an atm. of nitrogen. H. Moissan found that fuming **nitric acid** does not act on lanthanum, cerium, praseodymium, and neodymium carbides. Lanthanum carbide is not attacked by **phosphorus** at 700°–800°, nor is cerium carbide at the softening temp. of glass. Fused **potassium hydroxide** decomposes the carbides with the evolution of hydrogen; fused **potassium carbonate** also attacks the carbides. Fused **potassium permanganate, chlorate, or nitrate** attacks the carbides easily with incandescence.

§ 18. The Carbides of the Silicon and Tin Families of Elements

According to J. J. Berzelius,[1] in the preparation of silicon by the reduction of potassium fluosilicate by potassium, a mixture of silicon and *silicon carbide*, or *carbon silicide*, is obtained. The amorphous substance suffered no loss of weight when ignited in a closed vessel, but in air, the carbon burns to a carbon dioxide, and the silicon to silica—in proportions showing that the composition must have been C_8Si_3. In an attempt to synthesize diamonds, C. M. Despretz also obtained what were most probably crystals of silicon carbide when he passed an electric current through a carbon rod embedded in sand. The crystals were hard enough to cut the ruby, and scratch soft diamonds. R. S. Mardsen also in his work on the solubility of silica in molten silver obtained pale yellow hexagonal lamellæ which he mistook for graphite, but which were, in all probability, silicon carbide. A. H. and E. H. Cowles obtained hexagonal crystals of a substance which C. F. Mabery believed to be silicon suboxide, but which proved later to be crystalline silicon carbide. L. Franck found a few crystals of silicon carbide of adamantine hardness in commercial calcium carbide.

According to A. Colson, when silicon is heated to bright redness in a stream of ethylene, or of hydrogen sat. with benzene vap. at 50°–60°, a mixture of silicon oxycarbides—*vide infra*—with dark green **silicon dicarbide**, SiC_2, is formed. This substance is not attacked at a red heat by oxygen or chlorine; it is insoluble in acids; and is decomposed by fusion with potassium hydroxide, or with a mixture of lead chromate and lead oxide. E. Kohn-Abrest obtained what he regarded as *silicon pentatritacarbide*, C_5Si_3, by heating aluminium silicide in a graphite vessel.

P. Schützenberger obtained amorphous **silicon monocarbide,** SiC, by heating to bright redness for a few hours an intimate mixture of silicon and silica in a graphite crucible packed with lampblack inside a larger crucible. The contents were powdered, and boiled with moderately conc. hydrofluoric acid in order to dissolve the silica and the small quantity of silicon nitride which is formed. No free silicon is present. The insoluble residue containing nearly one-half of the silicon employed, is extracted with boiling conc. hydrofluoric acid, and the green powder which remains is silicon monocarbide. This substance is said to be formed by the action of carbon monoxide on the silicon. On treating it with chlorine at a low red heat, silicon chloride is evolved, leaving carbon and part of the carbide unchanged. After burning the carbon in a current of oxygen, a portion of the residue can be acted on by chlorine at a bright red heat, but the residue from this second treatment is not further attacked by chlorine.

H. Moissan said that carbon can dissolve in molten silicon, and the carbide can be detached from the crystals by boiling in a mixture of nitric and hydrofluoric acids, and further purified by treatment with a mixture of nitric acid and potassium chlorate. The crystals may be yellow and quite transparent, or they may have a sapphire-blue colour. In the presence of a solvent, silicon and carbon unite between 1200°–1400°. H. Moissan obtained almost colourless, prismatic needles of carbon silicide by allowing the vap. of carbon and silicon to react with one another. If iron silicide, mixed with an excess of carbon, be heated in an electric furnace, a regulus containing crystals of silicon carbide is formed. A mixture of iron, silicon, and carbon, or of iron, silica, and carbon, can be similarly treated. The regulus is first digested with aqua regia to remove the iron; then heated for several hours with a mixture of nitric and hydrofluoric acids, and then treated eight to ten times with a mixture of nitric acid and potassium chlorate. H. Moissan also made the carbide by melting a mixture of calcium carbide and silica, and by reducing silica with carbon in an electric furnace. In 1890, E. G. Acheson tried to crystallize carbon by dissolving that element in aluminium silicate in an electric arc. The blue crystals obtained were thought to be a compound of carbon and aluminium. The crystalline compound was called **carborundum.** Subsequent analyses showed the product to be silicon carbide, SiC, and it was then made by reducing silica by carbon in the electric furnace. According to A. Lampen, some of the non-crystalline carbide is found in the parts of the carborundum furnace which have not attained a temp. of 1950°. H. Moissan found crystals of silicon carbide in the meteorite from Cañon Diablo, and G. F. Kunz proposed for the mineral name *moissanite.* H. Hanemann observed no carbide formation by heating a mixture of iron, silica, and carbon to 1500°; about 1·37 per cent. of silicon was formed. O. Mühlhäuser purified carborundum by passing oxygen over it for an hour while at a dull red heat; boiling the product with potash-lye; and then heating it with a mixture of hydrofluoric and conc. sulphuric acids. L. Weiss and T. Engelhardt, and W. G. Mixter discussed the purification of carborundum.

G. Tammann found that the reaction between silicon and carbon, obtained by the action of mercury on carbon tetrachloride at 450°, started at 1220°; with soot from turpentine, at 1340°; with sugar charcoal, at 1410°; and with graphite, at 1390°. K. Nischk studied the formation of silicon carbide. According to S. A. Tucker and A. Lampen, the temp. of formation of crystalline carborundum from silica and carbon is 1950°; H. W. Gillet gave 1820° ± 20°; and L. E. Saunders, 1840° ± 30°. For amorphous carborundum, S. A. Tucker and A. Lampen gave 1600°; H. W. Gillet, 1540° ± 30°; and L. E. Saunders, 1600° ± 50°. For the temp. of decomposition of crystalline carborundum, S. A. Tucker and A. Lampen gave 2220°; H. W. Gillet, 2220° ± 20°; and L. E. Saunders, 2240° ± 5°. The range of temp. in the carborundum furnace is therefore comparatively small. J. N. Pring found that at a reduced press., 0·01 mm., carborundum is formed at 1250°; and H. C. Greenwood stated that in vacuo silica is reduced by carbon, and carborundum is formed at 1460°. R. S. Hutton and J. E. Petavel showed that at 100 atm. press., the formation of crystalline carborundum is hindered, and the formation of amorphous carborundum negligible. According to W. G. Mixter, the heat of formation of crystalline carborundum, $Si_{cryst}+C_{amorphous}=SiC+2·0$ Cals. per 40·4 grms. of carborundum, or 50 cals. per grm. of SiC; and the heat of combustion to silica and carbon dioxide is $SiC+2O_2=SiO_2+CO_2+283·8$ Cals. per 40·4 grms. of carborundum, or 7025 cals. per grm.; H. N. Potter obtained 7595 cals. per grm. W. G. Mixter said that his value falls within the limits of experimental error, so that the heat of formation may be positive or negative.

The first carborundum furnace consisted of an iron bowl lined with carbon, and fitted with a carbon rod. A mixture of carbon and clay was introduced into the bowl and about the rod. A current sufficient to fuse the mixture, or to bring it to a very high temp., was passed through the furnace with the iron bowl and carbon rod as electrodes. When the current was cut off and the furnace cooled, a few bright blue crystals of carborundum were found surrounding the carbon rod. The clay was afterwards replaced by glass-sand. A little salt was added to facilitate the running of the furnaces; and the mixture was made porous by the addition of sawdust so as to facilitate the escape of gas. The furnaces were then increased in size. The manufacture has been described by E. G. Acheson, F. A. J. Fitzgerald, C. A. Kohn, O. Mühlhäuser, J. A. Matthews, A. Dorsemagen, R. Volkmann, K. P. Gregorovitch, etc.

The furnaces are built of brick, and have the form of an oblong box, internally 16 ft. × 5 ft. × 5 ft. The ends have a thickness of about 2 ft. The terminals are fitted at the centre of each end. They consist of 60 carbon rods, 30 ins. long and 3 ins. diameter. The outer ends of the carbons are enclosed in a square iron frame to which is screwed a stout plate bored with sixty holes corresponding with the ends of the carbons. Through each hole is passed a short piece of $\frac{3}{8}$th in. copper rod, and this fits tightly into a hole drilled in the carbon. All the free space between the inside of the plate, and the ends of the carbon, is packed tightly with graphite. Each plate has four projections to which the four cables conveying the current are bolted The ends of the furnace are permanent, the remainder

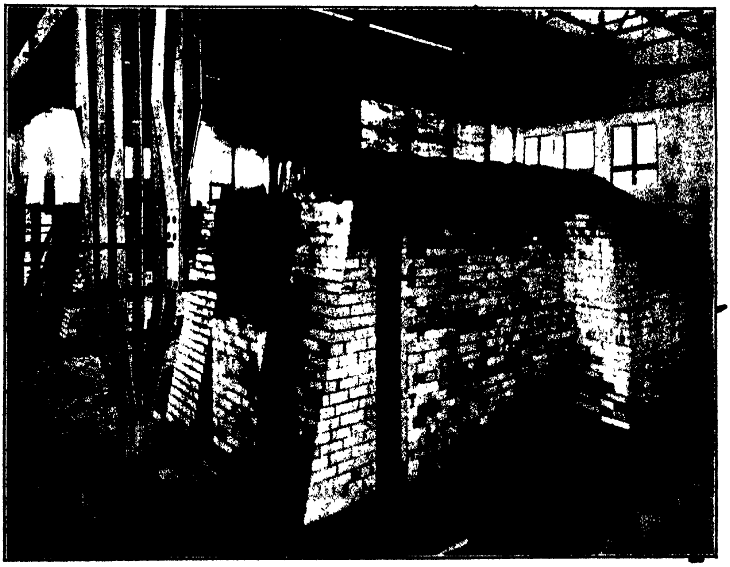

FIG. 23.—Carborundum Furnace ready for Operation.

is built each time the furnace is operated. The side walls are built about 4 ft. high. Pieces of iron plate are placed about 4 ins. from the inner ends of the terminals to keep the mixture from coming in contact with the terminals. The mixture of sand (53·5 per cent.), coke (40 per cent.), sawdust (5 per cent.), and salt (1·5 per cent.) is then thrown into the furnace until it is half full. A central longitudinal trench is then arranged with a radius of about 10½ ins. The bottom of the trench is a little above the level of the bottom row of carbons. The core of the furnace is introduced. The core is a cylinder of granulated coke, about 21 ins. diameter and 14 ft. long, and extending between the sheet iron plates at the ends. Finely ground coke is packed into the spaces between the ends and the pieces of sheet iron. The side walls are built up another foot; the pieces of sheet iron are removed; and more furnace mixture is added to make up a height of about 8 ft. Figs. 23 and 24 give an idea of the appearance of the furnace in Chippawa, Ontario, plant of the Norton Company of Worcester, Mass., where they manufacture carborundum under the name of *crystolon*. The resistance of the furnace diminishes rapidly, and in about an hour approximately 746 kilowatts or 1000 H.P. are being expended in heating the furnace. In about 24 hours, the current is cut off, and the furnace is allowed to cool for a few hours. The side walls are taken down, and the unchanged mixture raked from the top of the furnace until the outer crust of amorphous carborundum is exposed. Beneath the outer crust is another thin layer of light-green amorphous carborundum. Inside this, radiating from the core, is a 10 to 12-in. layer of carborundum crystals. The core has changed into a mass of graphitic carbon, for the high temp. of the furnace has volatilized the impurities of the coke. The carborundum is then crushed by levigation and sieved.

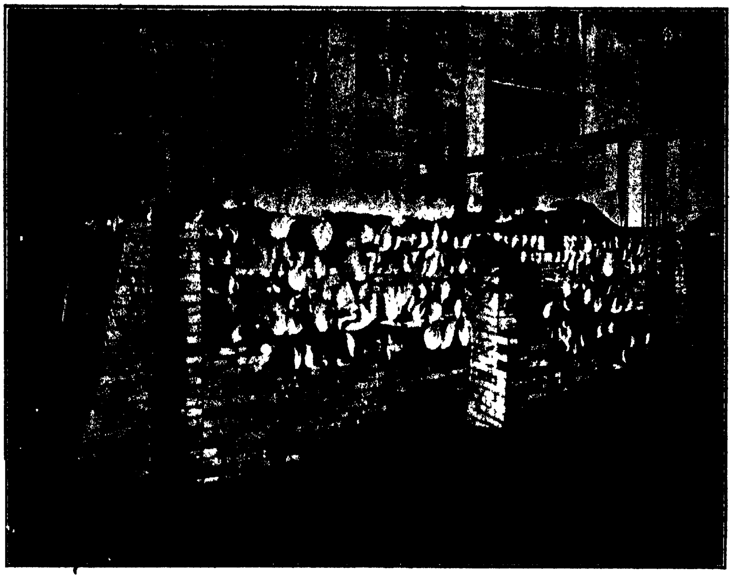

FIG. 24.—Carborundum Furnace in Operation.

The following are typical analyses of first, medium and low-grade carborundum when the theoretical values for SiC are 70·30 per cent. silicon, and 29·70 per cent. of carbon:

	Si (combined)	C (combined)	Fe	Al	Si (free)	Ca
First . .	60·60	29·40	0·09	0·55	0·13	0·09
Medium . .	67·70	28·60	0·65	1·40	—	—
Low . .	65·31	27·59	0·93	2·02	0·56	0·29

The so-called *carborundum fire-sand* is a layer of carborundum mixed with partly-reduced silica. Analyses range between the limits:

SiC	SiO_2	Al_2O_3	Fe_2O_3	C (free)	Ca
73·32–85·42	4·64–6·80	1·46–6·05	1·10–4·52	3·12–4·52	0·23

According to H. Moissan, carborundum free from traces of iron is without **colour**; the best commercial grades are pale green, while the less pure grades are black. H. E. Merwin said that the blue crystals are pleochroic, some with colours passing from light to dark blue, others from olive-green to greenish-blue. Some of the crystals have triangular markings and parallel striæ. There are often spiral markings of different form, maybe 30,000 to 50,000 lines per inch. The crystals of carborundum often exhibit a brilliant play of iridescent colours, which are attributed by W. R. Mott to a very thin film of transparent fused silica on the surface. The green crystals do not show the iridescence, for a black reflecting surface is needed to produce the effect. The iridescence is destroyed by hydrofluoric acid, and is restored by oxidation, or by etching with salt at a higher temp. Silicon carbide occurs both amorphous and crystalline; the crystalline variety first obtained by E. G. Acheson consisted of a mass of loosely aggregated **crystals.** F. J. Tone produced a dense mass of small, imperfectly developed crystals which had a steel-like appearance and fracture; and which was given the trade-name *silundum*. H. Moissan obtained well-defined crystals which appeared as regular hexagons. F. A. J. Fitzgerald said that sometimes in hollow places in the carborundum furnace, large hexagonal crystals may be found with a side measuring 0·5 in. B. W. Frazier said that carborundum crystals belong to the hemihedral division of the hexagonal system, and are characterized by the predominance of the basal pinacoid. Both direct and reversed rhombohedra may occur on the same crystals giving them the appearance of holohedral symmetry. The axial ratio of the ditrigonal pyramids was found by G. B. Negri to be $a : c = 1 : 1\cdot2265$. B. W. Frazier obtained a similar result. F. Rinne, C. L. Burdick and E. A. Owen, H. Espig, and R. N. Pease studied the **X-radiogram** of silicon carbide, and the latter found the diamond type of lattice with interatomic distances 1·92 A. H. Espig obtained evidence of an elementary parallelopiped with $a = 5\cdot65 \times 10^{-8}$ cm. and $c = 15\cdot3 \times 10^{-8}$ cm., and 24 molecules SiC per unit lattice. Some suggestions on the structure of the crystals were made by H. M. Dowsett in order to explain their physical properties. M. L. Huggins discussed the **electronic structure** of the silicon carbide mol. F. Becke found the **corrosion figures** corresponded with the ditrigonal pyramidal symmetry. O. Weigel also studied the corrosion figures with fused potassium carbonate and nitrate. The plane of **twinnings** is the unit rhombohedron. F. Rinne also made observations on the crystals. There is no distinct **cleavage.** The **fracture** of the crystals is subconchoidal. C. L. Burdick and E. A. Owen found the **X-radiogram** of carborundum to show that the silicon and carbon atoms are each arranged on face-centred rhombohedral lattices which are very nearly cubic, for $\alpha = 89^\circ\ 56'\ 10''$. The carborundum lattice is therefore very nearly that of the tetrahedral diamond lattice each being constituted of two interpenetrating face-centred lattices. The vol. of the elementary rhombohedra is $20\cdot70 \times 10^{-24}$ c.c. and the mol. wt., when the at. wt. of hydrogen is $1\cdot64 \times 10^{-24}$ grm., is $65\cdot5 \times 10^{-24}$ grm. The calculated density is therefore 3·11. The side of the elementary rhombohedron is 4·356, and the closest approach of the atoms is 1·88 A. F. Rinne has made observations on this subject. R. N. Pease calculated 1·94 A. for the atomic radii of the atoms in silicon carbide.

H. Moissan gave 3·2 for the **specific gravity** of silicon carbide crystals; F. A. J. Fitzgerald found the sp. gr. of carborundum ranged from 3·1716 to 3·214; and O. Mühlhäuser found the sp. gr. to be 3·22 at 15°; J. W. Richards, 3·125–3·200 at 20°; L. Franck, 3·10–3·30; and O. Weigel gave

	25·7°	100°	32·3°	113·9°
Sp. gr.	3·2104	3·2086	2·2021	3·2003

The difference, said F. A. J. Fitzgerald, is determined by the proportion of ferrous silicide present as an impurity. The **hardness** of carborundum lies between that of the ruby and that of the diamond or between 9 and 10 on Mohs' scale, perhaps nearer 10, added F. A. J. Fitzgerald, for, although carborundum is scratched by the diamond, carborundum will scratch many varieties of the latter. G. F. Kunz added that nothing definite is known about the difference in hardness between the units 9 and 10 on Mohs' scale, but there is probably as much difference between them as between the units 1 and 9. J. H. Pratt ranged the following scale of decreasing hardness: carborundum, Georgia corundum, alundum, Chester blue-corundum, Chester emery, and Canadian corundum. P. J. Holmquist measured the abrasive action of carborundum of different grain-size on quartz, topaz, magnetite, fluorite, and apatite. A. Hoenig discussed its use as an abrasive. According to T. W. Richards and co-workers, the **compressibility** of carborundum is $0·21 \times 10^{-6}$ kgrm. per sq. cm. between 100 and 500 atm. press., and is therefore but little greater than that of silicon which is $0·16 \times 10^{-6}$.

The coefficient of **thermal expansion** of carborundum between 15° and 100° is 0·00000658; between 700° and 800°, 0·00000438; between 800° and 900°, 0·00000298; and at 1000° ± 15°, 0·00000435. L. E. Muller and L. Baraduc-Muller gave 0·00000539 between 100° and 200°; W. C. Röntgen, 0·00000234 at 40°; while C. A. Boeck gave 0·00000474 between 100° and 900°, and for fused alumina 0·00000866 between 100° and 900°. A. Magnus found the coeff. of cubical expansion of carborundum between 0° and 25·027° to be $8·8 \times 10^{-6}$. According to O. Weigel, the true cubical and linear expansion coeff. parallel to the vertical axis are as follows:

	0°	100°	200°	300°	400°
Linear $\times 10^6$ . .	2·118	2·666	3·214	3·763	4·310
Cubical $\times 10^6$ . .	6·354	7·998	9·642	11·289	12 930

and he represented the length at $\theta°$ by $l_0(1+1·0_5 2118\theta+0·0_8 2741\theta^2)$. He also found for the change of the crystal angles

20 7°	402°	601·5°
30° 24′ 53″	30° 24′ 54′	30° 24′ 45″

H. N. Potter gave 0·1857 for the **specific heat** of crystalline carborundum. W. Nernst and F. Schwers determined the sp. ht. of carborundum below −176·5°, and A. S. Russell between −135° and 25°, and O. Weigel between 0° and 1000°. The latter gave:

	273°	473°	673°	763·7°	773°	873°	1073°	1273° K
Sp. ht. . .	0·140	0·233	0·277	0·282	0·282	0·275	0·225	0·129

Selecting values for the mol. ht. over the whole range of temp. on the absolute scale, we obtain:

	52°	63·1°	90·5°	138°	473°	673°	773°	873°	1073°	1273°
Mol. ht. .	0·099	0·197	1·013	2·06	9·39	11·16	11·36	11·08	9·07	5·20

Half the mol. ht. of carborundum, and the at. ht. of carbon and silicon are plotted with temp. in Fig. 25. There is thus a maximum value in the sp. ht. of carborundum in the vicinity of 447° or 720° K. A. Magnus found that the additive rule holds fairly well at ordinary temp., and he represented the thermal capacity between 0° and $\theta°$ by $Q = 0·155240\theta + 1·9807 \times 10^{-4}\theta^2 - 1·0666 \times 10^{-7}\theta^3 - 4·264 \times 10^{-11}\theta^4 + 5·551 \times 10^{-14}\theta^5$. O. Weigel also calculated the free energy of carborundum at different temp. and estimated it to be 2000 cals. at 0° K., falling to about 700 cals. at 700° K. O. Weigel estimated the **melting point** to be near 2227°, or 2500° K., and hence, from J. W. Richard's formula: **heat of fusion**$=1·06RT_s$, or 5250 cals., or from E. Grüneison's formula heat of fusion$=0·96RT_s$, or 4500 cals. E. Tiede and

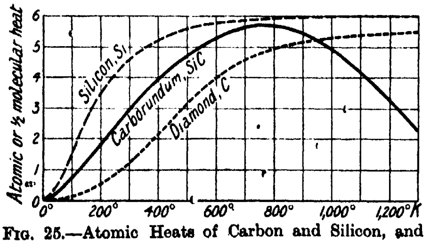

FIG. 25.—Atomic Heats of Carbon and Silicon, and Half the Molecular Heat of Carborundum at Different Temperatures.

E. Birnbrauer gave 1650° for the temp. at which vapour is given off. R. S. Hutton and J. R. Beard found the **thermal conductivity** of white Calais sand between 20° and 100° was 0·00060; that of fine carborundum, 0·00050; and that of coarse carborundum 0·00051 cal. per cm. cube per °C. per sec.; and O. S. Beecher reported the thermal conductivity of carborundum bricks to be 0·0150 cal. F. A. J. Fitzgerald found that carborundum at 435° transmits 79 per cent. more heat than fused alumina, and 117 per cent. more than silica; while S. Wologdine gave for the conductivity at 1000°, in gram cals. per cm. cube per °C. per sec., of bricks made from

	Carborundum	Magnesia	Chrome	Clay	Silica
Conductivity . .	0·0231	0·0071	0·0057	0·0042	0·0020

According to F. Becke, the **double refraction** of carborundum is positive, and the **index of refraction** for Na-light is $\omega=2{\cdot}786$, and $\epsilon=2{\cdot}832$; L. E. Jewell gave $\omega=2{\cdot}72$ for the red and 3·4 for the violet, and for $\epsilon=2{\cdot}80$ and 3·80 respectively. H. E. Merwin found the indices of refraction for light of wave-length λ to be

λ . .	755	726	671	535	468	422	416$\mu\mu$
ω . .	2·616	2·622	2·633	2·675	2·713	2·753	2·757
ϵ . .	2·654	2·660	2·673	2·721	2·763	2·808	2·812

O. Weigel represented his observations on ω by $0{\cdot}83921+5{\cdot}70990\lambda(\lambda^2-161^2)^{-1}$, with good results. He also measured values of ϵ and ω, and found the effect of temp. on ω to be for $\lambda=455{\cdot}4\mu\mu$, $2{\cdot}71255(1+0{\cdot}0_4232108\theta+0{\cdot}0_711237\theta^2)$; for $\lambda=493{\cdot}4\mu\mu$, $2{\cdot}68751(1+0{\cdot}0_4215999\theta+0{\cdot}0_710073\theta^2)$; for $\lambda=553{\cdot}6\mu\mu$, $2{\cdot}65921(1+0{\cdot}0_4206899\theta+0{\cdot}0_88063\theta^2)$; for $\lambda=614{\cdot}2\mu\mu$, $2{\cdot}63915(1+0{\cdot}0_4200600\theta+0{\cdot}0_87831\theta^2)$; for $\lambda=649{\cdot}7\mu\mu$, $2{\cdot}63013(1+0{\cdot}0_42003\theta+0{\cdot}0_87241\theta^2)$. O. Weigel discussed the **vibration-frequency** of carborundum, and he showed that when a clear, colourless carborundum crystal is heated to redness, it acquires a deep greenish-yellow colour, and again becomes colourless when the crystal has cooled down to its former temp. This behaviour indicates that considerable changes occur in the absorption spectrum as the temp. changes. The following is a selection from O. Weigel's measurements of the **transparency** and the **extinction coefficients** for different wave-lengths at different temp.:

79°	Wave length, λ .	417·3	429·0	446·4	504·4	620·5	701·8$\mu\mu$
	Transparency .	0·376	0·509	0·595	0·621	0·575	0·430
	Extinction . .	0·177	0·0685	0·0137	0·0029	0·0363	0·144
251°	Wave length, λ .	423·2	438·8	446·4	504·4	620·5	713·4$\mu\mu$
	Transparency .	0·314	0·466	0·578	0·595	0·583	0·433
	Extinction . .	0·242	0·100	0·0234	0·018	0·031	0·141
415·3°	Wave-length, λ .	429·0	440·5	452·2	504·4	620·5	713·4$\mu\mu$

	Transparency .	0·0734	0·196	0·356	0·501	0·587	0·446
	Extinction . .	0·763	0·410	0·195	0·072	0·0198	0·124
984·8°	Wave-length .	487·0	492·8	498·6	504·4	510·2	516$\mu\mu$
	Transparency .	0·127	0·170	0·263	0·310	0·387	0·452
	Extinction . .	0·562	0·461	0·304	0·234	0·165	0·100

W. W. Coblentz measured the ultra-red reflection spectrum of carborundum, and said that it is the most remarkable one yet discovered. It remains fairly constant up to 9μ, and then drops abruptly to a low value at about 10μ, and then attains an abnormally high value at beyond 13μ, as shown in Fig. 26. C. Schaefer and M. Thomas studied the ultra-red absorption spectrum of silicon carbide.

At ordinary temp., the **electrical conductivity** of carborundum is very low, being much less than that of carbon: the conductivity increases rapidly as the temp. rises, for the temp. coeff. of the **electrical resistance** is large and negative. G. W. Pierce and R. D. Evans showed that contact difficulties prevent accurate determinations of the conductivity of the crystalline materials. The Carborundum Co. give for the sp. resistance, *R*, of the dense crystalline material in ohms per cm. cube:

	25°	100°	200°	400°	600°	800°	1000°	1200°	1400°
R . .	50	46·4	36·9	26·6	14·6	7·8	3·7	1·3	0·65

The values of O. Weigel are plotted in Fig. 27. The effects of alternating and direct currents at 14·7° to 15·5° and different voltages on the resistance in ohms are as follow:

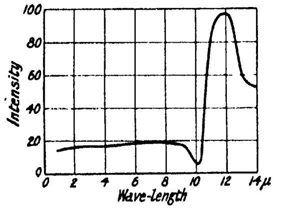

FIG. 26.—Ultra-red Absorption Spectrum of Carborundum.

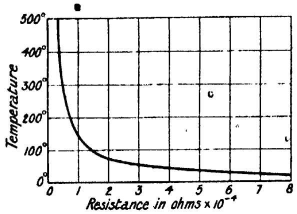

FIG. 27.—The Effect of Temperature on the Electrical Resistance of Carborundum.

Voltage .	0·036	0·384	0·840	1·690	5·58	8·10	12·2	31·3
R Direct .	14390	13529	13148	10243	9011	7513	6420	5873
R Alternating	8018	8116	8149	8116	8051	8018	7921	7921

The resistivity varies with the porosity and chemical composition, when the material is bonded into bricks with clay, the sp. resistance is much higher, being

	25°	200°	410°	600°	700°	800°	1100	1200°
$R \times 10^4$ . .	28·4	27·0	7·0	25·0	2·8	2·4	0·15	0·04

F. A. J. Fitzgerald has made analogous observations. G. W. Pierce and R. D. Evans found the **electrostatic capacity** of carborundum to be 0·006–0·022 microfarads; the existence of capacity was attributed to the existence of numerous alternating conducting and insulating strata within the crystal. The action of the carborundum as a detector for electric waves and as a rectifier for electric currents is independent of its action as a condenser; but it will detect electric waves or rectify only, provided contact is made to one or more of the conducting strata. It may detect electric waves with an adjustment that shows no capacity by the present method of measuring capacity. On the other hand, with every adjustment at which there was capacity, there was also a rectification and a detection of the electric waves. H. M. Dowsett measured the rectification effect of carborundum, and he found that the crystals act as normal conductors with a few hundred ohms' resistance for currents flowing parallel to the crystal faces, whereas at right angles to these directions, an e.m.f. has to be applied to force an elastic opening into the path or paths parallel to that crystal face; this opening has a high resistance—of the order 20,000–250,000 ohms—until its elastic limit is exceeded. The crystals of green carborundum find it easier to receive than to give up electrons, and conversely with the crystals of black carborundum. According to H. S. Roberts and L. H. Adams, in wireless telegraphy, the inducted alternating currents are of such high frequency that if the diaphragm of a telephone could be made to vibrate in unison, the sound would be so shrill as to be beyond the range of the human ear. To make them audible, the waves must either be broken up into like groups or trains which follow one another at an audible frequency as in wireless telegraphy, or modulated so that their amplitude varies in time with an audible vibration as in wireless telephony. In either case they remain high-frequency electromagnetic waves. In the receiving apparatus the high-frequency e.m.f. is impressed on a circuit whose function is to distort the alternating current wave so that more current flows in one direction than another. The distorted wave then behaves as if it were the sum of a high-frequency alternating current and a direct current, of which only the latter is capable of actuating the telephone receiver. The ideal detector would allow current to pass in one direction only, and it is therefore an electrical rectifier. The *crystal detector* consists of a small area of contact between two suitable conductors at least one of which is a crystal; it operates in virtue of the fact that the current flowing through such a contact is not proportional to the e.m.f. driving it. The effect with carborundum is illustrated by Fig. 28, where the current in millionths of an ampère is plotted against the potential difference in volts between the fusible metal in which the crystal carborundum was mounted and the spring contact against one of the corners of the crystal. The subject has also been discussed by H. M. Dowsett, and F. Luchsinger. Carbon silicide is not **magnetic.** The magnetic properties of commercial carborundum depend on the ferruginous impurities in the crystals. Medium grades of carborundum show from 5 to 10 per cent. of grains are susceptible to a magnet.

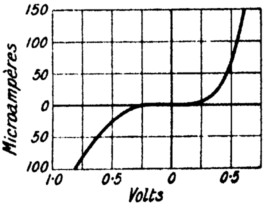

FIG. 28.—Current-Voltage Curve of Carborundum.

Carborundum is highly resistant to chemical action. There is little or no action when carborundum is heated in **hydrogen.** Similar results were obtained with **nitrogen** or **carbon monoxide.** According to H. Moissan, and L. E. Muller and L. H. Baraduc, carborundum is not altered at 1000°, in **oxygen,** but between 1000° and 1350°, it is slightly oxidized in **air**; between 1350° and 1500°, the silica which is formed is fused; between 1500° and 1600°, oxidation is much retarded by the fused silica coating; and at 1750°, oxidation proceeds quickly. The vap. of **water** and **carbon dioxide** become active only at their dissociation temp., 1775°–1800°. At 600°, carborundum is but superficially attacked by **chlorine** in 1½ hrs., but at 1200°, decomposition is complete. At 900°, the reaction furnishes silicon tetrachloride and carbon; at 1000° to 1100°, both carbon and silicon tetrachlorides are formed. Boiling **hydrochloric acid, hydrofluoric acid,** or a mixture of monohydrated **nitric acid** and hydrofluoric acid, which attacks silicon very readily, is without action on carborundum. The vap. of **sulphur** does not attack carborundum at 1000°, and boiling **sulphuric acid** has no action. Carborundum is attacked energetically by **silica** at 2000°–2500°, forming silicon. M. Wunder and B. Jeanneret found that when carborundum is heated for 3 hrs. with **phosphoric acid** of sp. gr. 1·75, at 230°, a syrupy liquid and a gelatinous precipitate are formed; any carbon present remains undissolved. O. Mühlhäuser, and B. Neumann found that it forms a metal silicide with **copper oxide** at 800°; with **iron or nickel oxide** at 1300°; with **manganese oxide** at 1360°; and with **chromic oxide** at 1370°. Carborundum does not attack **platinum** over an ordinary Bunsen burner, but the metal is attacked if it be heated over a blast-flame. Fused **potassium hydroxide** gradually disintegrates and slowly dissolves carborundum, forming potassium carbonate and silicate; carborundum is also decomposed by fused **potassium carbonate.** O. Weigel gave for the action of sodium carbonate: $CSi+3Na_2CO_3=Na_2SiO_3+2Na_2O+4CO$. Carborundum is decomposed by fused **alkali sulphates,** fused **borax,** or fused **cryolite**; and it is attacked by **calcium oxide** or **magnesium oxide** at 1000°. Fused **potassium chlorate** and fused **potassium nitrate** have no action. Carborundum is attacked by **sodium silicate** at 1300°, and the attack is specially active in the presence of oxidizing gases or oxidizing salts. Carborundum is slowly but completely oxidized by fused **lead chromate**; and when heated with a mixture of **potassium dichromate** and lead chromate, the reaction is explosive.

According to P. Schützenberger and A. Colson, when crystallized silicon is heated almost to whiteness in a porcelain tube in an atm. of carbon dioxide, the latter is absorbed, with formation of a greenish-white mass, which may be freed from silicon by washing with hot, moderately conc. potash. The residue is then treated with hydrofluoric acid, which dissolves out silica, leaving a greenish powder, insoluble in boiling soln. of the alkalies, and not attacked by any acids. It has a composition corresponding with **silicon oxycarbide**, $(SiCO)_n$, and is formed in accordance with the equation $3Si+2CO_2=SiO_2+2SiCO$. When heated in oxygen, it yields only a trace of carbon dioxide, but is oxidized with incandescence when heated with litharge or a mixture of litharge and lead chromate. By passing hydrogen gas mixed with benzene vap., or ethylene over silicon heated to bright redness, A. Colson obtained a mixture of silicon dicarbide, SiC_2, **silicon dioxycarbide**, $SiCO_2$, and **silicon trioxycarbide**, $SiCO_3$; and he obtained **silicon oxydicarbide**, Si_2C_2O, by heating silicon sulphocarbide, Si_4C_4S, in oxygen, or by the action of carbon dioxide on heated silicon. He found that when powdered silicon is placed in a gas-carbon crucible lined with compressed lampblack, and this, in turn, is placed inside a brasqued crucible and heated to whiteness, a regulus containing silicon oxycarbide is formed. The regulus is detached, freed from adhering charcoal, powdered, and purified by treatment with potash and hydrofluoric acid. The bottle-green powder thus obtained is **silicon dioxytricarbide**, $Si_2C_3O_2$. Prolonged action of oxygen at a red heat gradually removes the excess of carbon. If a mixture of somewhat thick iron wire with lampblack and silica be similarly treated, a crystalline **silicon hexaferrocarbide**, Fe_6Si_2C (sp. gr.=6·6), is formed. This compound is formed only after prolonged heating at a very high temp. There is nothing to show if these **oxycarbides**, or **carboxides**, are not simply mixtures of silicon, silica, and silicon carbide. E. G. Acheson noted their presence in the zone of the so-called amorphous carborundum in the electric furnace. In fact, this form of amorphous carborundum appears to be incompletely reduced silica, and is regarded as a solid soln. of silicon carbide in silica. A similar product with a felt-like structure was made by F. J. Tone. E. G. Acheson gave the material the trade-name *silixicon*; its composition ranges from Si_2C_2O to Si_7C_7O. The general formula is $(SiC)_nO$, where n varies from 1 to 7. The higher the temp. of formation, the greater the value of n. These oxycarbides oxidize more easily than carborundum when used as furnace linings: $(SiC)_nO+\frac{1}{2}(4n-1)O_2=nSiO_2+nCO_2$. It is analogous to the carborundum fire-sand. It has been described by G. Krell, P. E. Spielmann, N. Heym, F. Bölling, R. Amberg, etc. In 1894, O. Mühlhäuser noted the presence of a fibrous material in the manufacture of carborundum and assumed its composition to be $AlSi_2C_7$; and in 1897, C. A. Kohn made a similar observation, but regarded the material as finely divided carborundum. According to E. Weintraub, when silicon is heated in a graphite crucible at 1400°–1500°, a small quantity of calcium fluoride being present, the crucible becomes filled in a few hours with a fibrous mass of silicon oxycarbide. After breaking away the slag and reheating, a further quantity may be obtained. This material, known as *fibrox*, is made up of very fine, amorphous threads, sometimes carrying minute beads of vitreous silica. It is formed by reactions in the state of vap., and experiments in an electric furnace show that the presence of carbon dioxide is necessary. The sp. gr. varies from 1·84 to 2·2, increasing with the percentage of silicon. The apparent sp. gr. of the fibrous mass is only 0·0025–0·0030, or 2·5–3·0 grms. per litre. The thermal resistance in the loosely packed condition is very high, but diminishes with rising temp. Thus, the resistivity in ohms is 4190 at 100°; 3300 at 200°; 2265 at 300°; and 2195 at 500°. Fibrox is not hygroscopic and is permanent in air; above 1000°, it oxidizes slowly and is transformed into silica. It is a relatively good electrical conductor, and its conductivity increases with compression, and it also depends on the carbon content. For *monox*, see silicon monoxide.

According to L. Franck,[2] carbon unites with titanium in all proportions, forming crystalline carbides. P. W. Shimer isolated **titanium carbide**, TiC, in minute, metal-like, cubic crystals from the residue left on dissolving 250 grms. of pig-iron in dil. hydrochloric acid. H. Moissan prepared this carbide by heating a mixture of titanic oxide (160 parts) and carbon (70 parts) in an electric arc furnace for 10 min., $TiO_2+2C=TiC+CO_2$. F. M. Becket obtained the carbide by a similar process. H. Moissan obtained titanium carbide by heating titanic oxide with calcium carbide. The carbide occurs in fused masses with a crystalline fracture, or in crystal aggregates. There is always a slight excess of carbon which has crystallized from the fused mass as graphite. The graphite retains tenaciously traces of titanium. K. Nischk studied the formation of titanium carbide. P. W. Shimer gave 5·1 for the sp. gr. of titanium carbide, and H. Moissan, 4·25. W. R. Mott gave 4300° for the b.p. of titanium carbide at 760 mm. P. W. Shimer said that titanium carbide is soluble in nitric acid; H. Moissan said that, unlike titanium, the carbide is not attacked by hydrochloric acid; but it is slowly attacked by aqua regia. The vap. of water has no action at 600°. The reactions of the carbide resemble closely those of titanium, but the carbide burns more easily in oxygen, for it ignites at a dull red heat, and the evolution of heat causes the mass to become incandescent. When the powder is sprinkled in a Bunsen's flame, it furnishes sparks more vivid than those obtained with titanium.

According to J. J Berzelius,[3] **zirconium carbide** is formed when zirconium is prepared by reducing a zirconium compound with potassium containing carbon. It resembles zirconium in appearance; it dissolves in hydrofluoric acid, leaving a residue of carbon; with boiling hydrochloric acid it evolves hydrogen and some hydrocarbons; and when burnt it forms zirconia, which is not perfectly white because a portion of the carbon escapes combustion. L. Troost made a product with 77·6 per cent. of Zr, namely, **zirconium dicarbide,** ZrC_2, by heating an intimate mixture of zirconia and sugar charcoal in an electric furnace. It is not clear whether the product is a chemical individual or a mixture. It is readily attacked by dil. or conc. hydrofluoric acid, but not by other acids; L. Renaux made zirconium carbide from a mixture of zircon and calcium carbide; and E. Wedekind, from a mixture of zircon, carbon, and lime. According to H. Moissan and M. Lengfeld, zirconium dicarbide is obtained by heating to a high temp. in an electric arc furnace, a mixture of zirconia and sugar charcoal. W. R. Mott gave 5100° for the b.p. of zirconium carbide at 760 mm. This carbide, said H. Moissan, has a grey colour and a metallic lustre, scratches quartz but not rubies, and is not attacked by dry or moist air even at 100°. It burns in fluorine in the cold, in chlorine at 250°, in bromine at 300°, and in iodine at about 400°, and it is readily attacked by halogen hydracids. At a dull red heat, it burns brilliantly in oxygen, and is slightly attacked by sulphur vap. at the same temp. Water, ammonia, and hydrochloric acid do not attack the carbide even when strongly heated. Nitric and sulphuric acids attack it, and oxidizing agents such as potassium chlorate, nitrate, or permanganate, as well as the hydroxide, decompose it readily, but fused potassium cyanide is without action.

No *germanium carbide* has been reported. L. M. Dennis[4] and co-workers failed to obtain one by heating a mixture of carbon and finely powdered germanium up to the temp. at which the metal volatilized. O. Ruff and B. Bergdahl found that tin dissolves only traces of carbon, while lead dissolves 0·024 per cent. at 1170°, and 0·094 per cent. at 1555°. According to H. Moissan, tin does not unite with carbon; when stannic oxide is heated with calcium carbide, the metal is produced but no *tin carbide* is formed. He likewise failed to prepare **lead carbide.** According to J. F. Durand, calcium carbide precipitates impure lead carbide, PbC_2, from a soln. of normal lead acetate. The greyish powder is stable in air and water, but it gives acetylene when treated with dil. hydrochloric acid—*vide* the action of carbon on lead.

The *carbide of cerium* has been described in connection with the rare earth metal carbides—*vide supra*. L. Troost[5] found that a mixture of thoria and sugar charcoal in the electric arc furnace furnishes **thorium dicarbide,** ThC_2, more readily than does zirconia. H. Moissan and A. Étard prepared it in a similar manner; and E. Kunheim, by heating a mixture of thorium sulphate and retort carbon in the electric arc. According to H. Moissan and A. Étard, thorium carbide forms a homogeneous mass possessing a crystalline fracture. It consists of small, transparent, yellow crystals mixed with some graphite laminæ; its sp. gr. is 8·96 at 18°; L. Troost gave 10·15 at 15°, and he found that the product is not so hard as zirconium carbide, but it is brittle and scratches glass slightly. W. R. Mott gave 5000° for the b.p. of thorium carbide at 760 mm. H. Moissan and A. Étard said that thorium carbide closely resembles yttrium carbide in its properties. When exposed to moist air, thorium carbide slowly decomposes with intumescence. When heated in air, it readily burns with incandescence. It is decomposed by cold water giving off a mixture of gases containing

	C_2H_2	C_2H_4	CH_4	H_2
Per cent.	47·6	5·8	29·4	17·1

and some liquid and solid hydrocarbons. P. Lebeau and A. Damiens obtained from thorium carbide and water a mixture of gases similar to those obtained from uranium carbide, excepting that more acetylene homologues and less methane were present. H. Moissan and A. Étard found that sulphur vap. attacks heated thorium carbide with incandescence; selenium vap. acts in a similar way. In the one case, thorium sulphide, and, in the other case, thorium selenide are formed. With hydrogen sulphide at a red heat, the reaction proceeds slowly without incandescence. Hydrogen chloride attacks the carbide at a dull red heat with incandescence. Conc. acids have but little action, while dil. acids rapidly attack the carbide. When heated to about 500° in ammonia gas, thorium carbide furnishes hydrogen and thorium nitride. Fused potassium hydroxide, potassium chlorate, or potassium nitrate decomposes the carbide with incandescence. L. Troost said that if a mixture of thorium carbide and an excess of thorium oxide is heated in the electric arc furnace, it furnishes small metallic masses which do not alter in air. E. Kunheim confirmed many of these observations.

§ 19. Carbides of the Nitrogen, Vanadium, and Chromium Families of Elements

Cyanogen, C_2N_2, and paracyanogen represent the binary combination of carbon and nitrogen, *nitrogen carbide* or *carbon nitride*; and hydrogen cyanide, HCN, is the hydrogen derivative.

E. de Mahler[1] found that the soln. of the halides of the metalloids react quantitatively with G. I. Iotsitsch's halides of magnesium carbide to form a carbide of the metalloid. For example, **phosphorus tricarbide,** PC_3, or P_2C_6, was formed as a yellowish-white amorphous precipitate, $2PCl_3+3C_2Mg_2I_2=P_2C_6+3MgI_2+3MgCl_2$, insoluble in ordinary solvents, and not attacked by acids or alkalies. It takes fire when slightly heated and burns to phosphorus pentoxide without liberating carbon. The corresponding **arsenic tricarbide,** AsC_3, or As_2C_6, was similarly obtained as a brown amorphous precipitate with properties resembling the phosphorus compound. It explodes when warmed or rubbed, with the liberation of arsenic and carbon. H. Moissan failed to make *bismuth carbide* by the action of calcium carbide on the oxide. O. Ruff and B. Bergdahl found that arsenic and bismuth dissolve only traces of carbon; antimony dissolves 0·033 per cent. at 1055°, and 0·094 per cent. at 1327°. No *antimony carbide* has been made.

H. Moissan[2] prepared **vanadium carbide,** VC, by heating the oxide with carbon in the electric furnace. The crystalline mass has a sp. gr. 5·36; it scratches quartz, and fuses at a higher temp. than molybdenum. W. R. Mott gave 3900° for the b.p. of vanadium carbide at 760 mm. When heated to dull redness in oxygen the carbide burns with incandescence; it is not attacked by water at a dull red heat; it becomes incandescent in chlorine at 500°; it is not attacked by hydrogen chloride or sulphide at a dull red heat; it does not unite with sulphur vap. at the softening temp. of glass; and it is not attacked by hydrochloric or sulphuric acid. When heated to redness in nitrogen, or ammonia, the carbide forms the metal nitride; it is attacked in the cold by nitric acid; and when melted with potassium chlorate or nitrate.

A. Joly[3] heated potassium columbate with sugar charcoal and dry potassium carbonate in a carbon crucible to the m.p. of nickel, and purified the product by digesting it at ordinary temp. in conc. sulphuric acid; then at 50°–60° with 1 : 1 sulphuric acid; and finally washing thoroughly with water. The dark-blue, acicular crystals had a composition corresponding with **columbium carbide,** CbC. He also obtained a carbide by similarly treating columbite from Greenland. H. Moissan observed that carbon is slowly absorbed by molten columbium, and he made the carbide by reducing columbium pentoxide with carbon in the electric furnace. Similar products were prepared by A. Larsson, and W. von Bolton. The product is very hard; scratches glass and quartz; and is not attacked by acids excepting sulphuric and hydrofluoric acids. W. R. Mott gave 4300° for the b.p. at 760 mm. A. Joly, H. Moissan, and W. von Bolton prepared **tantalum carbide,** TaC, in a similar manner. It resembles columbium carbide in its properties. W. R. Mott gave 5500° for the b.p. at 760 mm.

According to H. St. C. Deville,[4] a compound of chromium and carbon is formed when chromium is reduced from the oxide by an excess of carbon; and H. St. C. Deville and H. Debray made observations to the same effect. W. Hempel and P. Rucktäschel made alloys of chromium with 2·23 per cent. of carbon. According to H. Moissan, chromium readily dissolves carbon at a high temp., forming two carbides, Cr_4C and Cr_3C_2; at still higher temp. relatively large amounts of carbon are dissolved, and these are rejected on cooling in the form of graphite lamellæ. He made **chromium ditritacarbide,** Cr_3C_2, by heating in an electric furnace a mixture of chromium and an excess of carbon. The same product was obtained by heating a mixture of chromic oxide and calcium carbide. The lamellar or acicular crystals have a sp. gr. 6·47 and scratch quartz and topaz. The carbide is stable at a high temp. O. Ruff and T. Foehr gave 6·683 for the sp. gr. at 21·3°/4°, and 1890 ± 10° for the m.p. W. R. Mott gave 3800° for the b.p. of chromium carbide at 760 mm. The carbide is not attacked by water at ordinary temp. or at 100°; it is not attacked by conc. hydrochloric acid, but is slowly attacked by the dil. acid; it is not attacked by ordinary or fuming nitric acid or by aqua regia; it is slightly attacked by fused potassium hydroxide; and it is readily attacked by fused potassium nitrate. O. Ruff and T. Foehr found it is decomposed by chlorine at a red heat, and when molten it reduces magnesia, alumina, and zirconia. H. Moissan sometimes found reddish-brown needles on the surface of ingots of chromium, and in geodes in the middle of the mass. The composition corresponds with **chromium tetritacarbide,** Cr_4C. The sp. gr. is 6·75. O. Ruff and T. Foehr observed no trace of Cr_4C in their study of the Cr-C system. O. Ruff studied the composition-temp. diagram for press. of 10 mm.; at 2270°, the mixture boils, and the vapour is wholly that of chromium; between 2050° and 2250°, the fusion is constant in composition and corresponds with Cr_3C_2; between 1875° and 2050°, graphite and carbon exist side by side as solid phases; and there is evidence of the existence of **chromium dipentitacarbide,** Cr_5C_2, which O. Ruff and T. Foehr prepared as silvery crystals of sp. gr. 6·915 at 24·8°/4°; and m.p. 1665°. It is not attacked by aqua regia, and is not decomposed on melting. K. Nischk studied the formation of chromium carbides, and claimed to have made *chromium hemicarbide,* Cr_2C, but O. Ruff said that K. Nischk has mistaken this for the dipentitacarbide. O. Ruff and T. Foehr obtained evidence of the existence of Cr_2C, or Cr_4C_2, but they could not isolate the compound from alloys with 23 per cent. carbon. When this alloy is treated with hot, 24 per cent. hydrochloric acid, and graphite is removed from the residue, the ditritacarbide remains. The portion of the f.p. curve which has been explored is indicated in Fig. 29, where the dotted lines are uncertain. C. R. Austin made some observations on this subject.

H. Debray[5] obtained **molybdenum carbide** by heating molybdenum oxide with carbon. H. Moissan found that molybdenum dissolves carbon readily in the electric furnace and it forms two carbides. More carbon is dissolved at a higher temp., and this separates out as graphite on cooling. He prepared **molybdenum dicarbide,** MoC_2, by heating molybdenum dioxide (250 grms.) for 10 mins. in an electric furnace with an excess of carbon (50 grms.). The excess carbon is transformed into graphite. It is also made by heating a mixture of molybdenum dioxide and calcium carbide. M. Guichard obtained the carbide by heating molybdenite in a carbon tube in an electric furnace. J. N. Pring and W. Fielding made the carbide by electrically heating a carbon rod above 1330° in an atm. of molybdenum pentachloride. The white mass has a crystalline fracture. It may be readily broken on the anvil, and well-defined prismatic crystals may be readily separated. Its sp. gr. is 8·9 ; and it readily scratches quartz and steel. W. R. Mott gave 4500° for the b.p. of molybdenum carbide. H. Moissan and K. Hoffmann prepared molybdenum carbide, MoC, by heating a mixture of molybdenum, carbon, and an excess of aluminium in an electric furnace. K. Nischk studied the formation of molybdenum carbide. The dark grey crystalline powder had a sp. gr. 8·48 at 20°, and a hardness between 7 and 8. The carbide is not attacked by hydrogen at a red heat, burns readily in fluorine, forming carbon tetrafluoride and molybdenum fluoride. is attacked at a red heat by chlorine, at a higher temp. by bromine, and is only superficially attacked at a still higher temp. by iodine ; is readily attacked by a mixture of hydrogen chloride and bromine vap. and oxidized by heating in air or oxygen, by projecting on to fused potassium chlorate or nitrate, or by the action of cold nitric acid. It does not decompose water even at 500°-600°, is only slowly attacked by hydrochloric, hydrofluoric, or sulphuric acid, whilst it is unaltered by soln. of alkali hydroxides. M. Ornstein studied the catalytic activity of molybdenum carbide on mixtures of methane and carbon monoxide.

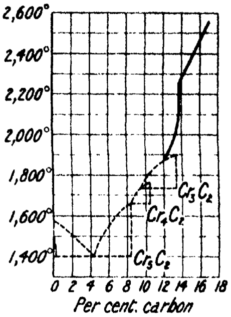

FIG. 29.—Part of Freezing-point Curve of the Chromium-Carbon System.

W. Riche [6] observed that tungsten becomes carbonized when melted in a carbon crucible in the electric arc ; and C. Matignon observed that at 2130°, a mixture of tungstic oxide and carbon forms tungsten and its carbide. W. Hempel and P. Rucktäschel prepared an alloy of tungsten with 3·3 per cent. of carbon. H. Moissan found that molten tungsten dissolves very large proportions of carbon, up to 18·8 per cent., and the soln. furnishes graphite on cooling. O. Ruff and R. Wunsch gave for the m.p. of soln. of carbon in tungsten :

C. . .	0·12	0·50	0·73	1·10	1·72	2·20	3·20	4·13 per cent.
M.p. . .	2706°	2692°	2706°	2664°	2806°	2585°	2682°	2682°

H. Moissan showed that if the tungsten or tungstic oxide be heated with an excess of carbon in the electric furnace, **tungsten hemicarbide,** W_2C, is formed as an iron-grey mass. He also made it by heating tungstic oxide with calcium carbide. J. N. Pring and W. Fielding prepared tungsten hemicarbide by electrically heating a carbon rod above 1500° in an atm. of tungsten hexachloride. M. R. Andrews made this carbide by heating electrically a tungsten filament in hydrocarbon vapour —naphthalene, benzene, toluene, anthracene, acetylene, methane, and coal gas. The existence of the hemicarbide and the monocarbide is shown by points of inflexion on the resistance curve of the filament. The carbide is decarbonized by heating the filament in vacuo at 2700° K., whereby carbon is volatilized without loss of tungsten. P. C. Rushen described the manufacture of tungsten carbide by working at a temp. higher than that required for the formation of the carbide, and removing the free graphite which separates during cooling by the addition of 7 to 8 per cent. molybdenum or one of its compounds. The molybdenum volatilizes completely and enables the free carbon to be readily removed. The sp. gr. of the tungsten hemicarbide is 16·06 at 18°. It is hard enough to scratch corundum. The properties approximate to those of the metal, but the carbide is more readily attacked by reagents.

According to H. Moissan, it is not attacked by water; it burns in oxygen at about 500° producing tungstic oxide and carbon dioxide. In cold fluorine the carbide becomes incandescent; when heated to redness in nitrous oxide or nitrogen peroxide it burns with incandescence; it is but slowly attacked by conc. sulphuric or hydrochloric acid; but it is dissolved by boiling nitric acid; and it is oxidized with incandescence by fused potassium chlorate, or a mixture of fused potassium nitrate and carbonate. P. Williams found that if tungstic oxide, carbon, and a large excess of iron be heated combination occurs at a much lower temp. than when the iron is absent, and a **tungsten carbide,** WC, is formed. O. Ruff and R. Wunsch obtained this carbide by rapidly cooling a soln. of carbon in the liquid metal; if slowly cooled, decomposition with the separation of graphite occurs. M. R. Andrews made this carbide by electrically heating a tungsten filament in hydrocarbon vapour. This carbide is an iron-grey powder, consisting of microscopic, cubical crystals, which are harder than quartz and have a sp. gr. = 15·7 at 18°. A. Westgren and G. Phragmen examined the X-radiograms of iron tungsten carbide. When the carbide is strongly heated in a closed vessel, it melts and decomposes into graphite and the carbide W_2C, whilst in presence of air or oxygen, it slowly oxidizes with the formation of tungstic and carbonic anhydrides. It is attacked by fluorine in the cold with incandescence, but it is not acted on by chlorine, bromine, iodine, and the halogen acids. Sulphuric and nitric acids have but little action on the carbide, but it is readily oxidized by heating with potassium chlorate or nitrate. M. Ornstein studied the catalytic action of tungsten carbide on mixtures of methane and carbon monoxide. W. R. Mott gave 6000° for the b.p. of tungsten carbide at 760 mm. S. Ozawa studied the tungsten-iron carbides. O. Ruff and R. Wunsch heated tungsten in a carbon-tube electric furnace and found carbon to be absorbed, and **tungsten tritacarbide,** W_3C, to be formed. It melts above 2700°, and it does not form solid soln. with tungsten. M. R. Andrews obtained no evidence of this compound when a tungsten filament is heated in the vapour of hydrocarbons.

According to H. Moissan,[7] the solubility of carbon in molten uranium approaches that of carbon in iron; and he prepared **uranium hemitricarbide,** U_2C_3, by heating an intimate mixture of uranium oxide (500 grms.) and sugar charcoal (50 grms.) in a carbon crucible in an electric furnace for 5–10 mins. When the emission of sparks has ceased, the liquid carbide is allowed to cool and solidify in the furnace. P. Lebeau's analyses bring the composition that of **uranium dicarbide,** UC_2, into line with the carbides of the rare earth elements. O. Ruff also agrees with this. The metallic-looking mass has the colour of bismuth, and a crystalline fracture. The crystals have a sp. gr. 11·28 at 18°. The compound scratches glass and quartz, but not corundum. When struck by a hard body, the carbide emits sparks, and when quickly powdered in a mortar, it takes fire and burns. The m.p. is above that of platinum. O. Ruff gave 2425° for the m.p. of the dicarbide; and E. Tiede and E. Birnbrauer, 2260°. W. R. Mott gave 4100° for the b.p. of uranium carbide at 760 mm. According to H. Moissan, uranium carbide burns brightly in oxygen at 370°, and when once started, the reaction is propagated throughout the whole mass—carbon dioxide and a dark violet uranium oxide are formed. With water at ordinary temp. there is a slow evolution of gas which is accelerated if the proportion of water be small or the temp. be raised—in the absence of air, a green hydroxide is formed, in the presence of air, the hydroxide is grey. The analyses of the gas gave

	Acetylene	Ethylene	Methane	Hydrogen
Per cent. .	0·17–0·72	5·16–6·77	78·05–80·60	13·52–15·01

The total carbon in the gas is about two-thirds short of that in the carbide when the reaction is complete. The missing carbon is obtained as a mixture of liquid and solid hydrocarbons by extracting the aq. soln. with ether. P. Lebeau and A. Damiens obtained H_2, CH_4, C_2H_6, C_3H_8, and small amounts of C_4H_{10}, C_5H_{12}, C_2H_4, and acetylene homologues from uranium carbide and water. According to H. Moissan, uranium carbide, at a dull red heat, is decomposed by steam with incandescence, forming a black oxide and carbon dioxide. In the cold, fluorine has no action, but if warm, the carbide burns with incandescence; chlorine attacks it with incandescence at 300°; bromine reacts at 390° with a slight glow; and iodine attacks it without incandescence below a red heat, forming an agglomerated mass slightly soluble in water, giving a green soln. At about 600°, hydrogen chloride reacts with the carbide with incandescence. Dil. hydrochloric, nitric, and sulphuric acids attack the carbide slowly in the cold, giving a soln. which is first green and then turns yellow: the conc. acids, excepting nitric acid, attack the carbide with difficulty in the cold, but the decomposition is rapid on heating. The carbide burns in sulphur vap. at the softening point of glass forming uranium and carbon sulphides; selenium acts at a lower temp., forming uranium selenide; at 600°, hydrogen sulphide forms uranium sulphide. The carbide is attacked by nitrogen at 1100°, forming some nitride. Uranium carbide becomes incandescent in nitric oxide at 370°, and a complex black residue is formed. At a red heat, ammonia forms some nitride. F. Haber found that when uranium carbide is heated in a mixture of nitrogen and hydrogen, uranium nitride is formed, and this acts catalytically on the mixed gases, forming ammonia. According to H. Moissan, uranium carbide reacts with fused potassium nitrate or chloride, becoming incandescent and forming alkali uranate.

§ 20. The Carbides of Manganese and of the Iron and Platinum Family of Elements

The early workers on manganese—*e.g.* J. F. John,[1] etc.—noted that when the metal is prepared by reducing the oxide with charcoal, no carbon remains as a residue when the metal is dissolved in acid. S. Brown stated that when manganese thiocyanate is ignited it leaves a residue of *manganese carbide*, MnC; and manganese cyanide, *manganese dicarbide*, MnC_2, in colourless octahedra. Neither statement has been confirmed. J. F. John observed that if manganese is fused a long time in a charcoal crucible it dissolves carbon, and gives it up on cooling as *manganese graphite*. W. H. Wollaston stated that the graphite which separates from manganiferous cast iron is largely manganese carbide; but this statement has not been verified. A. Gautier and L. Hallopeaù said that a little manganese carbide and sulphide are formed when manganese at 1400° is exposed to the vap. of carbon disulphide. W. Hempel and P. Rucktäschel obtained an alloy of manganese with 0·47 per cent. of carbon. A. Stadeler said manganese does not take up carbon when heated with sugar charcoal for 12 hrs. at 1100°. H. F. Jüptner von Jonstorff found that a ferromanganese can dissolve 7·75 per cent. of carbon, forming $Mn_{3.2}C$. L. Troost and P. Hautefeuille, and H. le Chatelier found that molten manganese in a carbon crucible took up 6·7 per cent. of carbon, and gave, on cooling, a crystalline solid with a composition corresponding to **manganese tritacarbide,** Mn_3C. H. Moissan noted that manganese rapidly dissolves carbon at the temp. of the electric furnace. The manganese can be all removed by volatilization leaving behind crystals of graphite free from manganese. H. Moissan obtained the tritacarbide by heating a mixture of 200 grms. manganosomanganic oxide and 500 grms. of sugar charcoal in the electric tube-furnace at a temp. upward of 1500°. He also made it by heating the same oxide with calcium carbide; the impurities can be removed by treatment with cold water. L. M. Bullier made this carbide by the action of calcium carbide on molten manganese chloride. O. Ruff and W. Bormann found the solubility of carbon in manganese increases slowly from 1360° to 1525°, the b.p. of the soln. at 30 mm. press. The results are shown in Fig. 30. The manganese then contains 7·12 per cent. of carbon. Manganese boils at 1510° under the same press. The vap. of the alloy contains 1·94 per cent. of carbon. The whole of the carbon in the rapidly quenched alloy is combined as manganese tritacarbide and they form a continuous series of mixed crystals. According to A. Stadeler, the mixed crystals range from 817° and 0·72 per cent. of carbon to 855° and 3·60 per cent. of carbon; they then break up into one series with almost pure manganese, and another series rich in carbide. There is evidence of the existence of a compound richer in carbon. The equilibrium diagram has been also studied by K. Kido. E. Müller and H. Barck found manganese carbide is formed when manganese is heated in an atm. of carbon dioxide. K. Nischk also studied the formation of this carbide.

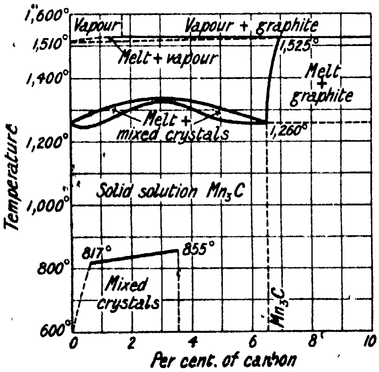

FIG. 30.—The Solubility of Carbon in Manganese.

Manganese tritacarbide forms a metallic-looking regulus with a brilliant crystalline fracture. A. Stadeler said that crystals occur as glistening fibres and needles in alloys with over 3·32 per cent. of carbon, and as polyhedra in alloys with less carbon. The crystals of manganese tritacarbide have been examined by E. Mallard, B. Rathke, and L. J. Spencer. All agree that they are pseudo-hexagonal prisms, and that they are isomorphous with iron tritacarbide. A. Stadeler said that the sp. gr. is 6·888; and H. Moissan, 6·89 at 17°. The mol. vol. is 25·70, the calculated value from the sp. gr. of the constituents is 29·80. The hardness is between that of talc and gypsum. G. Gin and M. Leleux found that manganese carbide dissociates at the high temp. of the electric furnace yielding the metal, which volatilizes, and graphite—*vide supra*. O. Ruff and E. Gersten found the molar heat of combustion to manganese and carbon dioxide to be 410·9 ± 2·0 Cals., and H. le Chatelier gave 412·4 Cals.; O. Ruff and E. Gersten found the heat of formation, $3Mn+C=Mn_3C+12·9 \pm 2·14$ Cals; and H. le Chatelier, 9·34 Cals. L. Troost and P. Hautefeuille's estimate of 191·4 Cals. is high. The last-named found that when the carbide is exposed to air for several days, it disintegrates. H. Moissan found that when gently heated in oxygen, manganese tritacarbide burns with incandescence. A. Stadeler found that alloys with over 3 per cent. of carbon fall to pieces at once in water, and even disintegrate spontaneously in closed vessels after a few weeks, "apparently owing to the evolution of retained gas." H. Moissan found that when treated with water, a mixture of methane and hydrogen, free from acetylene and ethylene, is evolved. The carbide with an excess of manganese gives a larger proportion of hydrogen: 56·43 per cent. of hydrogen and 43·75 per cent. of methane; while the carbides more or less rich in carbon, give 50·6 to 51·0 per cent. of methane, and 48·68 to 49·40 per cent. of hydrogen. The results are in agreement with $Mn_3C+6H_2O=3Mn(OH)_2+CH_4+H_2$. No liquid or solid hydrocarbons were observed amongst the products of the action. M. Berthelot showed that if acetylene, ethylene, or ethane were produced, the thermal value of the reaction would be less than that observed. The reaction has also been studied by E. Wedekind. S. Cleoz found that ferromanganese carbides gave liquid hydrocarbons. The alloy with Fe, 56·5; Mn, 38·2; and C, 5·0, was acted on by water only at 300°; an alloy with Fe, 5·7; Mn, 85·4; Si, 1·2; C, 3·7, was readily attacked at ordinary temp., and it gave hydrogen, olefines, and solid and liquid hydrocarbons. H. Moissan showed that the carbide is attacked by fluorine in the cold with incandescence; chlorine decomposes it at a rather higher temp., and the incandescence which occurs at the commencement is not maintained; and hydrogen chloride below a red heat furnishes manganese chloride, and hydrogen containing a small quantity of gaseous hydrocarbons. Dil. acids readily attack manganese tritacarbide; with hydrochloric acid, liquid hydrocarbons are formed. These were studied by R. Schenck and co-workers. S. Cleoz found that a ferromanganese alloy containing 56·5 per cent. Fe, 38·2 per cent. Mn, and combined carbon 5 per cent. with dil. sulphuric acid, gave a gas containing large proportions of paraffins and olefines. R. Schenck and co-workers have examined the action of acids on the manganese carbides. H. Moissan found that ammonia reacts with manganese carbide yielding hydrogen and the metal nitride; the carbide burns when heated in nitrous oxide or nitrogen peroxide. L. Troost and P. Hautefeuille obtained manganese boride by heating manganese carbide with boric oxide; and cupromanganese or antimoniomanganese was obtained free from carbon by heating manganese carbide with copper or antimony. Graphite is formed in this reaction.

According to J. F. Durand, when calcium carbide is added to a soln. of manganous chloride, an impure **manganous carbide or acetylide**, MnC_2, is formed.

In 1774, S. Rinman [2] showed that a drop of nitric acid simply whitens wrought iron, but leaves a black stain on steel. In 1781, T. Bergman showed that steel differs from wrought iron by containing 0·2 to 1·5 per cent. of plumbago. C. A. Vandermonde, C. L. Berthelot, and G. Monge said that iron unites chemically with carbon, but they gave no evidence of the formation of definite compounds. L. Clouet showed that steel is produced when the diamond is heated in contact with iron, but there was a complication in this experiment due to *l'aciération* of the iron by carbon derived from the furnace gases. This factor was eliminated by W. H. Pepys in 1815 for the mixture of diamond dust and iron was heated by the "agency of a powerful electric battery." C. J. B. Karsten's experiments on the residues left after treating some varieties of iron containing carbon with acids have been taken to prove the existence of *iron tricarbide*, FeC_3, but in his paper *Ueber die Carburete des Eisens*, 1846, he stated that "there is no satisfactory proof of the existence of such a carbide." P. Berthier found that the residues remaining after cast steel had been treated with aq. soln. of bromine or iodine correspond with *iron monocarbide*, FeC. The fact that some of the residues remaining after the treatment of steel with different solvents have a composition corresponding with definite carbides is to be regarded as a mere coincidence. Neither H. Caron nor C. Bromeis could satisfy himself that a definite carbide can be so obtained; and the former said that P. Berthier's carbide "was probably only a mixture of carbon and the metal, and the metal was mechanically protected by the carbon from the action of the solvent." Numerous solvents have been tried. T. Bergman, C. A. Vandermonde and co-workers, H. Behrens and R. van Linge, and F. Mylius and co-workers used dil. acids—hydrochloric, sulphuric, and acetic acids; P. Berthier, and H. Moissan used iodine or bromine water; C. Ullgren, F. Abel and W. H. Deering used a dil. soln. of chromic anhydride; W. Weyl, F. Osmond and J. Werth, J. O. Arnold and A. A. Read, F. Mylius and co-workers, and E. D. Campbell electrolyzed an electrolyte using the carbonized iron as positive electrode in order to isolate the carbides. A. Gurlt maintained that grey cast-iron contains *iron octitacarbide*, Fe_8C, mixed with graphite, and cast-iron with the maximum amount of carbon is *iron tetritacarbide*, Fe_4C. He said that the latter is formed at a comparatively low temp., and at a higher temp. is resolved into the octitacarbide and graphite. There is, however, no satisfactory evidence of the existence of these chemical individuals. R. von Carnall reported "octahedral crystals" of a carbide in cast iron, and J. F. L. Hausmann "three-sided rectangular laminæ" in wrought iron. F. von Ittner noted the carbonaceous nature of the residues obtained by igniting the ferrocyanides. J. J. Berzelius claimed to have made *iron dicarbide*, FeC_2, by distilling ammonium ferrocyanide in a retort. At first ammonium cyanide and water are evolved, and then nitrogen is given off. Towards the end of the operation, if the dicarbide is heated to redness, it seems to burn as if in oxygen gas. N. Ljubavin also prepared what he regarded as the dicarbide in a similar way. J. J. Berzelius also reported *iron sesquicarbide*, Fe_2C_3, to be formed when Prussian blue is treated in a similar way. J. von Liebig and C. F. Gerhardt accepted the view that these residues are combinations of iron and carbon, but P. J. Robiquet considered them to be mixtures of carbon and slightly carbonized iron, for the residues are magnetic; they readily rust in moist air, and acids readily extract iron from them. A. Terreil, and A. Étard and G. Bémont studied the decomposition of potassium ferrocyanide by heat, but obtained no signs of the formation of iron carbides. J. F. Durand obtained impure **ferrous carbide or acetylide**, FeC_2, by adding calcium carbide to a soln. of ferrous chloride.

In 1846, C. J. B. Karsten abandoned his earlier opinion that the residue left by the action of dil. sulphuric or hydrochloric acid on slowly cooled iron or steel is iron tricarbide, FeC_3. F. Abel obtained **iron tritacarbide,** Fe_3C, by treating drillings of annealed steel with a soln. of potassium dichromate and sulphuric acid; and likewise also F. C. G. Müller, and A. Ledebur, who showed that with very dil. sulphuric acid at ordinary temp., and a current of inert gas to prevent access of air, the residue corresponds with iron tritacarbide. If hot acid be used, the carbide is decomposed, and hydrocarbons are evolved. S. Rinman called this residue *cement carbon* and H. M. Howe *cementite*. The latter term has been used in a general way for all the carbides which exist in iron and steel, even when these carbides contain manganese, chromium, etc. F. Osmond and J. Werth, and J. O. Arnold and A. A. Read employed an electrolytic method and obtained the carbide as a greyish-black powder, or in brilliant magnetic plates or scales. The general principle employed in isolating the tritacarbide depends on the fact that iron is more readily attacked by reagents than the carbide, so that the latter remains after treating the iron with dil. mineral or organic acids, aq. iodine, chromic acid, etc. O. Werkmeister did not recommend the preparation of the carbide by the electrolytic process because there is formed so much brown carbonaceous matter which is difficult to separate. He made his specimens by melting a mixture of iron and sugar charcoal; or by the cementation of iron with sugar charcoal at a red heat; or by the cementation of iron at 600° with carbon monoxide. W. Hempel and P. Rucktäschel made a number of alloys in the electric furnace.

H. Moissan recommended the following process for preparing the carbide: Two pieces of iron, dipping in a soln. of 7 per cent. hydrochloric acid, were connected with the positive pole of two Bunsen's cells, and the two negative poles were connected with a carbon plate in the middle of the containing vessel. In 24 hrs. the pieces of iron were removed, and the adherent mixture of carbide and amorphous carbon brushed off. In another process, the pieces of iron together with a very dil. acid soln. and carbon were kept for some weeks in a glass tube drawn out at one end to keep out the air. $\frac{1}{2}N$-HNO_3 yields the carbide in a few hours. The carbide prepared by these methods contains liquid and solid hydrocarbons only slightly soluble in ether. The carbide may be purified by treatment with fuming nitric acid for 2 hrs. at 30°. The hydrocarbons and the free carbon are converted into soluble compounds and gases. The carbide is not attacked. The mixture is poured into an excess of water, the liquid decanted, and the residue washed with alcohol and ether, and dried at 100° in an atm. of carbon dioxide. The carbide should not be exposed to air in a moist state. The purifying action of nitric acid can be hastened by the addition of a little potassium chlorate. A boiling, 10 per cent. soln. of chromic acid can be allowed to act until the crystals of carbide assume a bright glistening appearance.

The carbon in iron and steel may therefore be present (i) in the form of *carbide carbon* or *combined carbon* such as occurs in cementite. The carbide carbon may be scattered through the metal in microscopic granules, or in relatively large distinct plates. The form of carbon which confers hardness to quenched steel is called *hardening carbon*, and is usually considered to be a form of carbide carbon. (ii) The carbon which separates as graphite during the solidification of highly carburized molten iron is called *graphite carbon* or simply graphite. I. Runge studied the velocity of diffusion of carbon in iron.

C. J. B. Karsten showed that iron completely sat. with carbon at the m.p. approximates in composition to *iron tetritacarbide*, Fe_4C; but of course this does not mean that the product is a chemical compound. J. B. J. D. Boussingault said the maximum solubility of carbon in iron is 4·1 per cent. and nearer Fe_5C than Fe_4C. Observations on the solubility of carbon in iron have been made by C. Benedicks, H. F. Jüptner von Jonstorff, H. Lutke, O. Ruff and O. Goecke, K. Thomsen, etc. According to R. Ruer and J. Biren, the solubility of graphite in molten Swedish iron increases as the temp. is raised from 1152° to 2700°. The solubility curve is linear from 1152° to 1700°; it then bends away from the conc. axis, slightly at first and then more strongly as the temp. increases. The conc. of the graphite eutectic at 1152° is 4·25 per cent. carbon, and that of the cementite eutectic at 1145° is 4·30 per cent. carbon. J. Percy estimated the maximum amount of carbon required to sat. molten iron to be 4·87 per cent. Equilibrium diagrams, developed later in connection with iron and steel, have been studied by H. W. B. Roozeboom, W. C. Roberts-Austen, H. le Chatelier, F. Osmond, H. Jüptner von Jonstorff, E. Heyn, R. Ruer and co-workers, C. Benedicks, F. Wüst, N. Gutowsky, J. I. Wark, P. Goerens and co-workers, A. Smits, G. P. Royston, G. Charpy, O. Ruff, W. Wittorf, H. Hanemann, D. M. Levy, E. A. Sperry, etc. The results shown in Fig. 31 summarize the observations of O. Ruff and co-workers. A soln. of carbon in iron rapidly quenched contains the following percentage amounts of carbon in a combined state:

	1220°	1522°	1823°	2122°	2169°	2220°	2271°	2420°	2626°
C .	4·58	5·46	6·59	7·51	8·91	9·60	8·97	8·09	7·45

These results give a portion of the curve *DHF*, Fig. 31; the solidus curve *A* is due to N. Gutowsky. The point *D* represents the conc. of a sat. soln. of carbon in molten iron at 1837°, and it corresponds with the composition of *iron tritacarbide*, Fe_3C; and the point *H* represents the composition of a soln. sat. at 2220°, and corresponds with the composition of *iron hemicarbide*, Fe_2C. The curve *BDHF* does not represent the equilibrium between the different iron carbides and the soln., but is rather the saturation curve of graphite when the carbide dissociates: $Fe_nC \rightleftharpoons C_{graphite}+nFe$. Hence the points *D* and *H* correspond respectively with the tritacarbide and the hemicarbide. The curve *HF* corresponds with the dissociation of the hemicarbide, $Fe_2C \rightleftharpoons 2Fe+C$, and the slope of the curve shows that the conc. of the hemicarbide decreases as the temp. increases. Below 2220°, along the curve *DH*, there is also a separation of graphite in accord with the change $3Fe_2C=2Fe_3C+C$. The conc. of the tritacarbide increases as the temp. is reduced, and attains a maximum at 1837°, or *D*. At lower temp., the conc. of the tritacarbide decreases since it decomposes into iron and carbon, $Fe_3C \rightleftharpoons 3Fe+C$. H. Hanemann gave the curve *Bd′*, and W. Wittorf the curve *Bd″*. From the existence of three breaks in his curve, W. Wittorf inferred the existence of the four carbides—iron tetritacarbide, Fe_4C; iron tritacarbide, Fe_3C; iron monocarbide, FeC; and iron dicarbide, FeC_2, but these observations have not been confirmed, and the phenomena occurring in this region have been discussed by O. Ruff, A. Smits, H. Hanemann, E. Heyn, H. M. Howe, E. D. Campbell and co-workers, etc. R. Ruer and J. Biren studied the solubility of graphite in molten iron; and G. Tammann and K. Schönert, the diffusion of carbon in iron.

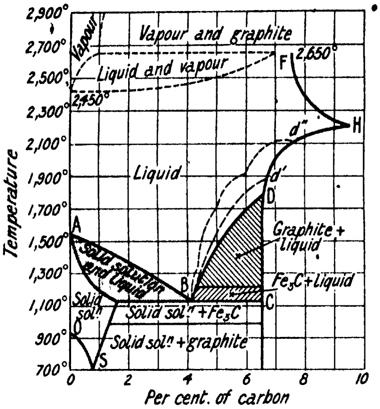

FIG. 31.—The Solubility of Carbon in Iron.

J. O. Arnold showed that almost all the carbon in steel containing 1·4 per cent. of carbon is in the free state after the steel has been heated for 72 hrs. at 1000°, and slowly cooled. It is therefore inferred that iron tritacarbide is unstable below 1000°. Nevertheless, this carbide has been repeatedly isolated. Hence, there is probably a range of temp. in the equilibrium diagram where this carbide can exist an indefinite length of time. This is represented diagrammatically in Fig. 30. G. B. Upton inferred that for the mixture with over one per cent. of carbon, *iron hexitacarbide*, Fe_6C, is first formed by the dissociation of the solid soln. of carbon in iron; and that this dissociates into the tritacarbide at about 800°, and this again into the hemicarbide, Fe_2C, at about 915°. The deduction was largely based on the breaks in H. C. H. Carpenter and B. F. E. Keeling's cooling curves. E. D. Campbell and M. B. Kennedy found the carbide obtained from annealed cast iron with a large proportion of carbon, varied in composition between the trita- and hemi-carbide, and hence inferred that both carbides have a real existence. The unsegregated eutectic with 0·89 per cent. of carbon is considered by J. O. Arnold to be an *iron subcarbide*, $Fe_{24}C$; it may be a compound of cementite and iron, $Fe_3C.21Fe$; or simply a congealed soln. of the tritacarbide in iron. W. Wittorf claimed to have made *iron dicarbide*, FeC_2, by cooling soln. of 6–10 per cent. of carbon in molten iron; crystallization begins at 2380°–2000°, furnishing a yellow carbide with a silvery reflex. It is slowly attacked by nitric acid, and when immersed in a dil. soln. of cupric sulphate, it acquires a film of copper. J. J. Berzelius' and N. Ljubavin's observations on the dicarbide have been previously described. L. Franck claimed to have made iron tetracarbide, FeC_4, and iron ditritacarbide, Fe_3C_2. A. Gautier and P. Clausmann found that two carbides—*iron pentitacarbide*,

Fe_5C, and *iron dodecitacarbide*, $Fe_{12}C$—produced when carbon monoxide is passed over red-hot iron. The former dissolves more quickly in sulphuric acid, and the less quickly dissolved residue is the pentitacarbide. They also obtained the dodecitacarbide by the action of a mixture of carbon monoxide and hydrogen on heated ferrosoferric oxide. The reaction between sulphuric acid and the dodecitacarbide is symbolized: $Fe_{12}C+12H_2SO_4=12FeSO_4+CH_4+10H_2$; the pentitacarbide gives methane, hydrogen, and other hydrocarbons when digested with sulphuric acid. In no case is there sufficient evidence to establish a belief in the real existence of these carbides. K. Nischk studied the formation of iron carbides.

J. O. Arnold and A. A. Read obtained iron tritacarbide in the form of microscopic granules, or small plates, and, added F. Mylius and co-workers, in small needles. The plates of iron tritacarbide or cementite often occur in patches alternating with ferrite—*i.e.* iron—to form well-marked microscopic striæ giving the metal the peculiar mother-of-pearl effect which led H. C. Sorby to call it the *pearly constituent of steel*, and H. M. Howe, *pearlite*. The rhombic prismatic **crystals** are pseudo-hexagonal and isomorphous with manganese carbide. They have been examined by C. F. Rammelsberg, N. T. Belaiev, E. Hussak, O. Sjöström, D. J. McAdam, E. Weinschenk, J. Fahrenhorst, G. Florence, E. Mallard, L. J. Spencer, and C. Hlawatsch. G. Tammann discussed the space-lattice of iron tetritacarbide; and A. Westgren and G. Phragmen showed that cementite has probably four mols. of Fe_3C per unit cell so that the chemical mol. is Fe_3C, and the crystal mol. $Fe_{12}C_4$. F. Wever found the **X-radiogram** corresponds with a rhombohedron space-lattice whose lengths of side are $a=4{\cdot}481\times10^{-8}$, $b=5{\cdot}034\times10^{-8}$, and $c=6{\cdot}708\times10^{-8}$ cm. respectively; and that four molecules are involved. The values of these constants at temp. above the magnetic transformation point show that the magnetic changes in iron carbide are similar to those of iron and nickel, and are not due to the lattice arrangement; the new rhombohedral lattice has sides of length $a=4{\cdot}52\times10^{-8}$, $b=5{\cdot}08\times10^{-8}$, and $c=6{\cdot}77\times10^{-8}$ cm. A. M. Portevin studied the **microscopic structure** of the iron carbides in iron and steel. A complex carbide, $(Fe,Co,Ni)_3C$, occurs in distorted crystals in meteorites. L. J. Spencer said the crystals are probably cubic. It has been studied by E. Cohen and E. Wienschenk, and called *cohenite*. It is tin-white in colour and becomes bronze-yellow on exposure to air. The sp. gr. is 6·977, and the hardness in 5·5 to 6·0. F. C. Thompson discussed the etching of the alloy steels to bring out the structure of the cementite. E. D. Campbell found the **specific gravity** of the crystals to be 6·944 at 23°; H. Moissan gave 7·07 at 16°; O. Werkmeister, 7·17 at 15°; and O. Ruff and E. Gersten, 7·396 at 21°. The mol. vol., according to O. Ruff and E. Gersten, is 24·34. The crystals are hard and brittle, but not so hard as glass; O. Ruff and E. Gersten represented the **hardness** as 3·2 to 3·3 on Moh's scale.

P. Oberhoffer and A. Meuthen calculate the **specific heat** to be 0·1581. H. Moissan found that if highly purified iron be fused with sugar carbon in an electric furnace, the fused mass becomes more and more viscid as the temp. rises until the containing vessel can be turned upside down without loss. On cooling, the metal soon becomes as mobile as water. On solidification, the metal has all the characteristics of grey cast iron. About one per cent. of the carbon is combined, and the mass contains numerous crystals of graphite—*vide* synthesis of diamonds. F. Mylius and co-workers, E. H. Saniter, and J. O. Arnold showed that the tritacarbide is decomposed below 1000°. A. Anthon tried to measure the **melting point**, and said that it is about 1300°; O. Ruff's diagram, Fig. 29, places it at 1837°. O. Werkmeister studied the thermal behaviour of the carbide; the results of O. Ruff have been previously discussed. A. Meuthen measured the **specific heat** of various iron-carbon alloys. L. Troost and P. Hautefeuille gave a small negative value for the **heat of formation** of the carbide: $3Fe+C=Fe_3C-20{\cdot}48$ Cals., and hence stated that the absorption of heat in the formation of iron carbide indicated that the carbon is simply dissolved by the iron. According to O. Ruff and E. Gersten, the **heat of oxidation** is $Fe_3C+3O_2=Fe_3O_4+CO_2+377{\cdot}2\pm0{\cdot}1$ Cal.; and since $C_{\text{graphite}}+O_2$

$=CO_2+94{\cdot}8$ Cals., $Fe+O=FeO+60{\cdot}4\pm1{\cdot}8$ Cals., and $3Fe+2O_2=Fe_3O_4+267{\cdot}1$ $\pm0{\cdot}2$ Cal., it follows that $3Fe+C=Fe_3C-15{\cdot}3\pm0{\cdot}2$ Cal. E. D. Campbell gave +8·494 Cals. for the heat of formation; R. Schenck and co-workers, +8·940 Cals. J. Jermiloff, +2·27 Cals.; and A. Baykoff said that the heat of formation has no perceptible value. From these discordant estimates not much more can be inferred than that the heat of formation has a small negative value. A. Meuthen measured the heat content of iron-carbon alloys containing between 0·06 and 4·03 per cent. of carbon, between 650° and 920°. The heat of transformation of pearlite, containing 0·9 per cent. carbon, is 15·9 Cals. per gram, and that of β- into α-iron, 5·6 Cals. per gram. One gram of α-iron separating from solid soln. develops 14·1 Cals. The horizontal line in the equilibrium diagram, which represents the transformation of β- into α-iron, does not extend beyond 0·32 per cent. carbon. Within the limits 650°–700°, the heat-content of the alloys is not directly proportional to the carbon conc., but the curve consists of two straight lines, intersecting at a considerable angle at a conc. just above that of pearlite.

F. Mylius and co-workers found that dry iron tritacarbide is not altered by exposure to dry **air**, but some specimens are pyrophoric. H. Moissan found that the carbide is not attacked in the cold by dry **oxygen**, but when heated to 150° in oxygen, it becomes incandescent. If heated to 100° in a stream of hydrogen, and then exposed to air, iron tritacarbide glows and forms iron oxide; the same phenomenon occurs occasionally when it is dried at a low temp. in carbon dioxide or nitrogen. In moist air, H. Moissan, and F. Mylius and co-workers noted that iron carbide is rapidly oxidized, it furnishes a brown powder consisting of a mixture of ferric oxide, carbon, and the carbohydrate, $C_{12}H_6O_3$, described by A. Bourgeois and P. Schützenberger, and J. A. Zabudsky. F. Mylius and co-workers say that this carbohydrate is most easily obtained by the action of a soln. of ammonium sulphate in dil. sulphuric acid on the carbide. According to H. Moissan, water or an aq. soln. of sodium chloride or magnesium chloride does not attack iron carbide when contained in a sealed tube at 0° to 150°. F. Mylius and co-workers found that the carbide is only slightly decomposed when heated with **water** at 145°; but at 400°–450°, in a current of steam and nitrogen, it increases 13 per cent. in weight in half an hour, and yields a combustible gas mostly hydrogen, and a black residue which is a mixture of carbon and iron oxide. At a red heat, in steam for half an hour, it yields ferrosoferric oxide, and a gaseous mixture of hydrogen and carbon mono- and di-oxides.

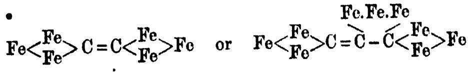
According to H. Moissan, the carbide becomes incandescent in **sulphur** vap. at 500°; it burns in **chlorine** below 100° with incandescence; it behaves similarly with **bromine** at about 100°; and it reacts with **iodine** vap. only at a red heat, without incandescence. **Hydrogen chloride** acts at 600°, forming iron chloride, and hydrogen mixed with some hydrocarbons. All the dil. **acids** attack the metal more readily than the carbide; complete decomposition occurs only on boiling the acid. F. Mylius and co-workers found that the carbide is not appreciably affected by very dil. acids, but with $\frac{1}{10}N$-**hydrochloric acid** at 80° a distinct evolution of hydrogen is observed. It is very gradually dissolved by normal hydrochloric acid, and 1 grm., after remaining sealed up in a vacuum tube for 10 days with normal hydrochloric acid, gave only 2·5 c.c. of a combustible gas. In conc. hydrochloric acid, it is easily soluble, and leaves only a minute residue which is insoluble in water, but easily soluble in alcohol or ether. In no case did the authors observe the formation of amorphous, intermediate, carbonaceous products during the dissolution. An analysis of the gas evolved on dissolving the carbide in hydrochloric acid gave 92·3 per cent. H, 6·3 per cent. hydrocarbons, 1·4 per cent. N. The ratio of the combined hydrogen to the carbon very nearly approaches that required for a member of the series C_nH_{2n+2}, and the density of the hydrocarbon is about the same as that of pentane. E. D. Campbell found that when heated with conc. hydrochloric acid, a mixture of hydrogen with sat. and unsaturated hydrocarbons is formed. Three-fifths of the carbon furnishes gaseous derivatives—a gram of the carbide gave approximately 250 c.c. of gas containing 15–17 per cent. of hydrocarbons, methane, ethane, and butane; and 9–10 per cent. of olefines—principally butylene and dibutylene. H. Moissan found that with dil. hydrochloric acid in a sealed tube, the gas contained 13·7 per cent. of methane and 86·3 per cent. of hydrogen; and with conc. hydrochloric acid, 26·5 per cent. of methane and 73·5 per cent. of hydrogen.

The peculiar nature of the gases evolved when iron carbide, or the solid soln. of the carbide in rapidly quenched steel or pig-iron, is treated with an acid, has been the subject of many investigations. R. Boyle, for instance, referred to "the belching up of copious and stinking-fumes" when steel filings are treated with an acid; and J. Priestley mentioned the fœtid odour of the inflammable air given off when iron is treated with acid In 1786, S. Rinman measured the relative vol. of gas given off by different kinds of iron and steel under these conditions, and noted that the gas evolved from steel contains more carbon than that obtained from soft iron. C. A. Vandermonde and co-workers noted the carbonaceous nature of the residue obtained when iron is treated with acids. In 1799, J. L. Proust observed that the vessel in which the iron has been dissolved has a film of a fatty substance which is not cleaned off by water, but it is removed by alcohol, which dissolves the fatty substance and acquires the same odour as the evolved gas. C. J. B. Karsten showed that when steel is treated with dil. acid, "an offensive kind of hydrogen containing carbon is evolved, and a brown solid is produced." M. Berthelot in 1858, C. E. Schafhäutl in 1859, J. E. Reynolds in 1861, H. Hahn in 1864, and O. Werkmeister in 1910, established the presence of olefines in these gases ranging from C_2 to C_{16}, but H. Hahn said that he was never able to prove the presence of acetylene in the gas. S. Cloez found that when 200 kgrms. of cast iron were treated with sulphuric acid, he obtained (i) 640 grms. of oily hydrocarbons condensed in the first wash-bottles; (ii) 2780 grms. of brominated ethylenic compounds; (iii) 532 grms. of hydrocarbons homologous with methane (paraffins), isolated by sulphuric acid; (iv) 3800 grms. of insoluble residue; and (v) 408 grms. of an oily body, extracted from the insoluble residue by alcohol, and separated from the alcohol by water. The paraffins, decanted from the sulphuric acid, washed with water, and dried, first with potassium hydrate, and then with sodium, were fractionally distilled; the liquid began to boil at 155° giving the following fractions:

155°–160°	178°–180°	195°–198°	215°–220°	234°–238°	258°	276°–280°
$C_{10}H_{22}$	$C_{11}H_{24}$	$C_{12}H_{26}$	$C_{13}H_{28}$	$C_{14}H_{30}$	$C_{15}H_{32}$	$C_{16}H_{34}$

The fact that with some steels and iron carbide all can be dissolved without residue in non-oxidizing acids leaves no room for doubting that the carbon must have been evolved as hydrocarbon. The evidence is not all concordant. H. Hahn said all the products are ethylenic, while S. Cloez, and H. Moissan found a large proportion of methane derivatives. The dark brown carbonaceous residue has been studied by A. Bourgeois and P. Schützenberger, and by J. A. Zabudsky. R. Schenck and co-workers studied the action of acids on the iron carbides.

C. Schols studied the effect of silicon on the solubility of iron carbide in iron. H. Jüptner von Jonstorff attempted to determine the mol. wt. of iron tritacarbide in soln. of iron; but the conclusions were not convincing. E. D. Campbell assumed that iron carbide has the constitutional formula:



$$\mathrm{Fe}{<}{\scriptstyle\mathrm{Fe}\atop\scriptstyle\mathrm{Fe}}{>}\mathrm{C}=\mathrm{C}{<}{\scriptstyle\mathrm{Fe}\atop\scriptstyle\mathrm{Fe}}{>}\mathrm{Fe} \quad \text{or} \quad \mathrm{Fe}{<}{\scriptstyle\mathrm{Fe}\atop\scriptstyle\mathrm{Fe}}{>}\mathrm{C}=\overset{\mathrm{Fe.Fe.Fe}}{\mathrm{C}-\mathrm{C}}{<}{\scriptstyle\mathrm{Fe}\atop\scriptstyle\mathrm{Fe}}{>}\mathrm{Fe}$$

and he represents the main reaction of acids by the equation $(Fe_3C)_2+12HCl =C_2H_4+4H_2+6FeCl_2$; and supposes that the ethylene condenses with itself or with hydrogen, forming more complex products. The reaction in H. Moissan's experiment can be symbolized, $Fe_3C+6HCl=3FeCl_2+CH_4+H_2$; or $(Fe_3C)_3+18HCl =9FeCl_2+6H_2+C_3H_6$ (or $CH_4+C_2H_2$).

Cold fuming **nitric acid,** said H. Moissan, has no action on iron tritacarbide even when finely divided or when in contact with a platinum wire; but the carbide is attacked by the boiling acid; and decomposition rapidly occurs if water be added. C. J. B. Karsten found that when nitric acid or aqua regia acts on rapidly cooled steel or pig iron, no hydrocarbon oil is formed, but a reddish-brown carbonaceous substance, studied by P. Schützenberger and A. Bourgeois, and by J. A. Zabudsky, is formed; it is considered to be a *nitrographitic acid*, $C_{22}H_{17}(NO_2)O_{11}$. The soln.

of cementite in nitric acid of sp. gr. 1·18 to 1·20 furnishes a brown soln., and the intensity of the colour, under constant conditions, is proportional to the amount of carbide in the soln. This principle is applied in the determination of carbon by the so-called *colour test of V. Eggertz.* Here the colour of a given amount of a soln. of a steel with an unknown amount of carbon is compared with that produced by the same weight of a steel with a known amount of carbon prepared under similar conditions. The catalytic activity of iron on methane is conditioned, according to M. Ornstein, by the formation of unstable iron carbide.

A number of complex iron carbides have been made. Thus, J. O. Arnold and A. A. Read[3] reported **ferromanganese carbides**. Fe_7MnC_3 and $Fe_{17}MnC_8$; H. Behrens and A. R. van Linge, **ferrochromium carbides**, $FeCr_3C_2$ and $Fe_7Cr_2C_3$; A. Carnot and E. Goutal, $Fe_9Cr_3C_5$ and $Fe_3Cr_9C_7$; and P. Williams, $Fe_9Cr_6C_7$. P. Williams reported **ferromolybdenum carbide**, $Fe_3Mo_2C_2$; and **ferrotungsten carbide**, $Fe_6W_6C_5$. S. Ozawa made a partial study of the ternary system: C—W—Fe. A. Westgren and G. Phragmen examined the X-radiogram of the tungsten iron carbide. H. Moissan and A. Kouznetoff investigated **chromotungsten carbide**, $Cr_9W_2C_7$. J. de Benneville reported **ferrochromomolybdenum carbide**, $Fe_7Cr_8Mo_8C_4$; and **ferrochromotungsten carbide**, $Fe_7Cr_6W_6C_4$; and J. W. Weitzenkorn, the *ferrochromotungstovanadium carbide*, $VCr_2W_{20}Fe_{22}C_9$, in ferrotungsten.

R. Vogel and G. Tammann studied the ternary system with iron and up to about 10 per cent. each of boron and carbon. The area *AVL*, Fig. 32, represents the ternary system with γ-iron mixed crystals, when the maximum carbon and boron contents are respectively 1·9 and 0·3 per cent. Here *LVNC* represents the ternary γ-iron mixed crystals, *LV*, when the carbon content is about 1·9 per cent. and the boron content up to 0·3 per cent.; and *CN*, cementite mixed crystals with carbon between 5·3 and 6·6 per cent., and boron up to 1·7 per cent. *AVB* represents ternary γ-iron mixed crystals *AV* with carbon up to 1·9 per cent., and boron between 0·08 and 0·3 per cent.; *B* represents iron boride, Fe_2B, corresponding with 91·2 per cent. of iron, and 8·8 per cent. of carbon. *VNB* includes the carbon and boron sat. ternary mixed crystals *V*, with carbon about 1·9 per cent. and boron 0·3 per cent. *N* represents the boron sat. cementite mixed crystals with about 5·3 per cent. of carbon, and 1·7 per cent. of boron. The dotted curves in Fig. 32 represent the eutectic lines. They found the eutectics in the binary systems, Fe—C, 1150°; Fe—B, 1165°; Fe_3C—Fe_3B, 1155°; and Fe—Fe_3C, 1100°. They also measured the hardness of the ternary alloys.

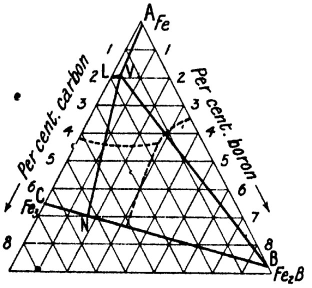


Fig. 32.—Ternary System Fe—C—B.

P. Berthier[4] noticed that when nickel is prepared by reducing the oxide, etc., with carbon, the product is carboniferous nickel. W. Ross, and R. Irving found that the button of metal obtained by reducing nickel oxide with carbon is often covered with soft, crystalline, steel-grey scales which was called *nickel-graphite.* This was probably graphite which separated during the cooling of the soln. of carbon in molten nickel. When nickel is heated in contact with carbon, the metal is carbonized in an analogous manner to iron, but, added H. Moissan, rather less carbon is dissolved. Thus, J. W. Döbereiner mentioned that when fused on charcoal before the oxyhydrogen blowpipe the metal takes up carbon and becomes brittle, but it remains magnetic. R. Tupputi, O. L. Erdmann, and J. B. J. D. Boussingault also made observations on the change produced in the properties of the metal when it is alloyed with carbon. L. Mond and co-workers noticed that nickel takes up carbon when heated with carbon monoxide—*vide* nickel carbonyl. R. Schenck and F. Zimmerman noted the action of rbon monoxide on nickel when studying the system $2CO \rightleftharpoons CO_2+C$. L. Mond and of the

C. Langer studied the action of nickel on hydrocarbons. J. J. Berzelius did not prove that the magnetic residue obtained on igniting nickel cyanide is a definite carbide. According to L. Pebal, nickel obtained by the reduction of the oxide by charcoal at a white heat, may contain as much as 1·4 per cent. of carbon. On treatment with acids the metal dissolves, leaving a residue of graphite. One specimen of the nickel containing 0·98 per cent. of graphite, and 0·28 per cent. of combined carbon, was melted in a graphite crucible, and rapidly cooled in an iron mould, and the product analyzed. It now contained 0·78 per cent. of graphite and 0·61 per cent. of combined carbon. W. Hempel prepared nickel alloys containing 1·71, 2·14, 4·69, and 6·25 per cent. of carbon respectively. K. Nischk studied the formation of nickel carbide. In the nickel alloys, the carbon is in the state of mechanical admixture, whilst in the iron and cobalt alloys a large proportion of the carbon is chemically combined with the metal. The solubility of carbon in nickel has been measured by O. Ruff and co-workers, and by K. Friedrich and A. Leroux. The results shown in Fig. 33 are due to O. Ruff and W. Bormann. The eutectic is at 1311° and 2·2 per cent. of carbon. The solubility of carbon in nickel increases with temp. up to 6·3 per cent. at 2075°, and then remains constant to the b.p. 2490° at 30 mm. press., only 0·28 per cent. of carbon is in the vap. at the b.p. Pure nickel is taken to boil at 2340°. The constant boiling mixture is assumed to contain **nickel tritacarbide,** Ni_3C. E. Gersten found −2095 cals. for the heat of formation of a gram of this carbide, or $3Ni+C=Ni_3C-394$ Cals. E. Briner and R. Senglet saw that nickel tritacarbide is formed at about 2100°, and it dissociates into its elements rapidly at 1600°, and slowly at 900°, so that the reaction $3Ni+C\rightleftharpoons Ni_3C$ is reversible. The reaction between the solid elements is endothermal, and between the gaseous elements, exothermal. J. F. Durand obtained impure **nickelous carbide or acetylide,** NiC_2, by the action of calcium carbide on a soln. of nickelous chloride.

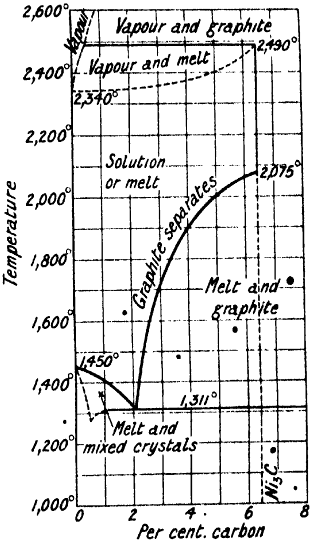

Fig. 33.—The Solubility of Carbon in Nickel.

L. Thompson[5] made a carboniferous cobalt by heating for six hours a mixture of cobalt oxide and alkali tartrate in a crucible lined with carbon. The product was very hard and brittle, and had a sp. gr. of 8·4; it was magnetic and contained 4 per cent. of carbon. K. Nischk studied the formation of cobalt carbides. R. Schenck and F. Zimmermann studied the action of cobalt on carbon monoxide; L. Mond and co-workers observed that no carbonyl is formed by heating cobalt with carbon monoxide; L. Mond and C. Langer noted the action of hydrocarbons on nickel and cobalt. H. N. Warren, and H. Moissan noted the formation of plates of graphite when a soln. of carbon in cobalt is cooled. W. Hempel and P. Rucktäschel prepared cobalt alloys with 0·44, 0·62, 1·87, 1·88, 2·65, 2·80, 6·47, and 8·45 per cent. of carbon respectively, and they noted that a large proportion of the cobalt is chemically combined. G. Boecker, and O. Ruff and F. Keilig studied the cobalt-carbon system. The results by the former are summarized in Fig. 34. There is a eutectic at 1300° with 2·4 per cent. of cobalt; and the solubility increases with temp. up to 7·3 per cent. carbon at 2415°, the b.p. of the system at 30 mm. press. The curve has a point of inflexion corresponding with the formation of **cobalt tritacarbide,** Co_3C. The sat. vap. has 2 per cent. of carbon. The b.p. of pure cobalt is 2415° at 30 mm.

press. The carbide decomposes so quickly on cooling that even in rapidly quenched specimens it is absent. J. F. Durand obtained impure **cobaltous carbide or acetylide,** CoC_2, by the action of calcium carbide on a soln. of cobaltous chloride.

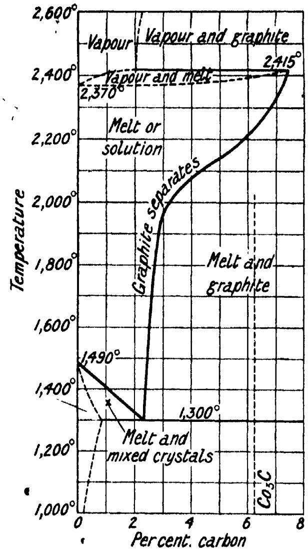

FIG. 34.—The Solubility of Carbon in Cobalt.

The union of platinum with carbon when the two elements are heated has been discussed by J. B. J. D. Boussingault,[6] A. Rémont, J. J. Berzelius, W. Hempel, P. Rucktäschel, R. Chenevix and H. V. Collet-Descotils, P. Schützenberger and A. Colson, C. G. Memminger, N. W. Fischer, V. Meyer, C. L. Berthollet, etc. In using platinum vessels, direct contact with hot smoking flames, the reducing zones of hydrocarbon flames, charcoal, coal, coke, etc., must be avoided, since the platinum becomes brittle under these conditions owing to the dissolution of carbon by the metal. A. B. Griffiths said that platinum fuses at a comparatively low temp. when in contact with carbon. P. Schützenberger claimed to have made **platinum dicarbide,** PtC_2, by heating platinum in a stream of cyanogen; and W. C. Zeise, by heating mesityl chloroplatinite, $[Pt(C_6H_{10}O)Cl_2]_2$, to redness, and cooling out of contact with air. J. J. Berzelius also mentioned **iridium carbide** to be formed by heating iridium in contact with carbon.

§ 21. The Carbon Oxides and Suboxides

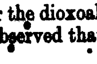
The complete oxidation or combustion of carbon furnishes the gas **carbon dioxide**, CO_2. There is an intermediate product in which the carbon is only partially oxidized or burnt. This product, **carbon monoxide**, CO, is itself a combustible gas which burns to form the end-product, carbon dioxide. If carbon be quadrivalent and oxygen bivalent, the constitutional formula of carbon dioxide is $O{=}C{=}O$; but there is then a difficulty with carbon monoxide, and it can be assumed that two of the four valencies in carbon are latent or dormant. With this hypothesis, H. Staudinger and E. Anthes[1] tried unsuccessfully to prepare the polymer $O=C=C=O$ by the action of metals on oxalyl bromide, Br.OC.CO.Br. With zinc and mercury, carbon monoxide is evolved, showing that if a polymer be capable of a separate existence, it is not stable at ordinary temp. With potassium or the liquid alloy of potassium and sodium, **potassium oxycarbide,** KO.C:C.OK, is formed. This compound explodes violently when subject to vibration. It can also be assumed, with J. A. R. Newlands, that carbon is bivalent, forming $C=O$, and $C<^{O}_{O}$; or, with J. H. Heyes, and J. W. Brühl, that oxygen is quadrivalent, forming carbon monoxide $C\equiv O$ and carbon dioxide $C\begin{smallmatrix}/\!\!/ O\\ \vdots\\ \backslash\!\!\backslash O\end{smallmatrix}$. As indicated above, this subject has been discussed by A. Geuther and R. Rübencamp, L. Mond, D. Lagerlof, etc.—*vide* 1. 6, 13. J. A. Wanklyn assumed that oxygen in carbon monoxide is tervalent.

P. G. Tait and T. Andrews[2] noted that when the silent electric discharge is passed through carbon monoxide, a bronze-coloured product appears on the platinum anode, and by passing an electric discharge through carbon monoxide, B. C. Brodie observed that the products are carbon dioxide and a reddish-brown solid which appears as a film on the walls of the tube. The dry solid appears to be either **carbon suboxide** or a mixture of two or more oxides—possibly C_5O_3 and C_6O_4—since the composition is not always the same. This suboxide is easily soluble in water, and the coloured soln. has a strong acid reaction. M. Berthelot represented the reaction $5CO=CO_2+C_4O_3$. He said that the suboxide is a brown, amorphous body, which is soluble in water and absolute alcohol, but not in ether. It has an acid reaction, and gives with silver nitrate, lead acetate and baryta-water, brown, amorphous precipitates. On heating to 300°-400° in an atm. of nitrogen, it yields equal vols. of carbon monoxide and dioxide, and a dark brown carbon tri-octitoxide, C_8O_3, thus, $3C_4O_3=2CO+2CO_2+C_8O_3$. When this oxide is more strongly heated, it is decomposed, carbon, still containing oxygen, being left behind. P. Schützenberger said that with thoroughly dried carbon monoxide, the composition of the product is variable, and the conversion ceases as soon as the gas contains 10 per cent. of carbon dioxide. If the ozone discharge tube be surrounded by dry air, the dry gas suffers very little condensation, but if it be immersed in acidified water —Fig. 5, 1. 14, 2—the condensation is much greater. Hence, he inferred that the presence of small quantities of water is essential to the formation of the black product, and that the electric discharge carries oxygen and water through the glass, and that there is also some evidence of a transport of matter in the opposite direction, since the total quantity of carbon in the condensed product and in the carbon dioxide was less than that in the carbon monoxide which disappeared. M. Berthelot, however, claimed that P. Schützenberger was misled in assuming that the discharge causes water to pass through glass; the traces of moisture he observed were derived from imperfectly-dried glass and mercury. These materials require for desiccation a moderately high temp.

Another carbon suboxide, C_3O_2, or **carbon ditritoxide,** was prepared by O. Diels and B. Wolf[3] in 1906. It is really **malonic anhydride,** C_3O_2, derived from malonic acid, $CH_2(COOH)_2$, by the loss of two mols. of water:

$$\begin{smallmatrix}H\\H\end{smallmatrix}\!>C<\!\begin{smallmatrix}COOH\\COOH\end{smallmatrix} \rightarrow \begin{smallmatrix}H\\H\end{smallmatrix}\!>C<\!\begin{smallmatrix}CO\\CO\end{smallmatrix}\!>O \rightarrow C\begin{smallmatrix}/\!\!/ CO\\ \backslash\!\!\backslash CO\end{smallmatrix}$$

A. Michael, however, considers it to be the lactone of β-hydroxypropiolic acid:

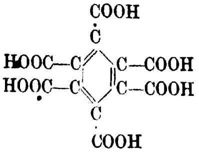


$$\begin{smallmatrix}\quad C\equiv C\\ O=\dot{C}-\dot{O}\end{smallmatrix}$$

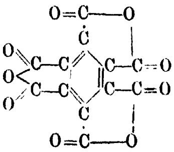
but O. Diels and J. Meyerheim prefer the dioxoallene formula O : C : C : C : O, and in confirmation, O. Diels and L. Lalin observed that the suboxide behaves like a ketene giving with formic acid the additive compound COOH.(COH) : C : (COH).COOH. A. Nowak showed it to be formed by the action of the silent discharge on carbon monoxide : $4CO = C_3O_2 + CO_2$. The compound shows certain analogies with the metal carbonyls, and it can therefore also be regarded as *carbon carbonyl*, $C(CO)_2$. H. S. Redgrove computed the mol. heats of combustion and formation, respectively 243·6 Cals. and 47·4 Cals. for O : C : C : C : O, and 286·1 Cals. and 4·8 Cals. for

O. Diels and B. Wolf made this compound by distilling malonic acid or one of its esters with a large excess of phosphorus pentoxide under reduced press. (12 mm. mercury) at about 300°. The gases are cooled so as to remove the unchanged acid, carbon dioxide, ethylene, etc. The condensate is allowed to boil at atm. temp. and the residue vaporized and collected at −60°. A. Stock and H. Stolzenberg found that the poor yields of carbon suboxide which are usually obtained by the action of phosphoric oxide on malonic acid are due largely to the polymerization of the suboxide under the catalytic influences of the dehydrating agent. If the suboxide be removed rapidly by carrying out the reaction in a good vacuum and condensing the product by means of liquid air, a vol. of the gas corresponding with as much as 25 per cent. of the malonic acid can be obtained. According to E. Ott and K. Schmidt, a superior yield—amounting to 41 per cent.—can be obtained by leading the vap. of diacetyltartaric anhydride, boiling under diminished press., over a platinum wire heated to bright redness. The process has the further advantage that the carbon suboxide so prepared can be preserved for long periods without change in sealed tubes, whereas the product obtained with the help of phosphorus pentoxide rapidly polymerizes, probably owing to the presence of traces of phosphorus oxide. Carbon suboxide is formed by the action of silver, zinc, or lead oxide on malonyl chloride : $CH_2(COCl)_2 + Ag_2O = C_3O_2 + 2AgCl + H_2O$; H. Staudinger and St. Bereza employed silver oxalate or malonate in place of the oxide. E. Ott claims a good yield of purer suboxide by using tartaric acid and acetic anhydride in place of malonic acid in O. Diels and B. Wolf's process. This suboxide at ordinary temp. is a colourless, mobile, volatile, refractive liquid with an odour resembling that of acrolein and mustard oil, and it is poisonous. The vap. attacks the eyes, throat, and respiratory organs producing symptoms of suffocation. When passed through a tube dipping in liquid air, a white solid with a pungent odour is obtained. The solid melts between −107° and −108° and boils at 7°. A. Stock and H. Stolzenberg give −111·3° for the m.p. ; 6° for the b.p. ; and 587–589 mm. for the vap. press. at 0°. O. Diels and co-workers add that the vap. density corresponds with the formula C_3O_2. When treated with water, carbon suboxide re-forms malonic acid, and hence this oxide is regarded as malonic anhydride ; and with hydrogen chloride, ammonia, and aniline it forms malonyl chloride, malonamide, and malonanilide respectively. The suboxide is combustible, and burns with a blue, smoky flame, forming carbon dioxide : $C_3O_2 + 2O_2 = 3CO_2$. The vapour and liquid polymerize at ordinary temp. in a few days ; the liquid becomes yellow and deposits a dark red solid soluble in water. The suboxide decomposes rapidly at 37° and instantaneously at 100°. It was suggested that the solid decomposition products are probably similar to and perhaps identical with the products of B. C. Brodie and M. Berthelot described above. A. Stock and H. Stolzenberg found that the polymerization of the gas to the red substance, which is soluble in water, is catalyzed remarkably by the polymeride itself. The gas may sometimes be kept for days, but once polymerization sets in, it completely disappears within a day. In contact with phosphoric oxide, the gas polymerizes in a fraction of a minute. Carbon suboxide is very soluble in carbon disulphide or xylene.

H. Meyer and K. Steiner[4] made a suboxide, $C_{12}O_9$, **carbon enneadodecitoxide** or **mellitic anhydride** by boiling acid, $C_6(COOH)_6$, under reflux with much benzoyl chloride during six hours. It separates from boiling benzoyl chloride in colourless crystals, which are perfectly stable and non-hygroscopic. It is practically insoluble in cold water, but unites with warm water to form mellitic acid. It gives characteristic colorations when treated with various solvents of high b.p.; thus, with naphthalene, retene, phenanthrene, and fluorene it yields rose-red to bluish-red soln., and with nitrobenzene, a bluish-green soln. It darkens when heated above 320°. The graphic formulæ for acid and anhydride are:



Mellitic acid, $C_6(COOH)_6$.



Mellitic anhydride, $C_{12}O_9$.

§ 22. The History of Carbon Monoxide

Carbon dioxide was for a long time considered to be the only oxide of carbon, and the lower oxide of carbon being combustible was for a long time confused with inflammable air—hydrogen. In 1716, F. Hoffmann [1] wrote on the toxic vapours which emanate from burning charcoal, but he did not recognize this gas. In his memoir: *Notices d'une suite d'expériences nouvelles, qui font connoître la nature et les propriétés de plusieurs espèces d'air ou emanations aëriformes, extraites par diverses voies d'un grand nombre de substances*, J. M. F. de Lassone described the preparation of a combustible gas by heating a mixture of charcoal and zinc oxide. A. L. Lavoisier also obtained a combustible gas with carbon dioxide when a mixture of carbon and alum was calcined; the combustible gas was shown to be different from inflammable air obtained by the action of acids on metals, and on combustion it yielded carbon dioxide. J. Priestley obtained an inflammable air by treating hammer-slag (iron-oxide) with well-calcined charcoal. P. J. Macquer (1778), L. B. G. de Morveau (1784), M. Meusnier and A. L. Lavoisier (1784), and A. F. de Fourcroy (1793) made confirmatory observations, but they did not distinguish between it and the inflammable gas composed of carbon and hydrogen. The gases were confused and called inflammable air. J. Priestley made much of the view of the antiphlogistians that the gas furnished by heating iron oxide and charcoal should be incombustible carbon dioxide, whereas, according to his version of the phlogiston theory, the oxides contain water, and the inflammable air from iron oxide and charcoal was considered to be phlogisticated water. In support of this hypothesis, J. Priestley argued that when steam is passed over red-hot charcoal it is phlogisticated to inflammable air. This explanation puzzled the supporters of A. L. Lavoisier's theory of combustion, and P. A. Adet attempted a reconciliation by assuming that even the most strongly calcined charcoal still contains hydrogen; but J. Priestley (1800) showed that P. A. Adet's hypothesis is not in accord with facts. J. Woodhouse (1799) prepared the combustible air by heating charcoal with other oxides—*e.g.* zinc, copper, lead, manganese, and bismuth oxides—he too showed that P. A. Adet's hypothesis is untenable; and that the combustible air contains carbon. He concluded that the gas in question is a compound of hydrogen and carbon.

In 1800, W. Cruickshank examined the gas obtained by heating carbon with different metal oxides, and he showed that it contained no hydrogen, for, on combustion, it yields no water, and furnishes nothing but an equal vol. of carbon dioxide. Hence, he concluded that it must be an oxygen compound, and called it *gaseous oxide of carbone*—it is now called carbon monoxide. F. Clément and J. B. Désormes made some analogous observations and confirmed W. Cruickshank's results; they determined the composition of the gas, and showed that it is formed when carbon dioxide is passed over red-hot charcoal. C. L. Berthollet opposed the views of W. Cruickshank, and F. Clément and J. B. Désormes, for he said that if carbon monoxide contains more carbon than carbon dioxide it should be specifically heavier. This is not the case, and hence the gas must contain hydrogen, and in 1803, he called it *hydrogene oxi-carburé*. He discounted the absence of any signs of water in the combustion of carbon monoxide by stating that the water remains intimately bound to the carbon dioxide. J. R. Deiman and co-workers (1798) even denied that carbon monoxide contains any oxygen at all, and they regarded it as a hydrocarbon. However, the subsequent work of A. F. de Fourcroy, J. L. Gay Lussac and L. J. Thénard, W. Henry, and F. Clément and J. B. Désormes has shown that carbon monoxide contains no hydrogen; that both carbon monoxide and carbon dioxide are compounds of oxygen and carbon; and that carbon dioxide contains just twice as much oxygen per atom of carbon as is contained in carbon monoxide; or, as J. Dalton expressed it, "carbonic oxide is a binary compound consisting of one atom of charcoal and one of oxygen . . . and carbonic acid is a ternary compound consisting of one atom of charcoal and two of oxygen," *i.e.* carbon monoxide in modern symbols is represented by CO, and carbon dioxide by CO_2. Carbon monoxide was liquefied by L. P. Cailletet in 1877; and solidified by S. von Wroblewsky in 1885.

§ 23. The Occurrence and Preparation of Carbon Monoxide

Traces of carbon monoxide in atmospheric *air* have been reported by A. Müntz and E. Aubin,[1] M. Gruber, F. Clowes, J. Ogier and E. Kohn-Abrest, O. Spitta, A. Mermet, etc. Carbon monoxide has been reported in the gases emitted from *volcanoes* by T. Poleck,[2] M. Scholz, E. T. Allen and E. G. Zies, H. Moissan, E. S. Shepherd, A. Gautier, K. W. Charitschkoff, etc. It has been found in various *minerals* by A. Gautier, W. A. Tilden, R. T. Chamberlin, etc.; in *Stassfurt salts* by H. Precht;[3] in the *diamantiferous earths* at Kimberley by W. Ramsay and M. W. Travers;[4] in *graphite* by J. Dewar and G. Ansdell;[5] in coal, lignites, and coke by A. W. H. Kolbe, F. H. Storer, etc.; in *meteorites* by J. W. Mallet,[6] T. Graham, A. W. Wright, J. Dewar and G. Ansdell, R. T. Chamberlin, etc.; in *iron* and *steel* by F. C. G. Müller;[7] in the *flue gases* from various industrial furnaces by A. Desgrez,[8] etc. It is one of the main constituents of water gas. It is also found as an intermediate product in the combustion of various hydrocarbons—*e.g.* in the interconal gases of Bunsen's flame. Carbon monoxide was found in *coal gas* by P. F. Frankland,[9] A. Wagner, A. Bunte, etc.; and *tobacco smoke* by J. Habermann,[10] R. Liebig, O. Krause, F. Wahl, H. Schwarz, H. Vohl and H. Eulenberg, etc. M. Nicloux [11] found carbon monoxide in the blood of newly-born infants, and numerous observations have been made on carbon monoxide in blood. A. Desgrez, and M. Nicloux found about 1·6 c.c. of carbon monoxide per litre in the normal blood of dogs. E. Pflüger found carbon monoxide in the intestinal gases of some herbivora, but J. Reiset found none. Carbon monoxide has been reported [12] to be formed in the germination of plants.

J. B. J. D. Boussingault [13] observed that small quantities of carbon monoxide are formed at ordinary temp. by the oxidation of organic substances by oxygen or atm. air—*e.g.* tannic and gallic acids, pyrogallol, etc., in the presence of an alkali. F. C. Calvert noted that after being in contact with pyrogallol, the oxygen will be contaminated with 2 to 4 per cent. of carbon monoxides according to the conc. of the alkali soln. of pyrogallol. The maximum amount is formed with one eq. of the pyrogallol and rather more than one eq. of alkali. The reaction is rather important when, in the analysis of mixed gases, the oxygen is removed by pyrogallol, because the results for carbon monoxide, determined after the oxygen, may be too high. The subject has been discussed by S. Cloez, W. Hempel, B. Take, L. de St. Martin, etc. F. Clowes found that the absorption of oxygen with a mixed soln. of 24 per cent. potassium hydroxide and 18 per cent. of hydroquinone is slow but complete, without the evolution of carbon monoxide.

Carbon monoxide and dioxide are found amongst the products of the dry distillation of coal and other organic compounds, and, according to L. Vignon,[14] this the more, the richer the coal is in oxygen; at 900°, he found less than one-third the oxygen in the coal appears as a mixture of these two gases. Carbon monoxide and dioxide are also formed when carbon or organic compounds are burnt in oxygen or air. The former gas is absent if a sufficient excess of oxygen be present—*vide supra*. The equilibrium conditions in the reaction $C+CO_2 \rightleftharpoons 2CO$ have been previously discussed. Carbon monoxide can be made on a large scale by passing carbon dioxide derived from lime-kilns, and flue-gases, through a bed of heated carbon.[15] F. C. G. Müller found that 85 per cent. carbon monoxide is produced when oxygen is passed downwards through a vertical quartz tube packed with wood charcoal the size of linseed. The upper part of the tube should be heated before oxygen is admitted, and the combustion should proceed under reduced press. According to A. K. Huntington, carbon monoxide can be recovered from flue gases, etc., by passing the gas under press. through a soln. of cuprous chloride in ammonium chloride, and the carbon monoxide recovered by reducing the press. A. Fritschi used a soln. of cuprous chloride in hydrochloric acid. The formation of carbon monoxide during the incomplete oxidation of hydrocarbons (*q.v.*) has been noted.[16] A. Kling and D. Florentin found the amount of carbon monoxide produced in the combustion of fuel gases depended rather on the nature of the burner than on the composition of the gas. R. Girard, and E. Kohn-Abrest have discussed this question. R. Bunsen[17] showed that the incomplete combustion of cyanogen furnishes a mixture of carbon monoxide and dioxide. The subject was also investigated by H. B. Dixon and co-workers. A. Gärtner has discussed the contamination of the air of rooms by gas stoves, etc. L. T. Wright, and T. E. Thorpe observed the formation of carbon monoxide in the combustion of coal gas; I. V. Brumbaugh and G. W. Jones, in the combustion of natural gas; Y. Henderson and H. W. Haggard, in the exhaust gases from gas-engines; and W. Cullen, and O. Poppenberg and E. Stephan, in the products of the explosion of blasting gelatin.

The formation of carbon monoxide by the action of steam on red-hot carbon has been previously discussed; so also has the formation of carbon monoxide by heating a mixture of carbon with the carbonates of the alkalies, alkaline earths, and iron; by heating a mixture of carbon and the sulphates of the alkalies and alkaline earths; by heating carbon with sulphur dioxide, or steam and chlorine. The formation of carbon monoxide by heating a mixture of charcoal and a metal oxide has been discussed in connection with the history of this gas. Carbon monoxide is accordingly made by heating to redness mixtures of graphite with the oxides of copper, zinc, lead, or iron; or by heating to redness mixtures of iron or graphite with the carbonate of an alkali or alkaline earth metal. The carbon dioxide is removed by scrubbing with a soln. of alkali hydroxide. H. Jahn found that various alcohols are decomposed into hydrogen, and carbon monoxide. According to E. Noack,[18] when carbon dioxide is passed over heated zinc dust contained in a combustion tube, it is reduced to carbon monoxide; the last traces of carbon dioxide are removed by passing the gas through a soln. of alkali hydroxide. L. P. Kinnicutt said that it is more convenient to heat chalk or magnesite with zinc dust, and added that after the first five minutes, the gas has a high degree of purity. G. Williams noted that hydrogen is produced by heating zinc dust with zinc or some other hydroxide, and H. Schwarz obtained a mixture of hydrogen and carbon monoxide by heating a mixture of 20 grms. of zinc dust, 22·8 grms. of calcium hydroxide, and 30 grms. of calcium carbonate. H. Köhler found that carbon dioxide is reduced by hydrogen sulphide: $CO_2+H_2S=S+H_2O+CO$; and A. Eiloart, by the vap. of carbon disulphide in the presence of red-hot copper: $CS_2+CO_2+4Cu=2Cu_2S+2CO$. H. W. Paulus prepared hydrogen chloride and carbon monoxide by passing a mixture of chlorine and steam through a column of incandescent carbon. The hydrogen chloride can be removed as hydrochloric acid by scrubbing the gases in a water tower.

R. Ehrenfeld[19] found that at a dark red heat, alcohol and charcoal give a mixture of carbon monoxide, methane, and hydrogen. J. A. Muller and E. Peytral observed the formation of some carbon monoxide in the pyrogenic decomposition of formic acid. V. B. Lewes found that phenol reacts $C_6H_5OH+C=CO+C_6H_6$. S. M. Losanitsch found carbon monoxide among the products of the action of the silent electric discharge on methyl alcohol. Cresol behaves similarly. M. Berthelot represented the reaction between acetaldehyde vap. (2 vols.) and hydrogen (5 vols.) at a dark red heat: $CH_3.COH=CO+CH_4$. According to R. Ehrenfeld, aluminium powder on ethyl alcohol at a red heat furnishes carbon monoxide, ethylene, water, and hydrogen, and, according to H. Jahn, zinc dust at 300°–350° gives with methyl alcohol a mixture of carbon monoxide, hydrogen, methane, etc.; ethyl alcohol at a red heat gives carbon monoxide, methane, hydrogen, and a little acetylene; ether, at 300°–350°, gives ethylene and water and traces of carbon monoxide and methane; formic acid gives carbon monoxide, hydrogen, and a trace of methane; acetic acid gives acetone, acetic anhydride, carbon monoxide, hydrogen, ethylene, and propylene; butyric acid gives carbon monoxide, water, propylene, and a ketone; and ethyl acetate gives carbon monoxide and dioxide, ethylene, hydrogen, and acetone. Quite a number of organic products give carbon monoxide and other products when heated *e.g.* aldehyde (A. Bistrzycky and M. Fellmann);[20] citronic acid (C. Wilde); dioxysuccinic acid and oxomalonic ester (R. Anschütz and H. Pauly);

benzoylformic acid (L. Claisen); etc. A. Bistrzycky found carbon monoxide is evolved when the tertiary acids are treated with sulphuric acid; and C. F. Cross and E. J. Bevan found much carbon monoxide is formed when cellulose is heated with sulphuric and chromic acids. P. Schützenberger[21] found that carbonyl chloride when heated with sodium gives sodium chloride and carbon monoxide; and J. Davy found that with antimony pentoxide, carbonyl chloride gives antimony chloride and trioxide and carbon monoxide, while with arsenic, antimony, tin, or zinc, the metal chloride and carbon monoxide are formed. C. von Than, and A. Emmerling and B. von Lengyel said that at a red heat, carbonyl sulphide decomposes into carbon monoxide, sulphur, etc. A. Cöhn and H. Becker found carbon monoxide among the products of the action of the light of a mercury lamp on carbonyl chloride. L. Mond also found carbon monoxide is given off when the metal carbonyls are heated.

According to J. W. Döbereiner,[22] carbon monoxide can be made by heating oxalic acid with sulphuric acid, and removing the carbon dioxide simultaneously formed by scrubbing the gas with calcium oxide or potassium hydroxide. In place of oxalic acid, J. B. A. Dumas used potassium oxalate, and T. D. Mitchell, and L. D. Gale used ammonium oxalate. G. Chevrier passed the mixed gases over red-hot carbon, and then through potash-lye and lime-water. J. S. Stas, and F. W. Skirrow employed his process. A. Scott said that the gas is contaminated with a little hydrogen or hydrocarbons.

Carbon monoxide is made by gently heating, say, 20 to 30 grms. of crystalline oxalic acid, $(COOH)_2.2H_2O$, just covered with conc. sulphuric acid. The rate of evolution of the gas is determined by the temp. of the mixture. Equal vol. of carbon dioxide and carbon monoxide are produced: $(COOH)_2+H_2SO_4=H_2SO_4+H_2O+CO+CO_2$. The former is removed by passing the gas through a series of wash-bottles containing a soln. of sodium hydroxide. This process is more troublesome than the formic acid process.

M. Berthelot heated equi-molar proportions of oxalic acid and glycerol to 100°, and decomposed the product at 190°–200°. The gas was washed in potash-lye. C. Moureu found that oxalates are decomposed by thionyl chloride into carbon monoxide and dioxide. B. Blount obtained carbon monoxide by heating a mixture of calcium oxide and oxalate. C. Engler and J. Grimm also noted that many formates and oxalates decompose when heated giving off carbon monoxide; for instance, 10 c.c. of ethyl oxalate in a sealed tube at 200° furnish a litre of a mixture of carbon monoxide and dioxide, and olefines in the respective proportions by vol. 48·4; 43·8; 7·8. W. Wislicenus found that the esters of oxaloacetic acid at 200° form carbon monoxide and malonic esters.

J. W. Döbereiner[23] prepared carbon monoxide by heating formic acid or a formate with conc. sulphuric acid. The process was employed by F. Göbel, J. Riban, G. André, E. Rupp, Lord Rayleigh, etc. V. Merz and J. Tibiriça used lead formate and sulphuric acid.

Carbon monoxide is perhaps most conveniently made in the laboratory by heating conc. sulphuric acid to about 100° in a flask fitted with a double-bored rubber stopper; one hole of the stopper is fitted with a gas delivery tube, and the other with a tap funnel containing conc. (98 per cent.) formic acid, H.COOH. The tip of the funnel dips below the surface of the sulphuric acid. Each drop of formic acid produces some bubbles of gas. The reaction is simple: $H.COOH+H_2SO_4=H_2SO_4.H_2O+CO$. There is no frothing, and the velocity of the stream of gas is regulated by the rate at which formic acid is dropped on the sulphuric acid. The gas is washed by bubbling it through a conc. soln. of sodium hydroxide. Conc. sulphuric acid can also be mixed with sodium formate in a flask provided with a safety funnel, and very gently warmed. Carbon monoxide is evolved. The rate of evolution of the gas depends on the conc. of the acid. The dynamics of the reaction have been studied by J. Meyer, V. H. Veley, J. S. Morgan, T. Okaya, P. Sabatier and A. Maihle, M. Wegner, and E. R. Schierz.

M. Berthelot found that formic acid decomposes largely into water and carbon monoxide when kept for some hours in a sealed tube at 200°–250°. C. Engler and J. Grimm found that 10 c.c. of the acid when heated 8 hrs. at 150°–160°, furnish 300 c.c. of gas containing 98·8 per cent. of carbon monoxide and 1·2 per cent. of carbon dioxide; ethyl formate under similar conditions gave 300 c.c. of gas with 18·2 per cent. of carbon monoxide; 29·5 per cent. of carbon dioxide, 7·2 per cent. of ethylene, and 45·1 per cent of hydrogen. Amyl formate behaves similarly, furnishing amylene in place of ethylene. When formic acid is decomposed by the electric current, carbon monoxide, carbon dioxide, and hydrogen are formed, the proportion of carbon monoxide is decreased by working under press. A 2 per cent. soln. of formic acid was found by J. Riban to give 1·18 c.c. of carbon monoxide, 0·35 c.c. of carbon dioxide, and 0·39 c.c. of hydrogen when heated for 24 hrs. G. André found that hydrochloric acid accelerated the decomposition of formic acid; and that in the absence of hydrochloric acid, some carbon dioxide is formed. M. Berthelot and H. Gaudechon found carbon monoxide among the products of the decomposition of formic acid by ultra-violet light. J. E. Lorin made carbon monoxide by the action of dehydrated alkali formates or acetates on formic acid at 135°–150°.

Other carboxylic acids—*e.g.* tartaric and citric acids—behave in an analogous manner to formic and oxalic acids. J. Peterson found that carbon monoxide is formed during the electrolysis of malonic acid: $CH_2(COOH)_2+H_2O=3H_2+2CO_2+CO$. The reaction is said to occur in a series of stages: $CH_2(COOH)_2=CH_2(COO)_2''+2H^{\cdot}$; $CH_2(COO)_2+H_2O=CH_2(COOH)_2+O$; $CH_2(COO)_2=CH_2+2CO_2$; and $CH_2+2O=CO+H_2O$.

The cyanides can be regarded as nitrile derivatives of formic acid. G. Fownes[24] made carbon monoxide by heating finely pulverized potassium ferrocyanide with 8–10 times its weight of conc. sulphuric acid: $K_4FeC_6N_6+6H_2O+6H_2SO_4=6CO+2K_2SO_4+FeSO_4+3(NH_4)_2SO_4$. A little carbon dioxide and sulphur dioxide are produced at the beginning of the action, but soon afterwards almost pure carbon monoxide is given off. If the temp. be too high, much frothing will occur. The process was employed by C. Grimm and G. Ramdohr, and by Lord Rayleigh. If the acid be too dil., hydrocyanic acid will be formed: $2K_4FeC_6N_6+3H_2SO_4=3K_2SO_4+K_2Fe_2C_6N_6+6HCN$:

Carbon monoxide is prepared by heating, say, 30 grms. of potassium ferrocyanide with 300 c.c. of conc. sulphuric acid in a capacious flask. In this case, the temp. of decomposition is high, and if the mixture be heated too quickly, the gas is apt to come off so quickly as to be beyond control. If dil. sulphuric acid be used, hydrocyanic acid as well as carbon monoxide may be formed. The process is more troublesome than the formic acid process.

J. Wade and L. C. Panting used potassium cyanide in place of the ferrocyanide. Here again, with dil. sulphuric acid, hydrogen cyanide is produced; and with conc. sulphuric acid, carbon monoxide is produced: $KCN+2H_2SO_4+H_2O=KHSO_4+NH_4HSO_4+CO$. Presumably hydrogen cyanide is formed in both cases, but in the presence of conc. sulphuric acid, formic acid is first produced, and this is converted into carbon monoxide. The carbon monoxide is freed from carbon and sulphur dioxides, and from hydrogen cyanide by scrubbing it twice with a conc. soln. of potassium hydroxide. The carbon dioxide is derived from the presence of carbonates in the potassium cyanide.

A. Geuther[25] obtained carbon monoxide by the action of an aq. or alcoholic soln. of alkali hydroxide on chloroform, $CHCl_3$. G. Moser added that some ethylene and formic acid are produced at the same time. According to A. Desgrez, the reaction with a mixture of 50 grms. of chloroform, 400 grms. of water, and 50 grms. of potassium hydroxide, is symbolized: $CHCl_3+2KOH=2KCl+HCl+H_2O+CO$; or, $CHCl_3+KOH=KCl+2HCl+CO$. The reaction is accelerated by heat and sunlight; it is retarded in darkness; and it is faster than when bromoform is used. J. Thiele and F. Dent said that 50–100 c.c. can be very conveniently made in a nitrometer by adding a few drops of chloroform to a 40 per cent. aq. soln. of potassium hydroxide, and shaking the mixture. G. André, and A. Desgrez noted that when chloroform is heated with ten times its vol. of water to 255°, it furnishes hydrogen chloride and formic acid, and that the latter breaks down into carbon monoxide, etc. G. André found that when a mixture of chloroform and aq. ammonia is heated for six hours at 200°–225°, ammonium formate and carbon monoxide are formed: $2CHCl_3+3H_2O+7NH_3=H.COONH_4+6NH_4Cl+CO$. At 180°, a part of the chloroform is not attacked. A. Desgrez and M. Nicloux stated that the proportion of carbon monoxide in blood increases during anæsthesia by chloroform. This subject has been also discussed by L. de St. Martin. According to M. Hermann, bromoform behaves like chloroform, but the action is slower. No reaction occurs with iodoform; but L. von Stubenrauch found that iodoform is decomposed by silver nitrate: $CHI_3+3AgNO_3+H_2O=3AgI+3HNO_3+CO$; the reaction is apparently favoured by the formation of the insoluble silver iodide.

According to M. Tanret, if a mixture of soln. of chloral-hydrate, $CCl_3.CH(OH)_2$, and potassium permanganate be made alkaline, say with potassium hydroxide, gas is evolved, the liquid becomes discoloured, and sesquioxide of manganese is precipitated. If several grams of chloral-hydrate be acted upon, and the temp. not raised above 40°, the reaction will last for some hours; then on filtering the liquid the filtrate will be found to contain chloride, carbonate, and formate of potassium. The gas evolved is carbon monoxide. The reaction occurs equally well with very dil. soln., and even if borax be substituted for potassium hydroxide. This decomposition leads to a theory to account for the action of chloral-hydrate upon the animal system; it is suggested that when this substance is taken into the circulation, it is submitted to oxidizing agencies; the alkalinity of the serum determines its decomposition; the carbon monoxide displaces the oxygen from the arterial blood, and produces an effect similar to that resulting from poisoning by carbon monoxide. The lowering of the temp. of the body and the prolonged action of the chloral-hydrate, owing to slow decomposition, tend to make this theory more tenable than the assumption of its conversion into chloroform. The slow decomposition of chloral by an oxidizing agent also explains the continuity of its action as a hypnotic, which would not be the case if it were transformed into chloroform. A. Desgrez also found that chloral is rapidly decomposed by an alkali hydroxide with the formation of carbon monoxide. It is assumed that chloroform and alkali formate are produced in the first stage of the reaction; that alkali carbonates or hydrocarbonates do not decompose the chloral; and that aq. ammonia does not act in the cold.

The reputed formation of carbon monoxide and dioxide by the action of radium radiations on silicon, titanium, zirconium, thorium, and lead, is probably a mal-inference from W. Ramsay's experiments.[26]

§ 24. The Physical Properties of Carbon Monoxide

Carbon monoxide may be obtained in all states of aggregation. At ordinary temp. it is a colourless gas without smell or taste; L. P. Cailletet[1] condensed the gas by cooling and obtained a colourless and transparent liquid; while S. von Wroblewsky by further cooling obtained a snow-white crystalline solid. A. Liversidge observed dendritic crystals. According to W. Wahl, when cooled by liquid air carbon monoxide crystallizes in the cubic system. The manner of growth indicates that the prevailing form is that of the rhombic dodecahedron. A. Eucken said that the solid exists in two allotropic forms with a transition temp. at −213°. W. Cruickshank gave 0·9678 for the **relative density** of the gas at 0°, air unity; F. J. Wrede gave 0·96779; R. F. Marchand, 0·96812 in 1845, and 0·87563 in 1848; T. Thomson, 0·9698; H. V. Regnault, 0·9673; A. Leduc, 0·96702; and Lord Rayleigh, 0·96716. The last-named found that the relative densities of the gas prepared by different methods are in close agreement. For the **weight of a litre** of the gas, at 0° and 760 mm., P. A. Guye gave 1·2504 grms.; and A. Jaquerod and F. L. Perrot gave 1·25025 grms. at 0° and 760 mm., and 0·25445 at 1067·4° and 760 mm. P. A. Guye also gave for the gas constant R, 22·413. From his data A. Leduc computed 27·793 for the **molecular weight** of carbon monoxide if that of oxygen be 31·96. Lord Rayleigh calculated that the mol. wt. is 27·9989, if that of oxygen be 32; A. Scott gave 27·99; and A. Jaquerod and F. L. Perrot, 28·009 (at 1067°). The computed mol. wt. is 28·002, and hence at ordinary temp. carbon monoxide approximates closely to an ideal gas. From A. Jaquerod and F. L. Perrot's datum it follows that there is no perceptible dissociation at 1067°, and the gas is virtually in an ideal state; they also pointed out that the mol. wt. of carbon monoxide is the same as that of nitrogen, and that the relative densities and a whole series of physical constants are the same for the two gases—**3**. 27, 4. The comparison was afterwards used by I. Langmuir. The **specific gravity** of the liquefied gas at different temp., and referred to water at 4°, is, according to E. C. C. Baly and F. G. Donnan:

	−205·0°	−200°	−195°	−190° (b.p.)	−185°	−184°
Sp. gr., D . .	0·8558	0·8348	0·8138	0·7929	0·7718	0·7676

and the data can be represented by the expression $D=0·8558-0·0042(T-68)$, when T represents the temp. on the absolute scale.

The **molecular volume** calculated by L. Meyer[2] from T. Graham's diffusion experiments is 15·4; from H. Kopp's rules, 23·2; and from assumption as to the vol. of the atoms, 18·8; and from J. Loschmidt's assumption, 25. The deviations are in part due to the different concepts involved in the term mol. vol.—in some cases the vol. occupied by the mol. is implied, and in others the sphere of action of the mol. A. Naumann also made observations on this subject. D. Berthelot gave 0·99954 for v_0 calculated from $v_0=(vp/p_0)\{1+0·00046(p-p_0)\}$, when v is the vol. under a very small press. p, and p_0 is the normal press. The **weight** of the mol. of carbon monoxide is $28\times1·56\times10^{-24}$ grm.; the **mean diameter** of the mol. is $3·76\times10^{-8}$ cm. C. E. Guye and R. Rudy calculated the mol. diameter from the electromagnetic rotation. The **mean free path** of the mol. computed by J. H. Jeans, etc., is $5·8\times10^{-6}$ cm.; the **collision frequency,** 4800×10^6 encounters per sec.; and the **molecular velocity** represented by the arithmetical mean of the mol. velocities is 454 metres per sec., and by the mean square of the mol. velocities, 493 metres per sec. E. D. Eastman gave for the molar entropy of carbon monoxide 45·6 cals. per degree at 25°. P. D. Foote and F. L. Mohler gave 10·1 and 14·3 volts for the **ionization potentials** of carbon monoxide. R. Gans discussed the symmetry of the mol. of carbon monoxide; M. F. Skinker and J. V. White, and H. B. Wahlin, the motion of the **electrons** in the molecule; and I. Langmuir, E. D. Eastman, V. Henri, H. Nagaska, and G. W. F. Holroyd, the **electronic structure** of the molecule—*vide* **4.** 27, 4; L. B. Loeb, the affinity of the mols. for electrons. The value of **J. D. van der Waals' constant** $a=1·38\times10^6$ to $1·43\times10^6$, say, $1·40\times10^6$; and of his $b=37·7$ to 38·6, say 38·1, when vols. are expressed in c.c. and press. in atm., and if in litres per mm., $a=1064$, and $b=0·061$. J. A. Muller estimated for the degree of **polymerization** in the critical state, 1·328.

O. E. Meyer[3] gave 0·000194 for the **viscosity** coeff. of the gas. T. Graham's values are 0·0001630 at 0° and 0·0001840 at 20°. A. Wüllner, and A. von Obermayer have made observations on this subject. W. Sutherland gave for the effect of temp. on the viscosity, η, of the gas $\eta=\eta_0(1+100a)(1+a\theta)^{\frac{1}{2}}(1+100/T)^{-1}$, where a is the coeff. of thermal expansion; η_0, the viscosity at 0°; θ, the temp. in centigrade degrees, and T the temp. in °K. C. J. Smith gave for the viscosities of mixtures of carbon monoxide and nitrogen, 0·0001665 C.G.S. units at 0°; 0·0001737 at 15°; and 0·0002118 at 100°; and the calculated mean **collision area** is $0·767\times10^{-15}$ sq. cm. The **surface tension** of liquid carbon monoxide was measured by E. C. C. Baly and F. G. Donnan,[4] who found that

	−205°	−203°	−198°	−193°	−188°	−183°
σ . . .	11·00	1·053	9·39	8·27	7·20	6·16
$\sigma(Mv)^{\frac{2}{3}}$ . . .	112·67	108·67	98·66	88·65	78·65	68·64

where M denotes the mol. wt.; v, the sp. vol. in c.c. per gram; and σ, the surface tension in dynes per cm. The effect of temp. on the surface tension was represented by $\sigma=23·77(1-m)^{0·8197}$, where m denotes the reduced temp. J. Dewar gave for the **specific cohesion,** $a^2=3·088$ per sq. mm. at −203°, 2·824 at −193°, and 2·494 at −183°. The effect of temp. on the mol. **surface energy** was represented by $\sigma(Mv)^{\frac{2}{3}}=1·996(132·47-T)$, corresponding with a liquid with normal mol. CO. According to W. J. M. Rankine, the **velocity of sound** in carbon monoxide gas at 0° is 337·40 metres per sec.; A. Masson gave 339·76 metres per sec.; and A. Wüllner, 337·129 metres per sec. Values were also obtained by C. Bender.

T. Graham[5] found that the **diffusion** of carbon monoxide through red-hot iron is such that a capillary tube with walls 1·7 mm. thick allowed 76·5 c.c. of hydrogen to pass per sq. metre per minute, and 0·284 c.c. of carbon monoxide under the same conditions. He also found that the time of transpiration of carbon monoxide through capillary tubes is 0·8750 when that of oxygen is unity; H. St. C. Deville and L. Troost verified this observation and found that even at ordinary temp., cast iron is not impervious to this gas. Similar observations were made by A. J. Morin, and P. J. Coulier. M. Berthelot found that at 625°–650° carbon monoxide can diffuse through glass, and at 800°–810°, the permeability is less. N. R. Campbell discussed the disappearance of carbon monoxide in electric discharge tubes. L. Spencer found carbon monoxide does not diffuse in silver. T. Graham found that the permeabilities of rubber to nitrogen, carbon monoxide and dioxide are in the proportion 13·585 : 12·203 : 1, but the velocities of diffusion are as 1 : 1·113 : 13·585. J. Dewar studied the rate of diffusion of carbon monoxide through indiarubber; and A. von Obermayer, the speed of the mutual diffusion of hydrogen and carbon monoxide, carbon monoxide and dioxide, and carbon monoxide and ethylene; and J. Loschmidt, carbon dioxide and carbon monoxide, and oxygen and carbon monoxide. J. C. Maxwell made observations on this subject. T. Graham found the speed of diffusion of carbon monoxide through a porous plug agreed with his law, velocity of diffusion=$D^{-\frac{1}{2}}$. J. Sameshima and K. Fukaya studied the **atmolysis** of carbon monoxide. F. G. Donnan found the speed of **effusion** of carbon monoxide through a fine opening agreed with T. Graham's law. E. Budde[6] observed a compression of $\frac{1}{727}$th vol. by a press. of 2·79 atm. J. O. Natterer measured the **pv-isothermal curves** of carbon monoxide. He showed that if unit vol. of carbon monoxide be compressed by 3600 atm. press., the vol. is not reduced $\frac{1}{3600}$th as required by Boyle's Law, but it is rather reduced $\frac{1}{800}$th. The values of p_0v_0/pv for different values of p, when p_0v_0 is unity, become

p atm. . .	77	307	629	911	1264	1584	1867	2209	2709
p_0v_0/pv . .	1·000	0·935	0·727	0·578	0·464	0·396	0·352	0·311	0·261

The values of p_0v_0/pv may be taken to represent the **compressibility** of carbon monoxide. E. H. Amagat found for press. p mm., the following relative values of pv at 18°–22°:

p . .	24·1	34·9	55·5	72·2	101·5	177·6	304·1
pv .	27147	27102	27025	27071	27420	29217	33919

H. V. Regnault found the compressibility of carbon monoxide to be 1·00005 between 75 and 150 atm.; Lord Rayleigh gave $\beta=p_{\frac{1}{2}}v_{\frac{1}{2}}/p_1v=1{\cdot}00028$ between 0·5 and 1·0 atm.; and at 13·8° and 0·5 atm., 1·0026. Since $pv=p_0v_0(1+ap)$, $\beta=1-\frac{1}{2}a$; and $a=d(pv)/pv.dp=2(1-\beta)$. For carbon monoxide, $a=-0{\cdot}00081$; and C. Schlatter gave $-0{\cdot}00048$. E. Mascart made some observations on the compressibility of this gas.

H. V. Regnault[7] found the **coefficient of thermal expansion** up to 100° at one atm. initial press.—press. variable and vol. constant—to be 0·0036667; and with press. constant at one atm., and vol. variable between 0° and 100°, 0·0036688. These values are very close to those of an ideal gas. A. Jaquerod and F. L. Perrot found 0·0036648 between 0° and 1067°, and initial press. 230 mm. at constant vol. A. Winkelmann gave for the **thermal conductivity**, 0·0000510 cal. per cm. cube per sec. per degree between 7° and 8°; A. Wüllner, 0·0000499 at 0°, and 0·0000545 at 100°. J. Stefan, and F. Soddy and A. J. Berry made observations on this subject. E. Mallard and H. le Chatelier found the **velocity of cooling** of carbon monoxide between 1800° and 300° to be represented by $V=kp^{-0{\cdot}75}e(e-200)$, where p denotes the gas press.; e, the excess of the temp. of the gas over that of its surroundings; and k is a constant independent of e and p, but dependent on the character of the containing vessel. The value of k for the iron cylinder they used was $0{\cdot}0_43381$.

According to H. V. Regnault,[8] the **specific heat** of carbon monoxide at constant press. is 0·2450–0·2479; and at constant vol., 0·2370–0·2399. E. Wiedemann found at constant press., 0·2425 between 23° and 99°; and 0·2426 between 26° and 198°. M. Berthelot and P. Vieille measured the sp. ht. of mixtures of carbon and nitrogen monoxides. P. Vieille estimated the mean **molecular heat** at ordinary temp. to be $C_v=4{\cdot}8$; at 3100°, $C_v=6{\cdot}30$; at 3600°, $C_v=7{\cdot}30$; and at 4400°, 8·10, on the assumption that dissociation does not occur. E. Mallard and H. le Chatelier represented the effect of temp. on the mol. ht. of carbon monoxide by $C_p=6{\cdot}5+0{\cdot}0006T$. K. Scheel and W. Heuse found for C_p, 7·006 at 18°, and 7·244 at −180°. A. Eucken found the mol. ht. of solid α-carbon monoxide, or carbon monoxide-*II* to be $C_p=2{\cdot}62$, and $C_v=2{\cdot}58$ at 17·5° K.; and $C_p=13{\cdot}64$ and $C_v=9{\cdot}99$ at 57·1° K. The value of C_p was calculated from that of C_v by W. Nernst and F. A. Lindemann's expression $C_p-C_v=ATC_p^2$, where the constant A is $3{\cdot}3\times10^{-4}$. For liquid carbon monoxide, $C_p=12{\cdot}28$ at 62·95° K., and 14·47 at 77·9° K. The value of P. Debye's constant θ is 119. A. Cazin found the **ratio of the two specific heats**, C_p/C_v, of carbon monoxide to be 1·41; A. Masson gave 1·413; A. Leduc, 1·401; and A. Wüllner, 1·40320 at 0°, and 1·39565 at 100°. K. Scheel and W. Heuse found 1·398 for the ratio at 18°, and 1·472 at −180°. J. R. Partington gave 1·205 for the **chemical constant**. H. C. Urey calculated the **entropy** of carbon monoxide at 25° to be 45·6, and R. C. Tolman and R. M. Badger also calculated values for this constant.

M. Faraday,[9] M. Berthelot, and J. O. Natterer failed to liquefy carbon monoxide—M. Faraday worked at 40 atm. press. and a bath of carbon dioxide in vacuo, and J. O. Natterer used a press. of 2790 atm. L. P. Cailletet observed that carbon monoxide remains in the gaseous state when cooled to −29° by sulphur dioxide, and kept under a press. of 300 atm.; if, however, the press. be suddenly relieved, an opaque mist is produced by the liquefaction of the gas. S. von Wroblewsky and K. Olszewsky found that carbon monoxide is not liquefied by a press. of 150 atm. at −136°, but if the press. is suddenly released, liquefaction occurs, and if the release of the press. be not too rapid, the gas is completely liquefied. They announced their discovery in a despatch to the Paris Academy, April 21, 1883, in these words: "Oxyde de carbone liquéfie dans les mêmes conditions que l'azote. Ménisque visible. Liquide incolore." In the modern apparatus, the liquefaction of carbon monoxide is a comparatively simple operation. S. von Wroblewsky found that if liquid carbon monoxide be evaporated in vacuo, the temp. falls to −200°. K. Olszewsky found that the liquid freezes to a snow-like mass or an opaque solid when the liquid is evaporated in vacuo. Before solidification occurs, S. von Wroblewsky said that the liquid becomes viscid and turbid. At a press. of 90–100 mm., and at −199°, a crust of solid forms on the surface of the liquid; the crust then crazes, and the whole mass solidifies. K. Olszewsky found the **temperature of liquefaction**, $\theta°$, of carbon monoxide under different press. p, in atm. to be:

p	25·7	21·5	18·1	14·8	4·6	1·0
θ	−145·3°	−148·8°	−152·0°	−155·7°	−172·6°	−190·0°

S. von Wroblewsky, K. Olszewsky, and E. Cardoso respectively give for the **critical temperature** −141·1°, −139·5°, and −138·7°; and for the **critical pressure**, 35·9, 35·5, and 34·6 atm. H. K. Onnes and co-workers gave −132° for the critical temp. and 35·9 for the critical press. E. Cardoso gave 0·3110 for the **critical density**; and D. A. Goldhammer, 0·2982. S. F. Pickering gave for the best representative values, $\theta_c = -134·4°$; $p_c = 34·6$ atm.; and $D_c = 0·3110$. Carbon monoxide furnishes a colourless transparent liquid with a marked meniscus. It evaporates very quickly. K. Olszewsky gave −190° for the **boiling point** at atm. press., and S. von Wroblewsky, −193°. The latter also said that it boils at −190° under a press. of 735 mm., and at −201·6° under 40 mm. press.; and if 6 per cent. of carbon dioxide be present, the liquid boils at −116° under atm. press. The **vapour pressures** of the liquid and solid have been measured by K. Olszewsky, S. von Wroblewsky, E. C. C. Baly and F. G. Donnan, and H. Happel. The values of S. von Wroblewsky are:

	−201·6°	−198·83°	−197·5°	−190°	−159·7°	−154·73°	−147·73°	−141·2°	−140·2°
Vap. press., p	40	100	160	735	12·80	16·21	23·58	34·42	39·0
	Solid p in mm.				Liquid p in atm.				

E. C. C. Baly and F. G. Donnan gave:

	−205°	−200°	−195°	−191°	−190°	−185°	−183°
Vap. press., mm. . . .	114·30	248·80	483·96	772·35	863·06	1429·98	1722·63

L. P. Cailletet found that carbon monoxide solidifies at −211°; S. von Wroblewsky, at −199°; and K. Olszewsky, at −207° and under 100 mm. press. The **melting point**, according to A. Eucken, is −212·6°, or 60·4° K. The solid exists in two forms with a transition point at −213° or 60° K. Hence,

$$CO_{gas} \overset{-191°}{\rightleftharpoons} CO_{liquid} \overset{-212·6°}{\rightleftharpoons} CO_{\beta\text{-solid}} \overset{-213°}{\rightleftharpoons} CO_{\alpha\text{-solid}}$$

A. Eucken found 144·1 cals. per mol for the **heat of transformation** of the solid; 224·1 cals. per mol for the **heat of fusion**; and 1414 cals. per mol for the **heat of vaporization.** K. Bennewitz and F. Simon studied Trouton's constant for carbon monoxide.

J. Thomsen[10] obtained for the **heat of formation** of carbon monoxide $C+O=CO+30{\cdot}315$ Cals.; M. Berthelot and C. Matignon $+26{\cdot}1$ Cals.; and M. Berthelot, 25·7 Cals. with diamond carbon, and 28·7 Cals. with amorphous carbon. H. Jüptner von Jonstorff found the **free energy,** F, of the reaction $C+\frac{1}{2}O_2=CO$ to be $F=28652{\cdot}2+2{\cdot}53T+4{\cdot}56T \log p_{O_2}^{\frac{1}{2}}/p_{CO}$; and for the reaction $C+CO_2=2CO$, $F=-40657{\cdot}8+40{\cdot}15T+4{\cdot}56T \log p_{CO_2}/p_{CO}^2$. G. Bodländer, and E. Baur made observations on this subject. The **heat of solution** of 28 grms. of carbon monoxide in an acid soln. of cuprous chloride was found by H. Hammerl to be 11·37 Cals. J. Bronn calculated 5000° for the temp. of combustion of carbon monoxide, and for the **heat of combustion** of carbon monoxide, P. L. Dulong gave 69·9 Cals.; and C. Grassi, 52·5 Cals. T. Andrews found for a litre of carbon monoxide with excess oxygen, 3·057 Cals.; for a litre of oxygen with excess carbon monoxide, 6·114 Cals.; for a gram of oxygen with excess carbon monoxide, 4·255 Cals.; and for a gram of carbon monoxide with excess oxygen, 2·431 Cals., P. A. Favre and J. T. Silbermann gave 2·403 Cals. per gram of carbon monoxide. J. Thomsen gave $CO+O=CO_2+66{\cdot}810$ Cals.; and (CO, O, aq.)=72·69 Cals. M. Berthelot gave 68·3 Cals.; D. Lagerlof, 68·4 Cals. at constant vol.; and M. Berthelot and C. Matignon, 67·9 Cals. at constant vol., and 68·2 Cals. at constant press. The subject has been discussed by H. E. Armstrong, A. Boillot, and by S. U. Pickering—*vide* combustion of carbon.

Carbon monoxide thus represents partially-burnt carbon. When formed by the combustion of carbon in air, the product is called *simple producer gas.* It is used as a fuel in the so-called gas-firing. In the ideal case, producer gas contains 34·7 per cent. by vol. or weight of carbon monoxide, and 65·3 per cent. of nitrogen. One pound of carbon furnishes 6·71 lbs. of simple producer gas:

	Heat units.
One pound of carbon burning to carbon dioxide gives	8080
6·71 lbs. of producer gas burning to carbon dioxide give	5588
Difference	2492

This difference, approximately 31 per cent., represents a kind of dead charge on the process of converting the solid fuel into gaseous fuel—simple producer gas. It shows that so far as mere fuel-saving is concerned, the use of gaseous fuel in preference to direct firing is not necessarily economical.

W. H. Miller[11] showed that carbon monoxide gas is transparent to the chemical rays. The **index of refraction** has been determined by E. Mascart, F. Perreau, J. Koch, H. C. Rentschler, M. Croullebois, C. and M. Cuthbertson, J. Klemencic, F. Mohr, and G. Gruschke. The following are selected from their results for light of wave-length λ:

$\lambda(\mu\mu)$.	334·2	471·3	501·6	546·2	589·6	644·0	670·9	867·8
Index	1·0003442	1·0003394	1·0003379	1·0003361	1·000349	1·0003328	1·0003325	1·00033255

T. M. Lowry inferred from the index of refraction and sp. inductive capacity that the mol. is not internally ionized. E. Mascart gave for the **dispersion** 0·0075. A. Kundt and W. C. Röntgen found 0·000232 for the electromagnetic **rotation of the plane of polarized light** in carbon monoxide at 20° and atm. press., referred to that of carbon disulphide at the same temp. E. von Bahr measured the absorption of the ultra-violet rays by carbon monoxide; H. Baerwald, A. Becker, and J. Robinson, the absorption coeff. for **cathode rays**; and J. J. McHenry, the action of the **positive rays** on carbon monoxide. A. Forshaw investigated the **luminosity** of the burning gas. The **spectrum** of carbon monoxide has been discussed in connection with that of carbon. E. C. Kembel[12] computed the relative intensities of the bands in the ultra-red spectrum; and C. Schaefer, and M. Thomas studied the structure of the ultra-red absorption spectrum; and V. Henri, the absorption spectrum. M. Duffieux calculated the mass of the particles that emit the spectrum of carbon monoxide. W. W. Coblentz measured the **ultra-red spectrum** of carbon monoxide at 0·8 mm. press. and obtained the result shown in Fig. 35. C. Schaefer measured the ultra-red spectrum of carbon monoxide.

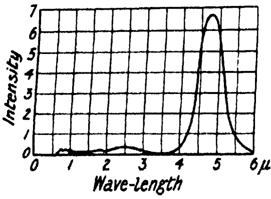

Fig. 35.—Ultra-red Emission Spectrum of Carbon Monoxide.

G. Gehlhoff[13] measured the **cathode fall of potential** of carbon monoxide eliminating the effects of decomposition. He was unable to confirm the statement that the cathode fall of potential of a compound gas is the sum of the separate values calculated for the component atoms. G. Stead and B. S. Gossling gave 15 volts, and C. G. Found 13·5 to 14 volts for the **ionizing potential**; and A. L. Hughes and A. A. Dixon, 7·2 volts. P. D. Foote and F. L. Mohler found two ionizing potentials, 10·1 volts and 14·3 volts; and C. A. Mackay gave 14·1 and 15·6 volts. H. B. Wahlin measured the affinity of the mols. of carbon monoxide for the electrons. E. P. Metcalfe measured the **ionization by α-rays** in various gases. Assuming that the additive law applies, the value for carbon was 0·42 from the series oxygen, carbon dioxide, carbon monoxide; while for the series methyl, ethyl, and butyl alcohols the value 0·69 was obtained, and a similar value was obtained for carbon from the series hydrogen, methane, ethane, propane, butane, and pentane. Hence, only for a series of related compounds is the additive law applicable. The combustion of dry filtered carbon monoxide gives rise to ions of an order of mobility totally different from those produced by the moist gas. Direct comparison of the ions produced in air by radium and by a dry carbon monoxide flame showed that the mobility of the positive ions is 20 per cent. greater, and of the negative ions 70 per cent. greater, in the case of radium. Hence it is inferred that the ions produced by the combustion of carbon monoxide and by radium have very similar mobilities and are probably identical. M. F. Skinner and co-workers, and R. N. Chaudhuri also studied the motion of the electrons in crossed electric and magnetic fields. M. Brotherton studied the emission of electrons when liquid alloys of sodium and potassium act on carbonyl chloride.

M. de Broglie, and V. Hoeper measured the **electromotive force** of carbon monoxide and oxygen gas cells, and found the e.m.f. of the combination Pt : CO : HCl : HgCl : Hg : HgCl : HCl : O : Pt is 0·45 volt, and when carbon is substituted for platinum, a similar value is obtained. H. Kallmann found that the e.m.f., E, of cells containing carbon monoxide, carbon dioxide, and oxygen on one side of a glass wall, and air on the other at 717° and at press. between 800–920 mm., could be expressed by the equation $E=1{\cdot}118-0{\cdot}0707 \log p_{CO_2}/p_{CO}p_{O_2}^{\frac{1}{2}}$. From the effects obtained by mixing air with the carbon monoxide, V. Hoeper inferred that carbon monoxide is not indifferent to oxygen but unites with it to form carbon dioxide. It was also found that the potential difference between platinum and a soln. of cuprous chloride is the same whether the soln. contains carbon monoxide or not. Similar results were obtained with carbon. The basis of W. Borcher's cell, Cu : CO : CuCl : O : C, is Cu : CuCl : C with an e.m.f. of 0·45 volt. The e.m.f. is not appreciably affected by introducing carbon monoxide about the copper electrode and oxygen about the carbon electrode. The oxygen, however, prevents the separation of copper at the carbon electrode, and thus the element cannot assume the form Cu : CO : CuCl : Cu with an e.m.f. practically zero. The carbon monoxide is oxidized to carbon dioxide at the copper electrode, and this gives a continuous current. F. Haber and A. Moser made cells in the following manner:

> The lower end of a test-tube was etched inside and outside with hydrofluoric acid, the roughened surfaces moistened with platinic chloride and heated so as to produce a coating of spongy platinum; electrical contact was made to the coatings by means of platinum

wires, and suitable tubes were introduced to allow carbon monoxide, oxygen, or other gases to be brought into contact with the platinum coatings. The whole was heated by a jacket of boiling sulphur or phosphorus pentasulphide. The hot glass itself acted as the electrolyte, the two coatings of platinum being the electrodes. Air about the outer coating may be considered as the gas about one electrode.

The e.m.f. observed for $CO+\frac{1}{2}O_2=CO_2$ were in agreement with those calculated from $F=67440-2{\cdot}42T\log T+0{\cdot}0017T^2-4{\cdot}56\log_{10}p_{CO_2}/p_{CO}p_{O_2}^{\frac{1}{2}}-5{\cdot}95T$, between 717° and 791°. When pure carbon monoxide is used, it decomposes in presence of the platinum, depositing carbon. This deposit of carbon produces an e.m.f. of nearly 1 volt. That the e.m.f. is due to the carbon is proved by the fact that it persists in presence of carbon dioxide, but disappears if oxygen be passed in. The resistance of the carbon monoxide-oxygen cell is about 500 ohms. When closed through an external resistance, a current was produced which at first rapidly diminished; after a minute it reached the value $0{\cdot}32\times10^{-4}$ ampère and the e.m.f. of the cell had fallen to 0·26 volt. M. Faraday, and J. Plücker found carbon monoxide to be diamagnetic. L. Boltzmann gave for the **dielectric constant** at 0°, and one atm. press., 1·000690; J. Klemencic, 1·000695, and A. P. Carman and G. T. Lorance, 1·00099. H. Riegger found 1·002633 at −189°. C. E. Guye and R. Rudy measured the **electromagnetic rotation** of the gas. H. Weigt gave $(0{\cdot}1180\pm0{\cdot}0016)\times10^{-18}$ for the **electrical moment** of carbon monoxide.

§ 25. The Solubility of Carbon Monoxide

H. Davy[1] reported that water absorbs $\frac{1}{50}$th of its vol. of this gas; J. Dalton said $\frac{1}{27}$th; and T. de Saussure, $\frac{1}{16}$th. Other observations have been made by K. Angström, A. Christoff, S. Gniewasz and A. Walfisz, G. Hüfner, E. Wiedemann, and A. Findlay and H. J. M. Creighton. R. Bunsen represented his determinations of the solubility by the formula: $\beta=0{\cdot}032874-0{\cdot}0008163 2\theta+0{\cdot}000016{\cdot}421\theta^2$, where β, the **absorption coefficient**, denotes the vol. of carbon monoxide reduced to n.p. θ, absorbed by one vol. of water when the press. of the gas apart from that of the solvent is 760 mm. F. Henrich recalculated R. W. Bunsen's data and gave the formula $\beta=0{\cdot}032784-0{\cdot}00080094\theta+0{\cdot}000015872\theta^2$. The following is a selection from L. W. Winkler's observations:

	0°	5°	10°	15°	20°	40°	60°	80°	100°
β .	0·03537	0·03149	0·02816	0·02543	0·02319	0·01775	0·01488	0·01430	0·01410
q .	0·0044	0·0039	0·0035	0·0031	0·0028	0·0021	0·0015	0·0010	0·0000

It also includes q, the number of grams of carbon monoxide absorbed by 100 grms. of water at a total press. of 760 mm. The **solubility coefficient**, l, representing the ratio of the vol. v of the gas absorbed at any press. and temp., to the vol., V, of the absorbing liquid such that $l=v/V$, can be calculated from the absorption coeff. by the relation $l=\beta(1+0{\cdot}003667\theta)$. G. Just gave 0·02586 for water at 20°, and 0·02404 for water at 25°. K. Angström estimated that the absorption by water of a vol. of carbon monoxide equal to its own vol. causes an expansion of 0·00127 vol.

According to F. Leblanc,[2] soln. of *cuprous chloride* in hydrochloric acid readily absorb carbon monoxide, and this is accompanied by a slight rise of temp.; ammoniacal soln. of cuprous chloride is also a good absorbent. The soln. sat. with carbon monoxide can be treated with much water without the separation of cuprous chloride, or the evolution of gas. The gas is given off when the soln. is boiled or treated in vacuo. These soln. of cuprous chloride are accordingly used as absorbents for carbon monoxide in gas analysis—*vide* cuprous chloride, **3**. 21, 13. A. Kropf found that a little stannous chloride in a hydrochloric acid soln. of cuprous chloride increased the absorptive power for carbon monoxide. A. T. Larson and C. S. Teitsworth studied the absorption of carbon monoxide by ammoniacal soln. of cuprous carbonate and formate. F. Jean showed that the gas is also absorbed by an ammoniacal soln. of *silver oxide*. A. Desgrez and co-workers, and A. Piutti discussed the rate of absorption of carbon monoxide by chromic acid, potassium permanganate, alkali peroxides, and iodine pentoxide, from currents of gas. A. B. Lamb and co-workers reported on the removal of carbon monoxide from air.

L. W. Winkler developed an empirical relation between the absorption coeff., β, and the viscosity coeff., η, such that at temp. θ and θ_1,

$$\frac{\beta_\theta-\beta_{\theta_1}}{\beta_\theta}=\frac{\eta_\theta-\eta_{\theta_1}}{\eta_\theta}\cdot\frac{M^{\frac{1}{3}}}{k}$$

where k is a constant, and M is the mol. wt. of the gas. T. E. Thorpe and J. W. Rodger showed that the real relation can be represented by

$$\frac{1}{\beta}\cdot\frac{d\beta}{d\theta}=k\frac{1}{\eta}\cdot\frac{d\eta}{d\theta}.$$

K. Angström found that the increase in the vol. of water sat. with carbon monoxide is 0·0000418, or 0·00127 per unit vol. of gas absorbed. The press. necessary to compress the gas from unit vol. to 0·00127 vol. is 3200 atm. L. Cassuto measured the effect of press. on the solubility of carbon monoxide in water. P. Villard observed no signs of the formation of a hydrate when carbon monoxide dissolves in water.

A. Christoff[3] measured the solubility coeff. of carbon monoxide in dil. *sulphuric acid*, at 25°, and found for water, 0·02482; for 35·82 per cent. sulphuric acid, 0·0114; for 61·62 per cent. acid, 0·00958; and for 95·6 per cent. acid, 0·0245. G. R. Fonda measured the solubility in aq. soln. of *sodium hydroxide*, of *potassium hydroxide*, and of *sodium nitrate*. The results with the alkali-lye are attended by the formation of sodium formate: $CO+NaOH \rightleftharpoons H.COONa$; if p_0 represents the initial press. of the carbon monoxide, and p the press. at the time t, $k=\{\log(p_0/p)\}/t$. The results are shown graphically in Fig. 36.

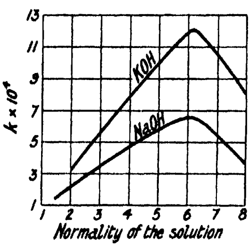

FIG. 36.—Solubility of Carbon Monoxide in Solutions of Potassium and Sodium Hydroxides.

The solubility of carbon monoxide in a number of organic solvents has been determined. M. Berthelot said that the solubility in *ethyl alcohol* is seven or eight times as great as it is in water. L. Carius found that the solubility in ethyl alcohol between 0° and 25° was constant within the limits of his experimental error such that $\beta=0·20443$, but G. Just gave for the solubility coefficients respectively at 20° and 25°, ethyl alcohol, 0·1901 and 0·1921; *methyl alcohol*, 0·1830 and 0·1955; *amyl alcohol*, 0·1706 and 0·1714, *aniline*, 0·05055 and 0·05358; *carbon disulphide*, 0·08112 and 0·08314; *nitrobenzene*, 0·09105 and 0·09366; *benzene*, 0·1645 and 0·1707; *acetic acid*, 0·1689 and 0·1714; *xylene*, 0·1744 and 0·1781; *toluene*, 0·1742 and 0·1808; *chloroform*, 0·1897 and 0·1954; *amyl acetate*, 0·2108 and 0·2140; *acetone*, 0·2128 and 0·2225; *isobutyl acetate*, 0·2314 and 0·2365; and *ethyl acetate*, 0·2419 and 0·2516. A. Christoff gave for the solubility coeff. of carbon monoxide in *ether* at 0° and 10° respectively 0·3618 and 0·3842. G. Claude measured the solubility of carbon monoxide in ether between 20° and −40°, and for press. up to 1600 atm. S. Gniewasz and A. Walfisz found 100 vols. of *petroleum* absorb 13·4 vols. of carbon monoxide at 10°, and 12·3 vols. at 20°. P. Falciola made cryoscopic observations on the solubility of carbon monoxide in water, *formic acid*, acetic acid, benzene, nitrobenzene, *acetophenone*, *phenol*, *p*-xylene, *bromoform*, and *ethylene dibromide*. O. Lubarsch gave for the solubility of carbon monoxide in mixtures of ethyl alcohol and water at 20° and 760 mm.

Per cent. alcohol	0	9·9	16·67	23·08	28·57	33·33	50·00
Per cent. CO absorbed	2·41	1·87	1·75	1·68	1·50	1·94	3·20

F. W. Skirrow observed the solubility of carbon monoxide in a number of mixtures at 25°—*e.g.* in a soln. of aniline, carbon disulphide, naphthalene, *phenanthrene*, *a-naphthol*, *β-naphthol*, ethyl alcohol, nitrobenzene, chloroform, toluene, or benzene in acetic acid, acetone, benzene, or toluene; also in mixtures of methyl alcohol with chloroform or glycerol, or in a mixture of carbon disulphide and ethylene dichloride. It was concluded that the solubility in various mixtures of organic solvents is, in general, an additive function.

According to A. Schwenkenbecher,[4] carbon monoxide is not absorbed through the *skin*. G. Hüfner found the absorption coeff. in hæmoglobin between 19·50° and 20·25° varies from 0·02018 to 0·02290. Hence, the gas is less soluble in hæmoglobin soln. than in water. A. Findlay and H. J. M. Creighton measured the solubility of carbon monoxide in the *blood* and *serum* of the ox. In both cases the solubility is less than in water. N. Gréhant found that 100 c.c. of blood absorbed from air mixed with carbon monoxide:

Parts of CO	0·001	0·0050	0·00250	0·00167	0·00083	0·00067	0·00038	0·00019
Absorbed CO in 1 hr.	8·0	4·1	3·0	1·6	—	0·59	0·44	0·22
Absorbed CO in 2 hrs.	10·0	7·8	4·2	3·1	1·63	1·18	0·88	0·45

J. Hunter[5] found that one vol. of wood *charcoal* at ordinary temp. adsorbed 21·2 vols. of carbon monoxide, reduced to 0° and 760 mm.; R. A. Smith found 6·00 to 6·03 vols. of gas were adsorbed. J. Dewar found that one c.c. of wood charcoal at 0° adsorbed 21 c.c. of gas, and at −185°, 190 c.c.; 27·5 cals. of heat were developed during the adsorption. J. F. Homfray, W. Hempel and G. Vater, and E. Blumtritt made observations on this subject—*vide supra.* T. Graham observed that at a dull red heat, *iron* absorbs 4·15 vols. of carbon monoxide which is given up at a higher temp. or in vacuo. H. Caron said that molten cast iron does not adsorb carbon monoxide—*vide supra,* diffusion of carbon monoxide. A. Sieverts and W. Krumbhaar found carbon monoxide dissolves in solid and in molten *nickel,* but it does not dissolve in copper at 1520°. A. Matthiessen and W. J. Russell said that *copper* melted under charcoal does not adsorb carbon monoxide, but H. Caron reported that molten copper absorbs some carbon monoxide and gives it up on cooling. T. Graham found that *silver* adsorbs 0·15 vol. and *gold* 0·29 vol. of carbon monoxide. The adsorption of carbon monoxide by iron, nickel, *cobalt,* copper, *palladium,* and *platinum* was studied by H. S. Taylor and R. M. Burns—*vide* the respective metals—and also by *copper, cobalt, manganese, and silicon oxides.* W. W. Hurst and E. K. Rideal studied the adsorption of carbon monoxide by copper, and copper-palladium. A. Berliner, F. H. Pollard, and D. Tommasi found that platinum absorbs carbon monoxide. According to M. Berthelot, the vol. of carbon monoxide retained by air-dried *clay-soil* is equal to the vol. of air which it can retain, and hence the retention of carbon monoxide by the earth after an explosion in a mine, for example, is not due to any specific action between the soil and the gas. For the solubility of carbon monoxide in glass, *vide supra,* diffusion.

§ 26. The Chemical Properties of Carbon Monoxide

Carbon monoxide can be preserved an indefinitely long time in a glass gas-holder.[1] According to W. Henry,[2] and J. Plücker, the gas is slowly decomposed by the passage of an **electric discharge**, forming, said H. St. C. Deville, carbon and carbon dioxide; if the latter gas be absorbed by a soln. of potassium hydroxide, the decomposition may be complete. H. Buff and A. W. Hofmann said that the induction spark is without action on the dried gas. J. N. Collie noted that carbon monoxide is far more stable than carbon dioxide. He stated that the gas may be treated with powerful sparks for half an hour without an appreciable result, and the product gives no turbidity with baryta-water. If, however, the current be sufficiently strong to make the negative electrode red hot, a very small amount of carbon dioxide is produced, too little to measure, but sufficiently great to cause a white precipitate with baryta-water, and small specks of something black, presumably carbon, collect on the positive electrode. P. G. Tait and T. Andrews observed that the silent discharge caused the gas steadily to contract. After 60 hrs.' exposure, the gas had contracted one-third in vol. and contained carbon dioxide, oxygen, and undecomposed carbon monoxide. A bronze-coloured deposit appeared on the positive electrode. This deposit was investigated by M. Berthelot, etc.—*vide* carbon suboxide. A. Grau and F. Russ studied the action of an electric arc between platinum electrodes in carbon monoxide contained in a quartz tube. A. T. Cameron and W. Ramsay found carbon dioxide is formed when **radium emanation** acts on carbon monoxide.

H. St. C. Deville[3] found that carbon monoxide is reversibly decomposed at a bright red **heat**: $2CO \rightleftharpoons C+CO_2$, but, said M. Berthelot, the amount decomposed is very small. Very little change was observed in carbon monoxide contained in a quartz tube at 1000°, and rapidly cooled. C. Langer and V. Meyer said that carbon monoxide is not appreciably affected at 1200°, and at 1690° the gas is partially decomposed; but H. C. Woltereck said that the dissociation begins between 570° and 580°. F. Würtenberger observed that the carbon monoxide in producer gas at 1000° was practically decomposed: $2CO=CO_2+C$. A. Gautier said that the formation of carbon dioxide at 560° is perhaps conditioned by the presence of a trace of hydrogen in the gas: $2CO+2H_2=CO_2+CH_4$. The reversibility of the reaction, and the equilibrium conditions have been previously discussed in connection with the action of oxygen on carbon. By using a catalytic mass of palladium deposited on activated charcoal or upon activated silicic acid, G. Fester and G. Brude found that the reaction $2CO=C+CO_2$ occurs at moderate temp., thus, at 65°, one per cent. carbon dioxide was formed; at 110°, 11 per cent.; and if the mixed gases were left in contact with the catalyst, 0·6 per cent. at 35°; 12 per cent. at 100°; and 55 per cent. at 240°. A little hydrogen was also derived from the moisture in the silica.

According to K. G. Falk,[4] and M. Berthelot, mixtures of carbon monoxide and **hydrogen** do not show any inclination to react when inflamed; and H. le Chatelier and O. Boudouard found the inflammability of the mixture is such that if n and n' respectively represent the lower limits of inflammability of carbon monoxide and hydrogen in air, and N and N' the limits for the gases separately mixed with air, then the relation $n/N+n'/N=1$ holds approximately. M. Berthelot found that if sparks from an induction coil be sent through a mixture of carbon monoxide and hydrogen, traces of acetylene are produced only when moist potassium hydroxide is present to absorb the moisture and carbon dioxide which are formed. B. C. Brodie found that when the mixed gases are sparked, the decrease in vol. is accompanied by the formation of some methane, carbon dioxide, and small drops of a liquid, probably formic acid, H.CO.OH. M. Berthelot obtained ethane, and a condensation product, $(C_4H_6O_3)_n$. With the equal vols. of the mixed gases in an ozone tube, S. M. Losanitsch and M. Z. Jovitschitsch, and A. de Hemptinne observed the formation of formic acid, H.CO.OH; M. Berthelot, the formation of carbohydrates $nCO+nH_2=C_nH_{2n}O_n-mH_2O$; and A. Slosse, and A. Nowak, and W. Löb, the formation of formaldehyde, H.CO.H, and methyl alcohol, CH_3OH. W. Löb observed that some glycollic aldehyde is also formed. E. Sarrau and P. Vieille observed the reduction of carbon monoxide to methane in the presence of finely-divided nickel. A. Gautier represented the formation of carbon dioxide in the reaction by assuming that water is first formed and that this reacts with the monoxide to form the dioxide. He said the reduction begins at about 400°, and that some methane is formed. When a mixture of carbon monoxide and hydrogen is passed over finely-divided nickel at 190°–200°, a reaction sets in, $CO+3H_2=CH_4+H_2O+51\cdot1$ Cals., which progresses smoothly at 250°. The nickel is not appreciably influenced during the operation. At 280°, some carbon dioxide is also formed. The reduction of carbon monoxide by hydrogen in the presence of finely-divided cobalt begins at 270° and proceeds smoothly at 300°. E. F. Armstrong and T. P. Hilditch found that towards 300°, in the presence of nickel, one of the reactions is represented by the equation $2CO+2H_2=CO_2+CH_4$. F. Fischer and co-workers studied the formation of methane from carbon monoxide and hydrogen in the presence of iron at 400°; the amount formed is small under ordinary press., but at 40 atm. press. 33·5 per cent. of methane and a little ethane were produced. The hydrogenation with cobalt is less marked than with nickel. With finely-divided platinum, palladium, or iron, methane is not formed below 400°. M. Mayer and co-workers noted that much methane is formed when nickel is the catalyst, and but little when iron is the catalyst. As indicated above, G. Fester and G. Brude passed a mixture of hydrogen and carbon monoxide over palladium deposited on activated charcoal or silica, and found 16·1 per cent. of carbon dioxide at 100°. F. Orloff noted the formation of some ethylene, C_2H_4, when nickel or palladium is used as catalyst at 95°–100°; but G. Fester and G. Brude could not confirm this. G. Fester, however, confirmed the observation that with nickel or palladized asbestos as catalyst, at 100°, unsaturated hydrocarbons and not methane are formed. The catalyst soon loses its activity. H. S. Elworthy and E. H. Williamson patented processes for converting water-gas—a mixture of carbon monoxide and hydrogen—into methane. D. Berthelot and H. Gaudechon found that in ultra-violet light, a mixture of carbon monoxide and hydrogen produces some formaldehyde. M. Mayer and V. Altmayer found that carbon monoxide is reduced to methane by **calcium hydride** at 400°–600°.

Carbon monoxide is combustible and readily burns in **air** or **oxygen**, forming carbon dioxide: $2CO+O_2=2CO_2$, so that, as J. L. Gay Lussac,[5] and B. Lepsius showed, two vols. of carbon monoxide unite with one vol. of oxygen to form two vols. of carbon dioxide. A mixture of the two gases is explosive. The flame of burning carbon monoxide is blue, and, according to J. W. Draper, the colour is the same when the gas burns in oxygen. According to M. Berthelot and G. Vieille, carbon monoxide burns more slowly than hydrogen or the fatty hydrocarbons; and still more slowly in the presence of carbon dioxide. The carbon monoxide and oxygen unite when heated, when exposed to electric sparks, or, according to W. G. Mixter, and A. de Hemptinne, when the mixed gases are exposed to the silent electric discharge; combination also occurs when the mixed gases are passed over finely divided platinum and some other metals. A. B. Ray and F. O. Anderegg studied the oxidation of carbon monoxide during its passage, mixed with oxygen or air, through the silent discharge or over catalysts. F. Haber and F. Richardt found that in the presence of heated palladium wire, the union of the two gases is complete at 300°. W. W. Hurst and E. K. Rideal studied the catalytic effect of copper and the promotor action when palladium is present. For catalytic actions, and the action of ultra-violet light, *vide infra*. S. Medsforth studied the catalytic action of ceria, thoria, beryllia, alumina, silica, zirconia, magnesia, the oxides of chromium, molybdenum, vanadium, and tin, and the metals copper, silver, and nickel—*vide* methane. R. T. Haslam considered that both the reactions usually represented: $2CO+O_2=2CO_2$ and $2H_2+O_2=2H_2O$, are trimolecular, and found the ratio of the velocity constants between 900° and 1500° to be $k_{H_2}/K_{CO}=2·86$, meaning that the hydrogen burns 2·86 times as fast as the carbon monoxide. It is supposed that the mechanism of the combustion of the individual gases alone is different from what it is when the gases are burned in the presence of one another. W. A. Whitehead and J. C. W. Frazer found that manganese oxide, and T. H. Rogers and co-workers, and D. R. Merrill and C. C. Scalione, mixtures of manganese oxide with silver or copper oxide, acting as catalysts in oxidizing carbon monoxide at ordinary temp. H. S. Taylor and H. A. Neville studied the effect of the carbonates of potassium, sodium, lithium, barium, and calcium, and of sodium chloride, borax, ferric oxide, sodium silicate, nickel, or copper—*vide* action of carbon on carbon dioxide. K. W. Rosenmund and P. Langer studied the effect of the support on which the catalyst is deposited on the oxidation.

H. B. Dixon found that X-rays did not inflame a dried mixture of carbon monoxide and oxygen. According to M. Berthelot, carbon monoxide and oxygen do not unite when exposed to sunlight. M. Potain and R. Drouin reported that when a mixture of carbon monoxide with a large proportion of air is exposed to light, carbon dioxide is slowly formed. The change is retarded and limited by the presence of the dioxide. M. Berthelot believed that the experimental conditions must have been faulty because he observed no change in moist and dry mixtures of carbon monoxide and oxygen after seven years' exposure. If the mixture be confined over a conc. soln. of potassium hydroxide for 15 months, the carbon monoxide is converted into formate which is absorbed by the liquid, the oxygen, however, is not changed and no carbonate is formed; nor is any ammonium carbonate produced, if a mixture of carbon monoxide and aq. ammonia be used. Ultra-violet light brings about the union of carbon monoxide and oxygen; and carbon dioxide is decomposed by that agency, so that the reaction $CO+O\rightleftharpoons CO_2$ is reversible. The reaction was studied by A. K. Sanyal and N. R. Dhar.

The **temperature of combustion** of a mixture of carbon monoxide and oxygen was estimated by M. Berthelot to be 3600°, and with air in place of oxygen, 3000°; M. Berthelot and P. Vieille gave for carbon monoxide with oxygen 2490°–3972°; 2351°–3745° with hydrogen and oxygen; and 2217°–2839° with nitric oxide and hydrogen. R. Bunsen gave 3033° for the maximum temp. of combustion of equal vols. of oxygen and carbon monoxide in a closed vessel; and E. Mallard and H. le Chatelier, 3200°, when about 30 per cent. of the carbon dioxide is dissociated. H. Valerius gave 1430° for the temp. of combustion of carbon monoxide in air, and P. Geipert found the temp. of producer gas burning in air to be 1569°, and F. Haber and H. J. Hodsman found the temp. of the flame of a theoretical mixture of oxygen and carbon monoxide to be 2600°; K. G. Falk gave 2764°. F. Pollitzer made some observations on this subject.

According to H. Davy, carbon monoxide is inflamed by contact with red-hot charcoal, or iron wire, or a heated platinum spiral. P. Sabatier and J. B. Senderens observed that in contact with nickel, oxidation does not commence before 230°; with iron, not before 330°; and with platinum, not before 450°. L. Mond and C. Langer noted that with nickel and cobalt at 350°–450° a carbide and carbon dioxide are formed; the carbide is decomposed by water vap. W. Henry noted that platinum foil slowly converts a mixture of carbon monoxide and oxygen (2 : 1) into carbon dioxide at ordinary temp.; J. W. Döbereiner, and W. Henry noted that platinum sponge acts similarly when warmed; and P. L. Dulong and L. J. Thénard observed the action in the cold. P. J. van Kerckhoff noted that slow oxidation occurs with platinized asbestos at 5°–15°; while pumice-stone, or porous earthenware acts very slowly at 80°–90°. F. C. Phillips found palladized asbestos acts below a red heat; A. Pleischl, and A. de la Rive and F. Marcet, platinized or palladized paper ash at ordinary temp.; and E. D. Campbell, palladized cupric oxide, at 100°–105°. H. B. Dixon found that a dried mixture of carbon monoxide and oxygen does not explode in contact with a red-hot platinum wire; and H. B. Dixon and H. F. Lowe found a red-hot platinum wire, freed from occluded hydrogen, glows intensely in the mixed gases, and completely oxidizes the carbon monoxide. According to A. F. Girvan, a silver or gold wire may be fused in the gases, dried by cooling to −80°, without causing visible union of the mixture; with an explosive mixture dried by cooling to −35°, a spiral of platinum wire at a red heat caused a quiet and feeble explosion; with a mixture dried by cooling between −80° and −180°, the platinum acted catalytically, and glowed for several seconds, but there was no other sign of chemical action; the coil was then heated white hot for a few minutes, and when cold, about one-eighth of the mixture was absorbed by a soln. of potassium hydroxide, the remainder represented the uncombined mixture. The catalytic oxidation of carbon monoxide was also studied by T. H. Rogers and fellow-workers, D. R. Merrill and C. C. Scalione, J. C. Clancy, etc. The carbon monoxide mixed with hydrogen is preferentially oxidized in the presence of mixed oxides of iron, chromium, cerium, thorium, bismuth, etc., as shown by J. Harger and H. Terrey, E. K. Rideal and H. S. Taylor, and R. N. Pease and H. S. Taylor and co-workers, A. B. Lamb and co-workers, R. S. Tour, etc. J. A. Almquist and W. C. Bray studied the effect of cupric and manganese oxides; and W. A. Whitesell and J. C. W. Frazer, the effect of manganese dioxide. I. Langmuir discussed the hypothesis that the oxygen is condensed on the platinum, the carbon monoxide mols. strike the surface, and a certain fraction is condensed, forming carbon dioxide which distils off at a certain rate.

E. Mallard and H. le Chatelier found the **ignition temperature** of mixtures of carbon monoxide with air and oxygen, and the results are shown in Table XVIII.

A. Krause and V. Meyer found that the explosion temp. of a theoretical mixture of carbon monoxide and oxygen, confined in thin sealed glass bulbs, to be between 518° and 606°; F. Freyer and V. Meyer gave 650°–730°; and V. Meyer and A. Münch, 636°–814°. According to K. G. Falk, the lowest ignition temp. for a mixture $2CO+O_2$ is 601°, and in the presence of an indifferent gas—nitrogen—the absolute temp. of ignition, T, becomes $T=T'+80(\text{Vol. N}/\text{Vol. CO})$. H. B. Dixon and H. F. Coward gave 637°–658° or 650° for the ignition temp. of moist carbon monoxide in oxygen; and in air, 644°–658° or 651°. W. M. Thornton made observations on the ignition of carbon monoxide under reduced press.

TABLE XVIII.—IGNITION TEMPERATURES OF CARBON MONOXIDE.

Percentage composition.				Ignition temp
CO	Oxygen.	Air.	CO_2	
85	15	—	—	630° to 650°
70	30	—	—	645° to 650°
30	70	—	—	650° to 680°
30	—	70	—	650° to 657°
35	15	—	50	695° to 715°
15	—	35	50	715° to 725°

According to A. Krause and V. Meyer, a considerable amount of carbon monoxide is oxidized at 448°; and K. W. Charitschkoff found that purified carbon monoxide is oxidized at 290°. H. Hélier passed a dry mixture (1 : 2) of oxygen and carbon monoxide at a constant velocity through a porcelain tube packed with porcelain rods, and surrounded by an iron tube; he found the following proportions of carbon dioxide were formed at different temp.:

	195°	302°	408°	500°	600°	680°	788°	855°
Per cent. CO_2 . .	0·13	0·44	3·03	6·2	21·14	46·36	60·3	65·0

The admixture of nitrogen lowers the proportion of carbon dioxide which is formed, and the presence of carbon dioxide hinders the reaction. According to H. Kühl, the velocity of the reaction at 570° appears to be somewhat irregular because, although the reaction in general appeared to be of the third order, the velocity varied according as one or the other of the gases was first introduced into the reaction vessel, which was made of internally glazed porcelain. Thus the initial velocity when dry oxygen is added to moist carbon monoxide is ten times greater than that observed when moist carbon monoxide is added to dry oxygen, carbon dioxide being originally present in both cases; when carbon dioxide has not been previously introduced, the velocities in question are in the ratio 2 : 1. The initial velocity is in general retarded when carbon dioxide is originally present; it is in the main independent of the oxygen concentration, but proportional to the first power of the carbon monoxide concentration; it increases with the amount of water vap. present, although somewhat irregularly, and to an extent less than proportionality. Further, the initial velocity is increased when the reaction vessel has been previously exhausted. These observations agree with the assumption that the seat of the reaction is on the surface of the containing vessel. According to M. Bodenstein and F. Ohlmer, the reaction $2CO+O_2=2CO_2$ is catalytically accelerated when it takes place in a vessel of quartz-glass. The rate of the change is adequately represented by the empirical formula $dx/dt=k(m+a-x)/(n+b-x)$, where a and b are the initial concentrations of oxygen and carbon monoxide respectively, m and n are constants. The chief feature of the investigation is the fact that carbon monoxide retards its own combustion in the quartz-glass vessel, so that the velocity of the reaction is almost inversely proportional to the conc. of carbon monoxide. This, therefore, is to be regarded as a case of negative autocatalysis. This peculiarity is not observed when the reaction takes place in an ordinary glass vessel containing pieces of quartzite or rock crystal. With both these catalysts, the reaction velocity is directly proportional to the carbon monoxide conc., and proportional also, although only roughly, to the square root of the oxygen conc. In all cases, the temp. coeff. (for an interval of 10°) was between 1·4 and 1·8. K. G. Falk found the reaction to be termolecular, but if an excess of carbon monoxide be present, the results do not follow the equation for such reactions.

E. Mallard and H. le Chatelier[6] found that there is a sudden and momentary rise in the press. during the explosive combustion of a mixture of carbon monoxide with air or oxygen, and give the following explanation of the phenomenon:

> The first portion of the mixture in exploding compresses the adjoining layer. If now the velocity of propagation of ignition is sufficiently rapid, this adjoining layer of the explosive mixture will be ignited before an equalization of press. can take place, and hence the press. due to this explosion will be superimposed on that derived from the first portion of the mixture. This will be repeated, the press. in each succeeding wave becoming greater, and the momentary press. due to one of these explosive zones will be that registered by the piston. This hypothesis is supported by the fact that the excess of press. above the normal increases with the velocity of propagation of ignition of the mixture.

M. Berthelot and P. Vieille found the press. at the moment of explosion to be 10·12 atm., with the mixture of carbon monoxide and oxygen, and 8·79 to 9·81 atm. with a mixture of these gases with hydrogen. The **velocity of propagation of the flame** was found by R. Bunsen to be less than a metre per sec. E. Mallard and H. le Chatelier gave 2·2 metres per sec. H. B. Dixon gave for the **velocity of the explosion wave** in a mixture of carbon monoxide and oxygen sat. at 10° with water vap., in a tube 13 mm. diameter, the value 1500 metres per sec. The velocity varies with the proportion of moisture. Thus, at 760 mm. press., with gas sat. at a temp. $\theta°$, the velocity, V, of the explosion wave in metres per sec. with the mixture $2CO+O_2$, increased to a maximum, and then diminished:

	Dried	Partially dried	10°	28°	35°	45°	65°	75°
V . .	1264	1305	1676	1713	1738	1693	1526	1266

K. Bötsch showed that if the press. be sufficiently reduced, the propagation of the flame can be prevented in the dried or moist gas. L. Meyer and E. Seubert found the gas burnt at press. as low as 219 mm. H. B. Dixon also found the velocity is diminished from 1676 to 1576 metres per sec. by reducing the press. from 760 to 400 mm. in a gaseous mixture sat. with moisture at 10°. H. B. Dixon also photographed the front of the advancing explosion wave, and of the wave reflected in the opposite direction. H. B. Dixon, E. H. Strange, and E. Graham observed that the explosion flame of a dried mixture of carbon monoxide and oxygen is longer than is the case with a moist mixture. By using carbon monoxide from carbonyl sulphide, E. J. Russell inferred that there is not "a great difference between the behaviour of nascent carbon monoxide and that of the ordinary gas."

M. Berthelot measured the speed of the explosion wave in mixtures of hydrogen, carbon monoxide, and oxygen; and H. B. Dixon and N. S. Walls measured the effect of the substitution of hydrogen for carbon monoxide in the $2CO+O_2$ mixture, and found for the rates of the explosion wave, V,

CO .	100	99·25	98·5	92·5	85	62·5	50	25	15	7·5	0
H_2 .	0	0·75	1·5	7·5	15	37·5	50	75	85	92·5	100
V .	1750	1754	1758	1796	1858	2020	2130	2301	2507	2643	2810

M. Berthelot measured the initial speed of propagation of flame in mixtures of these three gases, and found that the speeds in mixtures $2(H_2,CO)+O_2$ were greater than the arithmetical mean of the rates in $2H_2+O_2$ and $2CO+O_2$ mixtures, he concluded that the gases burnt separately—the hydrogen burning first.

W. A. Bone and W. A. Haward have made determinations of the time taken from the moment of firing until the maximum press. is reached when explosive mixtures of hydrogen and carbon monoxide with air are fired in a closed bomb initially under atm. press. The interval between the spark and the maximum press. is much less in pure hydrogen than in the pure carbon monoxide detonating gas, and they compared the time-intervals when different quantities of hydrogen replace carbon monoxide with the times calculated on the assumption that each explosive mixture carries the flame in turn at its own rate over lengths proportional to the vol. of each present. The "times" so calculated are the sum of the times taken by each explosive constituent; just as in a relay race the total time is the sum of the times taken by each runner over the distance he is set to run. The numbers so calculated in no way agree with the rates found for the mixed gases; and they directed attention to the great effect on the rate of combination when small quantities of hydrogen replace carbon monoxide in the explosive mixture, and, like M. Berthelot, they attributed this to the dominating influence of the hydrogen "which catalyses the reaction." Later, W. A. Bone and co-workers found that the comparative slowness at which the press. is developed in a mixture of carbon monoxide and air is not due to any inherent slow-burning property of carbon monoxide, and it is not much affected by the proportion of water vap. present in the system. When the nitrogen is wholly replaced by oxygen, carbon monoxide, or argon, the time required for the attainment of maximum press. is reduced from 0·18 sec. to 0·005, 0·010, and 0·025 sec. respectively. Hence, it was inferred that in the presence of nitrogen and high press., a considerable part of the energy radiated by burning carbon monoxide, instead of being absorbed by the walls of the explosion chamber, is intercepted and adsorbed by the nitrogen present whereby the nitrogen becomes chemically activated. The radiant energy so absorbed affected the maximum press. attained only when the conditions permitted a secondary oxidation of the activated nitrogen to nitric oxide. The radiant energy absorbed by the nitrogen is gradually liberated in a kinetic form after the attainment of the maximum press., as the activated nitrogen slowly reverts to the ordinary form. A. Payman and R. V. Wheeler found that for the slow initial uniform phase of combustion of gases the rates for mixtures are the means of the individual maximum rates: thus, "if on a speed-per cent. graph the maxima for any two gases taken singly are joined by a straight line, all the maxima for mixtures of these gases lie approximately on this line."

H. Davy[7] noted that a mixture must contain at least one vol. of oxygen to 3 vols. of carbon monoxide to explode by the electric spark. The limits, said M. Berthelot, vary with the intensity of the spark, and even when the mixture is non-explosive, the carbon monoxide is oxidized by the sparking. P. Eitner gave for the upper and lower limits of explosive mixtures, 75·1 and 16·4 per cent. of carbon monoxide; E. Terres, 73·5 and 16·1; and H. Bunte and J. Roszkowsky, 74·8 and 14·1. E. Berl and H. Fischer's results are indicated in Fig. 37. In a glass globe 27 mm. diameter the limits were 15·4–71·6; in a glass globe 18 mm. diameter the limits were 16·0–66·5; in an iron vessel at ordinary temp. the limits were 15·8–63·8; at 100°, 14·05–69·6; at 200°, 13·8–76·55; and at 300°, 14·10–75·6. The black portion represents oxidation without inflammation. H. F. Coward and F. Brinsley gave for the lower limit 12·5 per cent. carbon monoxide. J. Roszkowsky found that the dilution of the explosive mixture of carbon monoxide and oxygen with an indifferent gas like carbon dioxide decreases the tendency to explosion, and this decrease is less the higher the temp. This is probably due to the heat generated by the combination of the two gases being largely used in raising the temp. of the indifferent gas rather than in propagating the explosion. E. Terres found that

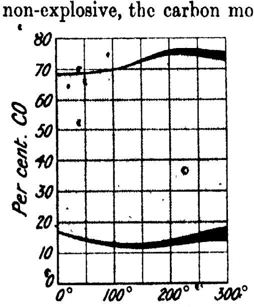

FIG. 37.—Explosion Limits of Carbon Monoxide and Air.

the limits of inflammability of carbon monoxide in air were 15·6–70·9 per cent.; and in oxygen, 16·7–93·5 per cent. N. N. Beketoff found that sulphur dioxide or nitrous oxide had no influence on the explosion of a dried mixture of carbon monoxide and oxygen, but 10 per cent. of cyanogen causes the immediate explosion of the dried mixture on sparking. He suggests that the action of cyanogen may be explained on the assumption that the heat liberated in the decomposition of the cyanogen is added to the heat of combustion of the carbon, and he further assumes that the dissociation temp. of the water mol. being lower than that of the oxygen mol. is the proper explanation of the fact that the presence of water in a mixture of carbon monoxide and oxygen assists the combustion of the latter gases. H. B. Dixon, however, showed that when a dried mixture of cyanogen, carbon monoxide, and an excess of oxygen is exploded, much of the carbon monoxide escapes oxidation. Similar results were obtained with carbon disulphide. G. Schlegel found that chlorine hinders or inhibits the combustion or explosion of a mixture of carbon monoxide and oxygen. H. B. Dixon and E. J. Russell observed that with nascent oxygen, as when a mixture of carbon monoxide and chlorine dioxide is exploded, the drier the mixture, the greater the proportion of carbon monoxide which escapes oxidation; the oxidation does not proceed any faster with oxygen *in statu nascendi.* Similar results were obtained by E. J. Russell with chlorine monoxide. W. A. Jones found that when carbon monoxide is led into a U-tube in which acidified water is undergoing electrolysis and is allowed to bubble directly against the electrode at which the oxygen is being evolved, no carbon dioxide is produced. Electrolytic oxygen, therefore, has not the power of oxidizing carbon monoxide.

H. B. Dixon[8] discovered that an explosion is not propagated in a dried mixture of carbon monoxide and oxygen. The addition of a minute trace of water or of a volatile body containing hydrogen renders the mixture inflammable, thus, a dried mixture of carbon monoxide and oxygen explodes in the presence of traces of water, hydrogen sulphide, ethane, formic acid, ammonia, pentane, or hydrogen chloride—but not in the presence of gases or vapours free from hydrogen—*e.g.* sulphur dioxide, carbon dioxide, carbon disulphide, nitrogen, cyanogen, carbon tetrachloride, etc. Hence, *only steam, or bodies which can form steam under the conditions of the experiment, are capable of determining the explosion of carbon monoxide and oxygen;* other gaseous bodies not capable of forming steam have no action. When a long tube full of the dried mixture has moisture introduced at one end, and the gases are ignited there, the flame traverses the moist gases but dies out on reaching the dried gases. H. von Wartenberg and B. Sieg supported the hypothesis that the reaction between burning carbon monoxide is preceded by the formation of an unstable additive compound. M. Traube also found that the flame of dry carbon monoxide burning in air is extinguished if plunged into dry air. N. N. Beketoff found that while no explosion occurs with the mixed gases dried by phosphorus pentoxide, the propagation of the flame is so slow that it can be followed by the eye when the gases have been dried by sulphuric acid, presumably because the latter desiccative leaves more moisture in the gas than the former. A. F. Girvan found that the drying of the gases by cooling will also prevent explosion. The vap. press. of the moisture in gases dried at different temp is approximately

	−36°	−45°	−51°	−56·5°	−61°
Vap. press. of water .	0·160	0·052	0·029	0·01	0·008

When the vap. press. of the water is less than about 0·03 mm., as is the case with the mixture after cooling at −50°, the gases will not explode. When the vap. press. is less than about 0·16 mm., the explosion is very feeble. In the first case, the amount of water vap. present is about one part in twenty-four thousand by vol., and in the second, one part in five thousand. At −61°, the amount of water vap. would be about one part in a hundred thousand of gas. It would appear then that the mixture will not explode when sparked at the ordinary temp. if there is less than one mol. of water vap. to twenty-four thousand mols. of the gas. K. Bötsch failed to confirm these observations, but H. B. Dixon showed that the gases were probably inadequately dried. L. Meyer found that if the gases are sufficiently well dried, the mixture can be exploded only by a very powerful spark, and a tolerably large gas press. is employed; while H. B. Dixon showed that with a dried mixture of the two gases, a spark between platinum wires 7 mm. apart produced no explosion, but a blue aureole appeared about the track of the spark. L. Meyer, and N. N. Beketoff found that the dried gases unite in the track of the spark; and H. B. Dixon and H. F. Lowe showed that the amount of combination depends on the nature of the spark, a limit being reached when the rate of combination is equal to the rate of decomposition of the carbon dioxide formed. They also showed that the dried gases combine completely without flame, in contact with a platinum wire. C. Montemartini observed that the corona effect in circuits traversed by continuous currents forms carbon dioxide and hydrogen from a mixture of carbon monoxide and water. A. Coehn and H. Tramm found that while a moist mixture of carbon monoxide and oxygen can be exploded by a spark at any press., a mixture, dried by a short exposure to the action of solid carbon dioxide and alcohol, cannot be exploded, but inflames and burns quietly, and that a mixture which has been cooled for a sufficient time cannot be inflamed; a pale blue zone forms round the spark gap and slight combination is indicated by a small diminution of press. Exposure of mixtures belonging to the three types to the ultra-violet rays from a quartz mercury lamp leads to practically the same result in each case, combination occurring to the extent of 4–5 per cent. within an hour. It follows, therefore, that the presence of aq. vap. does not play a part in the union of carbon monoxide and oxygen under the influence of radiant energy—*vide* photo-decomposition of carbon dioxide.

A. Smithells and F. Dent found that dry carbon monoxide proceeding from a half-burnt cyanogen flame will burn in dry air provided the two flames are close together, and N. N. Beketoff showed that an explosion of cyanogen and oxygen will cause the union of admixed carbon monoxide with the oxygen. F. Haber and J. E. Coates noted that some nitric oxide is formed during the combustion of carbon monoxide in air; and A. Bach stated that if the flame of this gas is allowed to impinge on cold water, the water afterwards exhibits the peroxide reaction. According to R. de Muynck, a mixture of oxygen and carbon monoxide is electrically conducting at the moment of the explosion; he calculates that one ion is produced for every 200 million mols. of carbon dioxide which are formed. This result favours the view that the conducting power of the exploded mixture is to be attributed to the heat liberated in the change. The drying of the gas had no perceptible influence on the effect.

K. A. Hofmann and co-workers studied the oxidation of carbon monoxide at ordinary temp. It was found that on a surface of copper moistened with alkali-lye, carbon monoxide is slowly oxidized in open circuit, the electrolyte ultimately containing, in addition to carbonate, traces of formate but scarcely any oxalate; the monoxide is gradually replaced by hydrogen, so that the reaction proceeds according to the scheme: $CO+2KOH=K_2CO_3+H_2$. In the closed circuit, the hydrogen is oxidized to water by oxygen liberated at the opposite electrode. Copper cannot, however, bring gaseous molecular hydrogen into a condition of electromotive activity, but can be very actively charged by nascent hydrogen, most simply by cathodic polarization. It was suggested that owing to the existence of subsidiary valencies, carbon monoxide has the power to unite with alkali hydroxide in the presence of copper yielding small amounts of an isoformate, Cu . . . C(OH)(OK), which then combines with a further mol. of the hydroxide to yield the alkali carbonate, whilst the hydrogen is liberated in the at. state at the copper. This conception is supported by the observation that active elements are not formed from copper, carbon monoxide, and water, or from carbon monoxide and alkali hydroxide alone, but only from copper, alkali hydroxide, and carbon monoxide in conjunction. It is further found that hydrated cupric oxide is reduced by carbon monoxide in the presence of alkali at an appreciable rate only if a certain amount of metallic copper is present. Again, the electromotive activity of carbon monoxide at a copper, and to a less degree at a platinum, surface is not immediately developed, whilst, in the absence of hydroxyl ions, carbon monoxide is not noticeably activated by copper. Cuprous oxide does not play a part in the phenomena, since it is found that hydrated cupric oxide is directly reduced in the presence of alkali to the metal, whilst the presence of a minute amount of oxygen diminishes the electromotive force of the system Cu-CO-alkali in a striking, if transitory, manner. F. Auerbach added that the calculated e.m.f. for the gas-cell $O_2 \mid CO$, is smaller than for the oxidation $2CO+O_2 \rightleftharpoons 2CO_2$.

M. Berthelot[9] showed that when a mixture of carbon monoxide and oxygen is sparked, some carbon suboxide, C_4O_3, is formed (*q.v.*). H. Fassbender found that when a mixture of carbon monoxide and oxygen is exposed to the silent discharge, the rate of explosion is increased. This is attributed to the formation of **ozone** by the discharge, for, when a mixture of the two gases is exploded, a piece of potassium iodide and starch paper is coloured blue by the ozone formed in the explosion; but H. B. Dixon did not detect any marked increase in the inflammability of a mixture of carbon monoxide and oxygen in the presence of ozone.

H. Thiele, and S. Chadwick and co-workers found that ultra-violet light from a quartz mercury lamp oxidized carbon monoxide in the presence of oxygen when the mixed gases were dried with sulphuric acid, and with phosphorus pentoxide, and when the gases were sat. with moisture at 16°. The last-named found that with the dried gases, there was at first a slow contraction, the rate of contraction then gradually increased, attained a maximum, and then slowly decreased until the change became very slow. With the moist gas, the rate of contraction was uniform throughout the experiment at less than half the speed of the maximum rate of the dried mixture. When the contraction had attained the same values:

	H_2SO_4–dried	P_2O_5–dried	Moist
Carbon monoxide oxidized . .	22·95	19·42	53·2 per cent.
Oxygen ozonized	39·63	37·48	2·6 ,, ,,

It was assumed that the first action of the ultra-violet light is to break up the oxygen mols. into atoms, the atoms of oxygen thus formed prefer to combine with the mols. of carbon monoxide when the gases are moist, but with oxygen mols. when the gases are dry. The rate of chemical change was not accelerated by the presence of moisture, although the course of the reaction was determined by the hygroscopic condition of the mixture. Against the view that the accelerating action of water vapour on the reaction between a heated mixture of carbon monoxide and oxygen is due to the production of formic acid, H. Tramm showed that mixtures of oxygen and formic acid do not explode while an eq. mixture of hydrogen, oxygen, and carbon monoxide does so.

I. Remsen and M. S. Southworth found that ozonized oxygen does not oxidize carbon monoxide in diffused daylight, in direct sunlight, or at 300°; and I. Remson showed that the ozone does not oxidize carbon monoxide at the moment of its transformation into oxygen. On the other hand, W. A. Jones found that oxygen, with 3·78 per cent. of ozone, slowly oxidizes carbon monoxide at ordinary temp. and more rapidly at 250°. In general, the oxidizing power of ozone was found to vary according to its conc. and temp. C. E. Waters observed no oxidation at ordinary temp., but at 240°–280°, some carbon dioxide was produced, the amount depending on the conc. of the ozone. P. Clausmann said the oxidation occurs in darkness, but more rapidly in light. Moisture accelerates the reaction. J. B. J. D. Boussingault noted that in the oxidation of moist phosphorus in the presence of air and carbon monoxide, some carbon dioxide is formed; and E. Baumann, and A. R. Leeds stated that when a mixture of air and carbon monoxide is passed over moist phosphorus, carbon dioxide is formed. I. Remsen and E. H. Keiser failed to confirm these observations, but W. A. Jones found that under these conditions some carbon dioxide is always formed, and that the amount varies with the quantity of phosphorus exposed and the rate at which the gas is passed over it. When pure carbon monoxide is brought into contact with phosphorus immersed in a soln. of hydrogen peroxide, carbon dioxide is not produced; and it is therefore very improbable that the oxidation of carbon monoxide by air and moist phosphorus is due to the action of the phosphorus on hydrogen peroxide formed in the course of the experiment. I. Remsen and E. H. Keiser said that the source of the carbon dioxide is the carbon in the phosphorus, but E. Baumann denied this. A. R. Leeds also showed that carbon dioxide is formed when organic matters are excluded. I. Remsen[10] found that carbon monoxide is not oxidized when in contact with decomposing **hydrogen dioxide.** This statement was confirmed by F. C. Phillips, W. A. Jones, and M. Traube. P. Waentig and O. Steche, and G. Senter investigated the effect of carbon monoxide on the catalytic decomposition of hydrogen dioxide by hæmase.

W. Henry[11] compared the action of the electric spark, heat, and of platinum sponge on mixtures of carbon monoxide, hydrogen, and oxygen, and found that the lower the temp., the greater the proportion of carbon dioxide produced. With a mixture of hydrogen, carbon monoxide, and oxygen in the proportions 1 : 2 : 1 by vol., the oxidation in the presence of platinum sponge at 171° converted 4 vols. of carbon monoxide per vol. of hydrogen; at the softening temp. of glass, two-thirds vol. of carbon monoxide per vol. of hydrogen; and with the electric spark, one-third vol. of carbon monoxide per vol. of hydrogen. E. von Meyer, and D. Tommasi found that the activity of the platinum is lowered in the presence of carbon monoxide. F. C. Phillips found that in the presence of hydrogen and oxygen, carbon monoxide is oxidized below 100° in contact with platinum sponge or palladium. M. Traube, and E. Baumann made observations on this subject. M. Traube found that oxidation does not occur in the presence of zinc and water.

R. Bunsen then studied the simultaneous oxidation of hydrogen and carbon monoxide. He made a mal-inference, for he said that if a mixture of carbon monoxide and hydrogen gases be exploded with a quantity of oxygen not sufficient to oxidize the mixed gases completely, the oxygen will divide itself between the carbon monoxide and hydrogen not in proportion to their quantities present, but so that the quantities of carbon dioxide and water formed will stand in some simple ratio. Thus, on exploding a mixture of carbon monoxide and hydrogen, R. Bunsen found the ratio $CO_2 : H_2O = 2 : 1$; and an increase in the quantity of hydrogen made no change in the value of the ratio until sufficient hydrogen had been added, when the ratio suddenly jumped to 1 : 1; similarly with further additions of hydrogen, the ratio jumped to 1 : 2, then to 1 : 3, and then to 1 : 4. E. von Meyer confirmed R. Bunsen's observation that the proportions in which oxygen is distributed between carbon monoxide and hydrogen alters *per saltum* but not in such simple proportions as R. Bunsen supposed, for E. von Meyer obtained ratios like 17 : 18; 18 : 19; etc. A. Horstmann showed that R. Bunsen's observations were vitiated by the condensation of steam on the walls of the containing vessel; and also by the counter-reaction $H_2O + CO \rightleftharpoons CO_2 + H_2$. The change is gradual and does not proceed *per saltum*; the law of mass action is valid in its simple form: $[H_2O][CO] = K[H_2][CO_2]$, where the symbols in brackets represent concentrations, and K is the equilibrium constant. This conclusion was also verified by H. B. Dixon, who, in his study of the distribution of oxygen between carbon monoxide and hydrogen during explosion, showed that the equilibrium constant K is nearly 4·0.

The decomposition of **water** vap. by carbon monoxide in contact with a heated platinum wire, or by heating the mixed gases in a tube, was established by W. R. Grove, H. Buff and A. W. Hofmann, B. Verver, L. Maquenne, J. Coquillon, etc. (1. 9, 9). L. Maquenne observed the reaction between steam and carbon monoxide at 150° in the presence of platinum sponge. W. G. Mixter, A. de Hemptinne, and S. M. Losanitsch and M. Z. Jovitschitsch found that carbon dioxide and formic acid are produced when carbon monoxide and water vap. are exposed in an ozonizer; W. Löb found formaldehyde, formic acid and carbon dioxide to be formed.

H. Thiele also noted the production of formic acid when a mixture of carbon monoxide and water vap. in a quartz bulb is exposed to ultra-violet light. A. Naumann and C. Pistor reported that at 560° steam and carbon monoxide do not react; at 600°, two per cent. of the carbon monoxide is oxidized; at 900°, 8 per cent.; and at 904°, 10·5 per cent. All the conditions which hinder the reaction between hydrogen and carbon dioxide, favour that between steam and carbon monoxide, since such a change is exothermal, $CO+H_2O_{gas}=CO_2+H_2+10{\cdot}72$ Cals., and the carbon dioxide is very stable at a high temp., while the steam is readily decomposed into hydrogen and oxygen, the latter of which can burn the carbon monoxide. L. Maquenne also inferred that carbon monoxide is a stronger reducing agent than hydrogen. J. Lang said that carbon monoxide is not attacked by water vap. at 600°; C. Engler and J. Grimm found that carbon monoxide free from oxygen does not react with water vap. at 250°, but does react at 300°, forming carbon dioxide; and C. Hoitsema found the velocity of the reaction $CO+H_2O\rightleftharpoons CO_2+H_2$ in either direction at ordinary temp. is practically zero; the oxidation of the carbon monoxide by steam at 600° is measurable, but the reduction of carbon dioxide by hydrogen cannot be observed below 900°. A. Gautier studied the reversibility of the reaction at 1200°-1250°, and observed that traces of formic acid are also formed. H. B. Dixon, and O. Hahn established the accuracy of the law of mass action for: $CO+H_2O\rightleftharpoons H_2+CO_2$, by proving the constancy of K for $[CO][H_2O]=K[CO_2][H_2]$. O. Hahn found at different temp.:

	786°	886°	986°	1005°	1086°	1205°	1405°
K . . .	0·81	1·19	1·54	1·68	1·95	2·10	2·49

and he represented the results by $\log K=2226T^{-1}-0{\cdot}0003909T+2{\cdot}4506$

C. N. Hinshelwood and co-workers studied the decomposition of formic acid on glass, silver, and platinum surfaces. The consecutive reactions are $H.COOH=H_2O+CO$, and $H.COOH=CO_2+H_2$. On glass surfaces the two reactions proceed at about equal rates at 280°; on platinum and silver, the second reaction predominates; at about 180°, the second reaction predominates on silver; and the first reaction on glass. H. St. C. Deville and H. Debray studied the catalytic decomposition of formic acid by rhodium, iridium, and ruthenium; and E. Müller, by rhodium and osmium.

Other observations have been made on the reaction between steam and carbon monoxide by H. Luggin, C. Harries, O. Boudouard, F. Pollitzer, W. H. Engels, etc. According to F. Haber, $\log K=-2170T^{-1}+0{\cdot}979\log T-0{\cdot}001082T+0{\cdot}0_61734T^2-0{\cdot}02858$ and the thermal value of the reaction $Q=-9916-1{\cdot}943T+0{\cdot}004945T^2-0{\cdot}0_515847T^3$ cals. E. F. Armstrong and T. P. Hilditch found that copper is a more active catalyst than iron oxide between 200° and 300°; the reaction with copper commences at 220°, whereas iron oxide is only slightly active at 250°, and does not reach full activity till 400°. At higher temp., iron oxide is the more active catalyst on the reaction $CO+H_2O\rightleftharpoons CO_2+H_2$.

Several explanations of the catalytic effect of water on the oxidation of carbon monoxide have been devised. H. B. Dixon showed that the dissociation of carbon dioxide at the temp. at which carbon monoxide and oxygen combine would explain the inertness of a dry mixture of carbon monoxide and oxygen; and he assumed that the carbon monoxide is directly oxidized by the steam: $CO+H_2O=CO_2+H_2$; and that the liberated hydrogen recombines with the oxygen to form steam: $2H_2+O_2=2H_2O$, and the cycle begins anew. The water vap. thus acts as a carrier of oxygen to the carbon monoxide. M. Traube argued that moist carbon monoxide does not furnish a trace of hydrogen and carbon dioxide when sparked for several hours, while hydrogen reduces carbon dioxide at a white heat; but H. B. Dixon, quoting his own and W. R. Grove's experiments, showed that carbon monoxide can be directly oxidized by steam. M. Traube[12] suggested that the water mol. deliver their oxygen to the carbon monoxide, and the remaining hydrogen unites with the free oxygen to form hydrogen peroxide: $CO+H_2O+O_2=CO_2+H_2O_2$; the hydrogen peroxide then reacts with carbon monoxide to form water, and carbon dioxide: $CO+H_2O_2=CO_2+H_2O$; the water then commences the cycle anew. D. I. Mendeléeff adopted a somewhat similar explanation of the reaction; but H. B. Dixon, and H. Wieland both oppose this interpretation of the mechanism of the reaction. H. Wieland assumes that formic acid is the first product of the reaction $CO+H_2O=H.CO.OH$; and that this then decomposes into carbon dioxide and hydrogen, $H.COOH=CO_2+H_2$; while the hydrogen unites with the oxygen to form water, which then repeats the cycle of changes. H. E. Armstrong assumed that two gases which are inert in a highly purified state are able to react when a conducting circuit is formed—*e.g.* carbon monoxide, conducting water, and oxygen:

$$\begin{array}{c|c|c} O & H_2O & CO \\ O & H_2O & CO \end{array} \rightarrow \begin{array}{c|c} H_2O & OCO \\ H_2O & OCO \end{array}$$

Against this, it has been urged that when dry cyanogen is exploded with an excess of oxygen, or burnt in a flame separator, it furnishes carbon monoxide and nitrogen, the monoxide then burning to carbon dioxide in the absence of water.

According to H. Moissan,[13] **fluorine** does not react in the cold with carbon monoxide. J. Davy found that dry **chlorine** does not act on dry carbon monoxide. The two gases unite slowly in daylight and rapidly in sunlight, forming carbonyl chloride, $COCl_2$ (*q.v.*). J. Schiel prepared carbonyl bromide, $COBr_2$, (*q.v.*), by exposing to sunlight a mixture of **bromine** vap. and carbon monoxide. S. P. Cowardins said that *carbonyl iodide*, COI_2, is not formed by heating a mixture of **iodine** and carbon monoxide, or by exposing the mixture to sunlight; or by heating carbon monoxide with **arsenic pentaiodide, or lead iodide.** S. M. Losanitsch and M. Z. Jovitschitsch exposed a mixture of carbon monoxide and **hydrogen chloride** to the silent electric discharge, and the resulting contraction indicated the possible formation of formyl chloride. K. Stammer found **ammonium chloride** is not altered by heating it in carbon monoxide; nor is **cupric chloride** altered. For the action of carbon monoxide on **cuprous chloride** see the last-named salt. K. Stammer, and A. G. Bloxam found that **silver chloride** is not altered by heating it in a stream of carbon monoxide, but F. Göbel said that some reduction occurs. F. C. Phillips found that soln. of **auric chloride** are reduced at 0° and at 100° by carbon monoxide, forming brown gold and carbon dioxide. J. Donau prepared colloidal gold by this reducing agent. K. Stammer said **lead chloride** is not reduced, F. Göbel said that it is reduced when heated in a stream of carbon monoxide. A. G. Bloxam found that at a red heat no reduction occurs with the dry gas, but with the moist gas, some hydrogen chloride is formed. P. Schützenberger obtained addition compounds of carbon monoxide with **platinous chloride** (*q.v.*). These were studied by F. Mylius and F. Förster, W. Pullinger, etc. F. C. Phillips found soln. of **platinic chloride** are attacked at 0° and at 100° with the formation of carbon dioxide. A lower chloride is slowly formed, and after a long time some platinum is deposited. F. von Fodor, and F. C. Phillips showed that soln. of **palladium dichloride** are rapidly reduced by carbon monoxide: $PdCl_2+H_2O+CO=Pd+2HCl+CO_2$, and C. Winkler showed that by the aid of this reaction 0·01 c.c. or 0·0000125 grm. of carbon monoxide can be detected. The test was investigated by M. Potain and R. Drouin, F. Jean, L. M. Dennis and C. G. Edgar, etc. The reaction was utilized by J. Donau for preparing colloidal palladium. F. C. Phillips noted that **rhodium chloride,** $RhCl_3$, is not reduced in the cold, but it is slowly reduced at 100°; and **iridium chloride,** $IrCl_4$, is also slowly reduced by carbon monoxide.

A. J. Balard found that carbonyl chloride was formed by the action of **chlorine monoxide** on carbon monoxide for a few hours. E. J. Russell found that when a mixture of an excess chlorine monoxide and carbon monoxide is sparked, 5–10 per cent. of the latter remains unburnt, while with **chlorine dioxide** under similar conditions, H. B. Dixon and E. J. Russell found that 50–70 per cent. remained unoxidized. A. J. Balard found that an aq. soln. of **hypochlorous acid** has no effect on carbon monoxide. F. C. Phillips said that **calcium hypobromite** is also not affected. A. Ditte found that carbon monoxide has no action on **iodic acid**, but if heated, carbon dioxide is formed and iodine is liberated. C. de la Harpe and F. Reverdin say the reaction occurs at 150°; and A. Gautier, at 60°–70°; and M. Nicloux represents it by $5CO+2HIO_3=5CO_2+H_2O+I_2$, and if **iodine pentoxide** is used, A. Gautier gives $I_2O_5+5CO=5CO_2+I_2$. The reaction is employed in the determination of the amount of carbon monoxide in air and other gases. The quantitative determination of small amounts of carbon monoxide is based upon A. Ditte's reaction: $I_2O_5+5CO=5CO_2+I_2$, which is quantitatively complete between 60° and 70°, and enables carbon monoxide to be estimated in the presence of 20,000 times its vol. of air. Hence, if air is being investigated, it is first cleaned from the gases which react with iodine pentoxide by passage through tubes containing potassium hydroxide, and sulphuric acid; and then through a U-tube containing iodine pentoxide heated in a suitable bath. The liberated iodine passes on and may be absorbed in a soln. of potassium iodide, and subsequently titrated with $\frac{1}{1000}N$-sodium thiosulphate. The vol. of air aspirated over the hot iodine pentoxide is also measured. C. de la Harpe and F. Reverdin employed this method for detecting the gas; and M. Nicloux used it quantitatively by estimating the liberated iodine colorimetrically in chloroform soln. A. Gautier measured the carbon dioxide evolved. The action of carbon monoxide on iodine pentoxide has been studied from the point of view of the analyst by A. Lévy and A. Pécoul, A. Gautier and P. Clausmann, M. Pellet, J. L. R. Morgan and J. E. McWhorter, L. P. Kennicut and G. R. Sanford, B. Nowicki, etc. F. C. Phillips found that **potassium iodate** at 593° is not reduced by carbon monoxide.

C. Than[14] showed that carbonyl sulphide, COS, contaminated with much carbon monoxide, is formed when a mixture of carbon monoxide and **sulphur** vap. is passed through a heated tube; or, according to G. Chevrier, when the mixture is sparked. F. Gonzalez and E. Moles denied the latter statement. M. Berthelot found that slight traces of *carbonyl selenide*, and *carbonyl telluride* are formed when **selenium** and **tellurium** are similarly treated. Carbon monoxide does not react with **hydrogen sulphide**, but S. M. Losanitsch and M. Z. Jovitschitsch exposed a mixture of the two gases to the silent electrical discharge, and found that sulphur and formaldehyde are rapidly formed: $CO+H_2S=H.COH+S$, followed by $HCOH+H_2S=H_2O+HCSH$. M. Berthelot said that a trace of methane is formed when a mixture of carbon monoxide and hydrogen sulphide acts on heated iron. K. Stammer found that **copper, lead, and iron sulphides** are not changed by carbon monoxide. M. Berthelot noted the reduction of **sulphur dioxide** by carbon monoxide when the mixed gases are passed through a red-hot tube; or treated with electric sparks: $SO_2+2CO=S+2CO_2$. W. Smith and W. B. Hart confirmed this reaction.

K. Stammer found that **ammonium sulphate** is reduced to the sulphite by heating it in an atm. of carbon monoxide. E. Jacquemin found that **potassium, sodium, magnesium, strontium and barium sulphates** are decomposed when heated in an atm. of carbon monoxide and steam, forming hydrogen sulphide and carbon dioxide; at a high temp., sulphur is formed; and probably the metal sulphide is an intermediate product of the reaction. According to K. Stammer, A. Levol, and M. Berthelot, potassium sulphate is reduced to the sulphide: $K_2SO_4+4CO=4CO_2+K_2S+16{\cdot}6$ Cals.; and with sodium sulphate: $Na_2SO_4+4CO=4CO_2+Na_2S+17{\cdot}6$ Cals. W. Smith and W. B. Hart, and K. Stammer observed no action with sodium sulphate below dull redness, but at a bright red heat, the sulphite and sulphide are formed. K. Stammer noted the reduction of barium sulphate; and K. Stammer, and A. Herzfeld and K. Stiepel the reduction of **calcium sulphate.** K. Stammer also reported that **cupric sulphate,** and **silver sulphate** are reduced to the metals; magnesium sulphate is not changed; **zinc sulphate** forms zinc oxide; **aluminium sulphate,** alumina; **lead sulphate,** lead and lead sulphide; **manganese sulphate,** manganese oxide and sulphide; **ferrous sulphate,** ferrous sulphide and iron; and **barium selenate,** barium carbonate and selenium.

F. Briegleb and A. Geuther[15] found that carbon monoxide reacts with heated **magnesium nitride,** forming cyanogen, magnesia, and carbon. S. M. Losanitsch and M. Z. Jovitschitsch, and D. Berthelot and H. Gaudechon found that under the influence of the silent electrical discharge, carbon monoxide and **ammonia** combine to produce formamide: $CO+NH_3=CHO.NH_2$. A. Slosse under similar conditions obtained white crystals of a substance resembling carbamide. P. R. V. de Lambilly obtained ammonium formate by passing the mixed gases through a tube packed with pumice-stone or animal charcoal at 80°–150°. H. Jackson and D. N. Laurie said that when heated in contact with platinum, or exposed to an electric discharge of high frequency, ammonium cyanate is formed, which rapidly changes to carbamide; some ammonium carbonate is also produced. M. Berthelot observed no formation of hydrocarbons when a mixture of dry carbon monoxide and ammonia is passed over copper filings or over sodium. E. J. Mills, and R. L. Barr and co-workers said that, when a mixture of ammonia and carbon monoxide is passed several times over a heated mixture of potassium hydroxide and carbon, a potassium salt with 70 per cent. of cyanide is formed. M. Berthelot found an alcoholic soln. of ammonia absorbs no carbon monoxide at ordinary temp. J. T. Conroy obtained potassium cyanide by the action of carbon monoxide on **potassium amide,** KNH_2; F. Beilstein and A. Geuther obtained analogous results with **sodium amide.** W. Henry found that a mixture of carbon monoxide and **nitrous oxide** or **nitric oxide** is explosive, and carbon dioxide is formed; nitrous oxide or nitric oxide was also found by S. Cook to be reduced by carbon monoxide in contact with platinum. W. G. Mixter found that some carbon monoxide is oxidized when a mixture of that gas and nitric oxide is subjected to the silent discharge. At the moment of explosion, M. Berthelot and P. Vieille found a press. of 11·41 atm. is developed by a mixture of carbon monoxide and nitric oxide. C. W. Hasenbach found that carbon monoxide is oxidized at ordinary temp. by **nitrogen peroxide,** at the same time a liquid, decomposable by water, is formed. K. Stammer found that cold or boiling **nitric acid** of sp. gr. 1·2 does not attack carbon monoxide, but F. C. Phillips found that with the fuming acid carbon dioxide is produced. A. Vogel said that carbon monoxide does not act on molten **potassium nitrate**; K. Stammer stated that red-hot potassium nitrate and **barium nitrate** are reduced. F. C. Phillips found that an ammoniacal soln. of **silver nitrate** produces ammonium nitrite and silver. M. Berthelot observed the reduction of an ammoniacal soln. of silver nitrate, and J. Habermann said that 0·5 per cent. by vol. of carbon monoxide produces a distinct brown coloration, but 0·1 per cent. gives no coloration. A. Gautier made some observations on the subject. A. R. Leeds found that when carbon monoxide and air are allowed to stand in contact with moist **phosphorus,** some carbon dioxide is formed—*vide* action of ozone. Carbon monoxide does not react with **phosphine.** T. E. Thorpe and A. E. H. Tutton found that **phosphorus tetroxide** does not react with carbon monoxide at ordinary temp. or when heated. K. Stammer found that **lead, iron, and copper phosphates** are not altered when heated in carbon monoxide. F. Schlagdenhauffen and M. Pagel found that **arsenic trioxide or pentoxide** or **antimony trioxide or pentoxide** is not reduced at 150° or 300°, but I. W. Fay and co-workers said that reduction occurs at 60°. Carbon monoxide does not react with **arsine.** K. Stammer found that **sodium arsenate** or **antimonate** furnishes arsenic or antimony, respectively, when heated in carbon monoxide. A. W. Hofmann, and A. M. Butleroff obtained carbonyl chloride by heating **antimony pentachloride** with carbon monoxide: $SbCl_5+CO=COCl_2+SbCl_3$.

According to H. Moissan,[16] at 1200°, amorphous **boron** reduces carbon monoxide to carbon. M. Foix found that when the diamond is heated above 1100° in an atm. of **carbon dioxide,** the reaction $CO_2+C\rightleftharpoons 2CO$ does not occur in the time available, but amorphous carbon is deposited on the diamond, which itself is not changed. A. Frank found that **calcium carbide** at 200°–250° reacts with carbon monoxide, forming carbon and calcium oxide. A. T. Larson and

C. S. Teitsworth studied the absorption of carbon monoxide by ammoniacal soln. of **cuprous carbonate and formate**; and they measured the partial press. of carbon monoxide in contact with these soln. According to M. Berthelot, carbon monoxide and **methane** give propylene; W. Odling said acetylene and water are formed: $CH_4+CO=H_2O+C_2H_2$; but F. C. Phillips could not verify this statement. S. M. Losanitsch and M. Z. Jovitschitsch found that with the silent discharge, acetaldehyde is formed, $CO+CH_4=CH_3.COH$, a conclusion in agreement with that of A. de Hemptinne. E. Sarrau and P. Vieille studied the equilibrium conditions between a mixture of carbon monoxide, methane, hydrogen, and nitrogen. A. de Hemptinne formed some aldehyde and what was thought to be acetone by the action of the silent discharge on a mixture of carbon monoxide and **ethane**: $C_2H_6+CO=C_3H_6O$. S. M. Losanitsch found that with the silent discharge, **ethylene** and carbon monoxide furnish a substance, $(C_2H_4)_2CO$, soluble in ether, and an insoluble substance; and with **acetylene,** there is formed a yellowish-brown substance which rapidly absorbs oxygen. A. Frank represented the action of carbon monoxide on acetylene by $C_2H_2+CO=3C+H_2O$; and H. le Chatelier and O. Boudouard found the inflammability of the mixed gases is similar to that of mixtures of carbon monoxide and hydrogen (*q.v.*). E. Frankland found a mixture of carbon monoxide and **carbon dusilphide** inflames at 210°. M. Berthelot, and S. M. Losanitsch and M. Z. Jovitschitsch obtained carbonyl sulphide by the action of the silent discharge on the mixed gases. P. Schützenberger found that when a mixture of carbon monoxide and **carbon tetrachloride** is passed over pumice-stone at 350°-400°, carbonyl chloride and tetrachloroethylene are formed: $2CCl_4+2CO=2COCl_2+C_2Cl_4$. K. Stammer said that **potassium carbonate** is not altered when heated in carbon monoxide, but **potassium oxalate** furnishes carbon, carbon dioxide, and potassium carbonate. E. Carstanjen and A. Schertel found that carbon monoxide does not react with **cyanogen** in direct sunlight. C. Böttinger found that carbon monoxide is copiously absorbed by liquid **hydrogen cyanide**, but is not miscible with conc. hydrochloric acid. On removing the product from the freezing-mixture, carbon monoxide was evolved in a regular stream. On gently warming, the gas is given off more rapidly, and ultimately the liquids mix, when the evolution of gas becomes turbulent. According to E. Carstanjen and A. Schertel, no carbonyl cyanide is produced when carbon monoxide is passed over heated **mercuric cyanide**. F. C. Phillips found that **potassium ferricyanide** has no action on carbon monoxide; and J. Milbauer obtained a trace of potassium cyanide and a volatile product—possibly carbonyl sulphide—by passing carbon monoxide over heated **potassium thiocyanate**. The action of carbon monoxide on many **organic compounds** has been studied.[17] I. L. Bell[18] found that graphitoidal **silicon** is not changed when heated in carbon monoxide, while **titanic oxide** loses 4·7 per cent. of oxygen, and forms some carbon. F. H. Pollard found that carbon monoxide is adsorbed by platinized asbestos.

The action of carbon monoxide on the metals is discussed in connection with the metal carbonyls—*vide infra*. When heated with magnesium, **magnesium** oxide and carbon are formed; **nickel** undergoes a slight carbonization; and **chromium** and **manganese** are oxidized. N. N. Beketoff[19] found that at 290°-310°, **sodium oxide** reacts with carbon monoxide, forming sodium carbonate and sodium; and F. Haber and L. Brunes, that fused **sodium hydroxide** gives sodium carbonate and hydrogen. M. C. Boswell and J. V. Dickson found that at 410°-430°, carbon monoxide is oxidized by fused sodium hydroxide, forming sodium carbonate, and evolving hydrogen: $2NaOH+CO=Na_2CO_3+H_2$, *i.e.* essentially $CO+H_2O=CO_2+H_2$. R. E. Wilson and co-workers studied the removal of small quantities of carbon monoxide from gases by absorption at 400° by soln. of sodium hydroxide: $2NaOH+CO=H_2+Na_2CO_3$. M. Berthelot found that when **potassium hydroxide** is heated with carbon monoxide in a sealed vessel on a water-bath, some potassium formate, H.COOK, is formed. The reaction is faster if more water be used, than that required just to moisten the alkali; with methyl or ethyl alcohol in place of water the reaction is 10–15 times as fast—with ethyl alcohol, a little propionic acid is formed; with amyl alcohol the action is about half as fast as with methyl or ethyl alcohol; with glycerol the action is slower than with water; with ether the absorption is faster than with any other substance tried; and with methyl or ethyl nitrate, the reaction is faster than with water. According to A. Geuther, and V. Merz and J. Tibirica, the formation of salts of formic acid by the action of carbon monoxide on alkali hydroxides takes place at about 200°, but the temp. should not exceed 220° since sodium formate is then decomposed into carbonate and hydrogen; with potassium formate the temp. of decomposition is lower than 220°. The gas should be moist; and in order to saturate the alkali completely it is best to use soda-lime. The commercial production of formates by these reactions has been exploited. By working under press. and with a mixture of sodium carbonate and calcium hydroxide the Farbwerk vorm. Meister, Lucius, und Brüning prepared sodium formate: $Na_2CO_3+Ca(OH)_2+2CO=2HCOONa+CaCO_3$. F. C. Phillips said that **calcium hydroxide** alone does not absorb carbon monoxide. W. H. Engels studied the production of hydrogen by the action of carbon monoxide on calcium hydroxide at 500°. The main reaction is represented: $Ca(OH)_2+CO=CaCO_3+H_2$; and the side reaction: $CO+H_2O=CO_2+H_2$. The presence of iron accelerates the reaction tenfold. M. Berthelot found that the absorption by **calcium oxide** in the presence of alcohol is not more energetic than by an aq. soln. of potassium hydroxide. The last-named also studied the absorption of carbon monoxide by **barium oxide** in the presence of alcohol or ether.

G. Bodländer [20] discussed the theory of the reduction of metal oxides by carbon monoxide—*vide* the respective oxides. I. W. Fay and co-workers compared the reducing action of carbon monoxide, hydrogen, ammonia, and methane:

	Au_2O_3	Ag_2O	Hg_2O	HgO (red)	PbO	CuO	Cu_2O	CoO	ZnO
CO	<0°	0°	0°	90°	160°	75°	—	140°	170°
H_2	<0°	0°	80°	115°	190°	125°	—	—	—
NH_3 . . .	—	—	67°	157°	299°	225°	208°	—	233°
CH_4 . . .	—	—	220°	205°	210°	280°	230°	—	156°

For yellow mercuric oxide with carbon monoxide and hydrogen the numbers are respectively <0° and 50°; for lead dioxide, 110° and 150°; for red lead, 150° and 170°. In many cases the carbon monoxide is burned preferentially before the hydrogen, as shown by E. D. Campbell, C. R. A. Wright and A. P. Luff, I. W. Fay and co-workers, etc. A. F. Benton considered the mechanism of the reduction involves adsorption of the gas, isomeric change, and evaporation of the gaseous product of the reaction from the surface of the oxide. A. de Hemptinne studied the reducing action of the electric discharge on metal oxides in the presence of carbon monoxide. H. Quantin studied the joint action of carbon monoxide and chlorine on some metal oxides. The reduction of **cuprous oxide** by carbon monoxide has been studied by F. Schlagdenhauffen and M. Pagel, and by C. R. A. Wright and A. P. Luff; that of **cupric oxide** by K. Stammer, A. de Hemptinne, I. L. Bell, and C. R. A. Wright and co-workers—*vide* the respective oxides. The reduction of **silver oxide** by carbon monoxide has been studied by F. Schlagdenhauffen and M. Pagel, and A. Gautier—*vide infra*. The latter showed that with moist silver oxide a basic carbonate is formed: $3Ag_2O+CO=Ag_2O.Ag_2CO_3+2Ag$. H. Dejust gave for the heat of the reaction at ordinary temp.: $CO+Ag_2O=2Ag+CO_2+61{\cdot}2$ Cals. For **mercuric oxide**, *vide infra*. K. Stammer found that carbon monoxide does not reduce **zinc oxide**. F. J. Brislie studied the reduction of **cadmium oxide** and of bismuth oxide by carbon monoxide. F. C. Phillips found that a soln. of **cerium dioxide** in sulphuric acid is not reduced by carbon monoxide. The reduction of **lead oxide** has been discussed by C. R. A. Wright and A. P. Luff, A. de Hemptinne, and F. J. Brislie; **tin oxide**, by K. Stammer, and F. Schlagdenhauffen and M. Pagel; **manganese oxide**, by I. L. Bell, K. Stammer, C. R. A. Wright and A. P. Luff, and

G. Charpy; **chromic oxide,** by G. Charpy, F. C. Phillips, A. Gautier, and F. Schlagdenhauffen and M. Pagel. According to K. A. Hofmann, carbon monoxide is oxidized by a soln. of **chromic acid** to which mercuric oxide has been added as catalyst—*vide supra.* The oxidation is then sufficiently rapid to remove carbon monoxide from air and other gases with sufficient rapidity for analytical and hygienic purposes. The reduction of **molybdenum oxide** by carbon monoxide was observed by F. Schlagdenhauffen and M. Pagel; **iron oxide,** by W. Müller, O. Boudouard, E. Baur and F. Glässner, B. Osann, L. Gruner, A. de Hemptinne, A. Gautier and P. Clausman, J. Braithwaite, G. Charpy, I. L. Bell, etc. G. Chaudron found that below 580°, the reaction is $Fe_3O_4+4CO\rightleftharpoons 4CO_2+3Fe$; above 580°, there are two equilibria: $Fe_3O_4+CO\rightleftharpoons 3FeO+CO_2$; and $FeO+CO\rightleftharpoons Fe+CO_2$; and all three solid phases are in equilibrium at 580°; ferrous oxide is unstable below 580°, reacting $4FeO\rightleftharpoons Fe_3O_4+Fe$—*vide* iron oxides. The action of carbon monoxide on **nickel oxide** has been studied by I. L. Bell, C. R. A. Wright and A. P. Luff, O. Boudouard, etc.; on **cobalt oxide,** by C. R. A. Wright and A. P. Luff, I. L. Bell, and O. Boudouard; and on **osmium tetroxide,** by F. C. Phillips. O. Boudouard found that soln. of **potassium ruthenate** are rapidly reduced by carbon monoxide. K. Stammer found that **potassium chromate** is reduced by carbon monoxide, forming chromic oxide and potassium carbonate; while **lead chromate** furnishes lead and chromic oxides. F. C. Phillips found that neutral, acid, and alkaline soln. of **potassium permanganate** are easily reduced by carbon monoxide. V. Meyer and M. von Recklinghausen, H. Hirtz and V. Meyer, and C. Engler and W. Wild made observations on this subject. A. Mermet found that a soln. of potassium permanganate, acidified with nitric acid, and mixed with silver nitrate, is decolorized by carbon monoxide.

The physiological action of carbon monoxide.—The toxic nature of the fumes from burning charcoal was commented upon by F. Hofmann[21] in an essay: *Grundliches bedenken von dem schädlichen Dampfe der Holzkohen* (1719), and H. Davy, and F. Clément and J. B. Désormes showed that when mixed with one-fourth its bulk of air and inspired, carbon monoxide immediately produces giddiness and fainting fits. In acute poisoning there is a preliminary period of excitation followed by a sensation of heaviness, dizziness, noises in the ear, accelerated cardiac and respiratory movements, oppression on the chest, and maybe nausea and vomiting; there is also muscular weakness, drowsiness, loss of sensation, coma, and convulsions which precede death. The earlier symptoms of slow chronic poisoning are headache, neuralgic pains, anæmia, loss of flesh, and a sensation of breathlessness developed by incommensurate exertion. According to L. Hill, and C. le Neve Foster and J. S. Haldane, when the blood is 20 per cent. sat. with carbon monoxide, there occurs dizziness and shortness of breath on exertion; the symptoms are aggravated by increasing the conc. of the gas; at 50 per cent. sat., it is scarcely possible to stand, and the slightest exertion causes a temporary loss of consciousness. Exertion, by using up the oxygen in the muscles, hastens the failure of the heart's action; and with those rescued from death, degenerative changes may set in and a lasting weakness of the heart be produced. Any quantity above 0·14 per cent. of carbon monoxide in the air is dangerous; and 0·4 per cent. will nearly always cause death.

Carbon monoxide is present in the products of combustion from domestic fireplaces, stoves, etc., and is exhaled from the various chimneys of a large city in considerable vol. A smoky chimney or a defective flue may introduce carbon monoxide into the living rooms. The fumes from slow combustion stoves or fireplaces with a restricted exit contain carbon monoxide. The fumes evolved from burning charcoal or coke in a closed room are toxic in virtue of the contained carbon monoxide. The poisonous nature of these fumes has been utilized particularly in France and Germany, as a method of suicide, on account of the supposed painlessness of the death; and also as an instrument of murder. The products of combustion of coal gas may under certain conditions contain much carbon monoxide

T. E. Thorpe, for example, showed that an ordinary Bunsen burner, heating a sand tray, evolves 0·022 c. ft. of carbon monoxide per hour. The gas burners employed to heat large masses of cold water in bath-rooms are a source of danger unless provision be made for abundant ventilation. Coal gas contains carbon monoxide, and poisoning by coal gas is practically poisoning by carbon monoxide. Employees in works where water gas or producer gas is made incur the risk of both acute and chronic carbon monoxide poisoning. Water gas, used as a substitute for, and as an adjunct to, coal gas contains up to 40 per cent. of carbon monoxide, and its poisonous qualities are still more dangerous owing to the absence of a characteristic odour. The slightest leak in the household gas fittings—and few are perfect—is an insidious source of chronic poisoning.

J. S. Haldane showed that the toxic action of carbon monoxide is directly due to its combining with the hæmoglobin of the blood to form *carboxyhæmoglobin* [22] which interferes with the activity of the hæmoglobin in forming oxyhæmoglobin, and acting as a carrier of oxygen. He found that (i) when animals were placed in oxygen at 2 atm. press., the blood dissolves enough oxygen to render the animal independent of the red corpuscles; carbon monoxide at one atm. press. was then added but no toxic effects were observed; and that (ii) animals with no hæmoglobin were not affected when placed in an atm. containing 75 per cent. carbon monoxide and 25 per cent. oxygen. The carboxyhæmoglobin is more stable than oxyhæmoglobin and is more slowly decomposed and eliminated. According to N. Gréhant, if air with 0·07–0·12 per cent. of carbon monoxide be breathed for half an hour, one-fourth part of the hæmoglobin in the blood is put out of action as a carrier of oxygen, owing to the formation of carboxyhæmoglobin. According to L. Hill, if blood be shaken with 0·07 per cent. of carbon monoxide, and 21 per cent. of oxygen, the two gases will be shared equally with the hæmoglobin so that carbon monoxide has 200 times more affinity for hæmoglobin than oxygen. According to P. Spica and G. P. Menegazzi, subcutaneous injections of hydrogen dioxide can convert carboxyhæmoglobin into carbon dioxide, etc.

The blood in the case of death from asphyxia is dark in colour; in the case of carbon monoxide poisoning it is bright florid red. P. A. Piorry noticed that the blood—living or dead—is coloured a bright red by the action of carbon monoxide. This is due to the formation of carboxyhæmoglobin, which retains its colour under conditions where oxyhæmoglobin would lose its oxygen and assume the dark appearance of reduced hæmoglobin. The spectra of hæmoglobin, oxyhæmoglobin, and carboxyhæmoglobin by J. Formanek are shown in Fig. 38; that of oxyhæmoglobin is characteristic of flesh blood diluted with water. There are here two bands: the one near the sodium line is well-defined with a head of wave-length 5781; the other, less well-defined, is in the green, and has a head of wave-length 5417. The

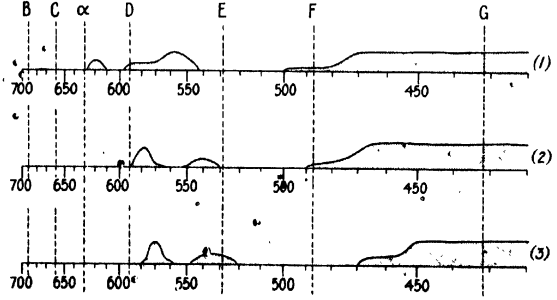

FIG. 38.—Absorption Bands in the Spectra of Hæmoglobin (1), Oxyhæmoglobin (2), and Carboxyhæmoglobin (3).

spectrum of carboxyhæmoglobin is somewhat similar, but the two bands are slightly displaced towards the violet end of the spectrum and have heads of wave-length 5720 and 5381 respectively. The difference is so small that the changed position is appreciable only when the two spectra are compared side by side. H. Hartridge has developed a method of estimating the magnitude of the displacement by the movement on a micrometer required to bring one of the two bands of the carboxyhæmoglobin spectrum coincident with the corresponding band of the oxyhæmoglobin spectrum. When ammonium sulphide is added to the dil. blood soln., the absorption bands of carboxyhæmoglobin remain unaltered, while those of oxyhæmoglobin are merged into one broad band. Since in the case of carbon monoxide poisoning death ensues before all the hæmoglobin has been converted into carboxyhæmoglobin, the spectrum does not necessarily remain unchanged on the addition of ammonium sulphide; but the two persistent bands of carboxyhæmoglobin may be superposed on the broad band of the reduced hæmoglobin.

Carbon monoxide, according to G. Senter,[23] has no effect on the action of ferments, although G. Bredig showed that it retards the catalytic activity of colloidal platinum. W. B. Bottomley and H. Jackson, A. Marcacci, L. Just, and G. Linossier have discussed the effect of carbon monoxide on plants, and on the germination of seeds.

The methods of detecting and measuring small amounts of carbon monoxide in a gas can be divided into two classes: (1) those in which carbon monoxyhæmoglobin is formed; and (2) those in which it is oxidized to carbon dioxide. The methods employed in the first class are virtually all modifications of F. Hoppe-Seyler's method[24] which is based on the fact that both carbon monoxyhæmoglobin formed by the action of carbon monoxide on arterial blood, and oxyhæmoglobin give distinct absorption spectral bands—*vide supra*. Of the oxidation methods, the one employing iodine pentoxide is well suited for the work—*vide supra*. The reducing action of carbon monoxide on mercuric or silver oxide at 60° has been recommended for the quantitative determination of this gas: $Ag_2O+CO \rightleftharpoons CO_2+Ag$, by V. Nesmjeloff, L. Moser and O. Schmid, F. Schlagdenhauffen and M. Pagel, and E. Glaser. Other reactions utilized in the determination of carbon monoxide have been previously discussed; they involve the absorption of the gas by an ammoniacal soln. of silver hydroxide: $Ag_2O+CO=CO_2+Ag$, or by an ammoniacal or hydrochloric acid soln. of cuprous chloride; and the effect of the gas on palladious chloride. The gas can also be estimated by oxidizing it with palladized asbestos and air, or cupric oxide at 250° under conditions[25] which do not affect methane. A. B. Lamb and co-workers discussed the preferential combustion of carbon monoxide in the presence of hydrogen when *hopcalite*—*i.e.* a mixture of metallic oxides, say, 60 per cent. of manganese dioxide, and 40 per cent. of cupric oxide—is used as catalyst at ordinary temp. Hydrogen is not affected.

§ 27. The Metal Carbonyls

E. Müller[1] has discussed the amphoteric nature of the carbonyl radicle. Some metals unite with carbon monoxide, forming a series of carbonyls. Most of these substances are volatile. They differ considerably in their physical properties, but they are very similar in their chemical properties. Thus, all these carbonyls have very similar chemical properties – for instance, when heated, they all decompose into carbon monoxide and the metal, which is deposited in the form of a bright metallic mirror. They are not attacked by non-oxidizing acids, but are quickly dissolved by oxidizing acids, and specially by aq. soln. of the halogens, with the evolution of carbon monoxide. At least one of the carbonyls of each metal is volatile without decomposition, and can be purified by distillation or sublimation. They are all more or less soluble in the usual organic solvents, such as ether, ethyl alcohol, benzene, oils, etc., and are all insoluble in water.

J. L. Gay Lussac and L. J. Thénard showed that when potassium or sodium is heated to redness in carbon monoxide, the gas inflames furnishing the metal oxide and carbon. At a low temp., G. B. H. Kühnemann found that the carbon monoxide absorbed by potassium is decomposed, and at a temp. below redness, there is formed potassium oxide, and a black product which furnishes *potassium rhodizonate* when treated with water. The early chemists noted the formation of a compound of carbon monoxide and potassium during the preparation of this element by the reduction of potassium compounds with carbon. They referred to it as "croconaceous" matter. Thus, A. Fleischl said that when the croconaceous matter has attracted a little moisture from the air there is formed a product which sometimes explodes spontaneously; and, after any contaminating potassium has been distilled from it, it furnishes potassium rhodizonate or croconate. According to J. von Liebig, and J. F. Heller, at a low temp. molten potassium absorbs carbon monoxide and forms the so-called *Kohlenoxydkalium*, and, added B. C. Brodie, at about 80°, potassium unites with carbon monoxide, forming an aggregate of crystals with a composition approximating K_2CO; at a lower temp., carbon monoxide is given off and the dark red product with the composition KCO is probably a mixture of potassium oxide and rhodizonate; J. U. Lerch said that moisture is probably necessary for the formation of the red product. C. Winkler noted the formation of the explosive compound of potassium and carbon monoxide when a mol of potassium carbonate and two gram-atoms of magnesium powder are heated together. R. Nietzki and T. Benckiser regard the potassium carbonyl, $K_6C_6O_6$, formed by the action of carbon monoxide on potassium, to be the potassium derivative of hexahydroxybenzene, $C_6(OH)_6$. They say that this compound is not explosive, but becomes so on keeping. When treated with dil. alcohol, potassium dioxycarboxylate, $C_6(OK)_4O_2$, is formed. J. U. Lerch also studied the products obtained from potassium carbonyl. According to A. Joannis, when purified and dry carbon monoxide is passed into a soln. of potass-ammonium in liquefied ammonia at about $-50°$, the blue colour gradually becomes weaker, and at last changes to pink. At this point the reaction is complete, and if the ammonia is allowed to evaporate, the compound **potassium carbonyl,** $K_2C_2O_2$, is obtained as a pale, rose-coloured powder which detonates in contact with air or water, or when heated to 100°. If, however, it is allowed to come in contact with water vap. in a vacuum, it deliquesces and forms a yellow soln. The corresponding **sodium carbonyl,** $Na_2C_2O_2$, is obtained in a similar manner as a white powder with a lilac tint. It detonates at 90° in vacuo, or when brought in contact with air or water, but deliquesces quietly in contact with water vap. in a vacuum. When it detonates, very little gas is evolved, and a small quantity of sodium cyanide is formed, but the principal reaction is represented by the equation $2Na_2C_2O_2=Na_2CO_3+Na_2O+3C$. When detonation takes place in the presence of water, the small quantity of gas evolved contains 86 per cent. of hydrogen and 14 per cent. of carbon monoxide.

The action of carbon monoxide on copper has been discussed in connection with the metal (**3.** 21, 13). L. Mond[2] and co-workers did not succeed in preparing **copper carbonyl.** According to G. Bertrand, if carbon dioxide be passed over heated cupric oxide, no unusual effect is observed, but if the gas be first passed over red-hot carbon, a mirror-like deposit of copper is produced, presumably owing to the intermediate formation of copper carbonyl; but E. Mond and C. Heberlein could find no evidence of the existence of this carbonyl. N. D. Zelinsky has described an application of the reaction to cover organisms with a film of metallic copper. According to M. Berthelot, when silver foil is heated for four hours at 500° in a sealed tube containing dried carbon monoxide, about 3·6 per cent. of carbon dioxide is formed, and some carbon is deposited. This reaction begins even at 300°, but at this temp. its progress is very slow. Carbon monoxide, when heated at temp. not exceeding 550°, yields carbon dioxide without depositing carbon; it is therefore probable that the deposition of carbon in the foregoing experiment results from the decomposition of a *silver carbonyl* compound analogous to the corresponding iron derivative.

According to H. Moissan,[3] calcium at a dull red heat decomposes carbon monoxide, but no carbonyl has been reported. G. Roederer found that when a soln. of strontium-ammonium is treated with carbon monoxide at $-45°$, a dull yellow, pulverulent mass of **strontium carbonyl,** $Sr(CO)_2$, is obtained; this becomes bright yellow on exposure to moist air, forms a limpid, yellow soln. with water, and blackens when heated under reduced press., yielding a mixture of strontia, strontium carbonate, and carbon. Similarly, A. Guntz and M. Mentrel found that when carbon monoxide is passed into a soln. of barium-ammonium in liquid ammonia, **barium carbonyl,** $Ba(CO)_2$, is formed as yellow powder which is unstable in air, becomes brown at 100°, and incandescent at 250°, forming barium oxide and carbonate and carbon. Carbon monoxide reacts with metallic barium at 500°, producing a superficial layer of barium carbide.

J. Parkinson,[4] C. Matignon, and C. Winkler found that magnesium at a dull red heat burns brilliantly in carbon monoxide with the separation of carbon. G. Gore passed a stream of carbon monoxide for two days through a soln. of potassium cyanide in which dipped a strip of magnesium; he found that the metal acquired a black film. A. Guntz and A. Masson found that if aluminium be heated to dull redness in an atm. of carbon monoxide containing a small proportion of the vap. of aluminium chloride or iodide, the metal becomes incandescent and is more or less completely converted into aluminium carbide. According to A. von Bartal, when dry carbonyl chloride is passed into fused aluminium iodide, at 195°–200°, until its weight has increased 25 per cent., and iodine and unaltered iodide are removed from the product by washing with carbon disulphide, a light brown amorphous residue of aluminium dicarbonyl dichloroiodide, $Al_3(CO)_2Cl_2I$, remains; this compound cannot be melted even by heating in a sealed tube; it decomposes on heating at 270°–300° in an open tube, aluminium chloride and iodine volatilizing, and a black compound of **aluminium carbonyl,** $Al_2(CO)_2$, insoluble in water and acid, remains; the carbonyl is converted into aluminium oxide and carbon dioxide on prolonged heating in air.

A. Guntz heated finely divided manganese in carbon monoxide, and found that a reaction occurs: $Mn+CO=MnO+C+34{\cdot}5$ Cals. G. Charpy obtained an analogous result with ferromanganese, and with chromium, carbon and chromic oxide was formed. L. Mond and co-workers[5] tried to prepare carbonyls of manganese, chromium, and tungsten by the action of carbon monoxide on the finely divided metals at press. up to 500 atm., and at temp. up to 450°, but without success. Finely divided molybdenum, prepared by reducing the oxychloride by hydrogen at a low temp., at 200–250 atm., and about 200°, is attacked by carbon monoxide and forms highly refracting white crystals of **molybdenum carbonyl,** $Mo(CO)_6$. The sp. gr. of the compound is 1·96, and it is soluble in benzene. The crystals evaporate before melting, and can easily be sublimed in an atmosphere of hydrogen or of carbon monoxide at a temp. of 30° or 40°. The vap. begins to decompose at 150°. The chemical properties resemble those of the other carbonyls. It is scarcely attacked by non-oxidizing agents, but quickly by oxidizing agents, especially by bromine; carbon monoxide is eliminated, and molybdic acid is left in suspension. R. L. Mond and A. E. Wallis give $Mo_5(CO)_{26}$ for the composition of molybdenum carbonyl. Two years were required to prepare 170 mgrms. It is insoluble in common solvents.

In 1871, I. L. Bell[6] stated that when nickel is heated with carbon monoxide, a little carbon is formed, but most of the gas remains unaltered. In the presence of finely divided nickel, P. Sabatier and J. B. Senderens say that the reaction $2CO=C+CO_2$ begins at about 230°, and is completed at about 349°. G. Charpy said that nickel turnings at 1000° are not attacked. In 1890, L. Mond and co-workers showed that when carbon monoxide is passed over finely divided metallic nickel at a temp. between 350° and 450°, carbon dioxide is formed, and a black, amorphous powder is obtained consisting of nickel and carbon. The composition of this powder varies very widely with the temp. employed, and still more according to the time the operation has been carried on. A small quantity of nickel can decompose a very large amount of carbon monoxide. At the commencement, a fast current of carbon monoxide is completely changed into carbon dioxide by a comparatively small quantity of nickel. By-and-by, the change becomes less complete, but the gas may be passed for several weeks before carbon dioxide ceases to be formed. They have in this way obtained a product containing as much as 85 per cent. carbon and 15 per cent. nickel. Further,

> When finely divided nickel, such as is obtained by reducing nickel oxide by hydrogen at about 400°, is allowed to cool in a slow current of carbon monoxide, the flame of a Bunsen burner into which the escaping gas is introduced becomes highly luminous, and when the

tube through which the gas passed is heated, a mirror of metallic nickel, mixed with a small quantity of carbon, is produced. The gas contains a compound of nickel and carbon monoxide—nickel carbonyl. The carbon monoxide is very readily absorbed by the nickel as soon as the temp. has descended to about 100°, and if the current of carbon monoxide is continued, or if this gas is replaced by a current of an inert gas (such as carbon dioxide, nitrogen, hydrogen, or even air), a mixture of gases is obtained which contains upwards of 30 per cent. of nickel carbonyl. After a time (with a moderate current of gas, about an hour), the quantity of this compound given off becomes less and gradually diminishes till it practically ceases altogether. The property of the nickel to form this compound is restored by heating it again to about 400°, and cooling it down; and, for a time, it yields the compound more abundantly after repeated use. When these mixtures of gases are heated above 150°, their vol. increases and nickel separates, which, according to the temp., is more or less contaminated with carbon resulting from the action of the nickel upon the carbon monoxide generated.

Nickel carbonyl is conveniently made by passing carbon monoxide over finely divided nickel at 30° to 50°; the nickel is made by the reduction of the oxide with hydrogen at 400°. The carbonyl is condensed from the escaping gases by passing them through a tube cooled by a refrigerating mixture of ice and sodium chloride. According to J. Dewar, the reaction may be advantageously carried out under a press. of 2–100 atm. when the temp. may be raised to 250° without fear of decomposition, and the reaction is then greatly accelerated; the condensation of the carbonyl is also best performed under press. so that the excess of carbon monoxide is led back over the nickel while under the same press. E. Tassilly and co-workers passed carbon monoxide over reduced nickel deposited on puzzolana, and they found the optimum temp. to be 45° at 30 mm. press. According to H. Frey, sodium decomposes ethyl oxalate into ethyl carbonate and carbon monoxide. If ethyl oxalate be added from a dropping funnel to finely divided nickel chloride or bromide and sodium suspended in dry ligroïn, at 90°, the escaping gas contains nickel carbonyl. J. H. Weibel observed the formation of nickel carbonyl when an aq. soln. of a nickel salt is treated with carbon monoxide at 100 atm. press. at 150°. According to R. Lessing, nickel carbonyl for organic preparations is conveniently stored in an absorbent material like charcoal or coke impregnated with oil; when desired for use, it is taken up by passing hydrogen, nitrogen, or other gas into the stored material.

At ordinary temp., nickel carbonyl is a colourless volatile liquid. L. Mond and co-workers gave 1·3185 for the sp. gr. at 17°; and L. Mond and R. Nasini gave 1·36153 at 0°; 1·34545 at 8°; 1·32446 at 14°; 1·31032 at 20°; 1·29832 at 25°; 1·28644 at 30°; and 1·27132 at 36°. Hence, the vol. of the liquid at $\theta°$ is $v_0(1+0·0016228\theta+0·0_5608\theta^2+0·0_8505\theta^3)$, where v_0 represents the vol. at 0°. The mean coeff. of cubical expansion between 0° and 36° is therefore 0·001853. L. Mond and co-workers found the vap. density to be 6·01 corresponding with a mol. wt. of 160; the formula $Ni(CO)_4$ requires a vap. density 5·9. L. Mond and R. Nasini further found the lowering of the f.p. in benzene soln. is normal in agreement with the formula $Ni(CO)_4$. The b.p. is 43° at 751 mm.; M. Berthelot gave 46°; and J. Dewar and H. O. Jones, 43·2° to 43·33° at atm. press. L. Mond and co-workers found the liquid solidified to needle-like crystals at −25°. According to J. Dewar and H. O. Jones, the critical temp. is about 200°, and the critical press. about 30 atm. A. Mittasch found the vap. press. p mm., at the indicated temp., to be

	2·05°	7·56°	15·27°	20·20°	24·26°	29·52°	34·29°	39·07°
p . .	133·1	170·5	238·2	294·3	349·7	444·2	532·6	647·2

According to L. Mond and R. Nasini, nickel carbonyl begins to decompose at about 36°, and A. Mittasch estimates the percentage decomposition:

	62°	69°	79°	90°	98°
Decomposition	0·38	0·80	1·10	2·60	5·80 per cent.

L. Mond and co-workers said that when passed through a hot tube at 180°–200°, the nickel is deposited as a brilliant metallic mirror. J. Garnier attributed the separation of nickel in the flues of furnaces heating ferro-nickel to the formation and decomposition of a gaseous nickel compound. The vap. may explode if rapidly heated to 60°, but, added J. Dewar and H. O. Jones, only in the presence of air or oxygen. L. Mond said that the liquid carbonyl does not explode, but it decomposes rapidly when heated. It may be distilled if it is dissolved in a liquid of higher boiling point, but even then it also decomposes with the evolution of carbon monoxide and the deposition of nickel in a very finely divided state.

According to M. Berthelot, the reaction $Ni(CO)_4=Ni+4CO$ is endothermal and reversible; while the reaction $Ni(CO)_4=Ni+2C+2CO_2$ is exothermal and reversible. He said that the former reaction occurs if the compound is slowly heated, and the latter if rapidly heated. A. Mittasch observed no signs of the formation of carbon dioxide; and M. Berthelot (1901) obtained only 1 c.c. of carbon dioxide after heating a 35 c.c. bulb of gas for some hours at 550°. According to A. Mittasch, if x denotes the conc. of carbon monoxide when the system is in equilibrium, $a-x$ will be the conc. of the nickel carbonyl; and since the conc. of the solid phase—nickel—is a constant, for equilibrium, $Ni(CO)_4 \rightleftharpoons Ni+4CO$, $x^4=K(a-x)$, where K is the equilibrium constant. The observed values of K are in agreement with this assumption. The internal heat of the reaction calculated from $(d \log K)/dt=Q/RT^2$ give $Ni+4CO=Ni(CO)_4+43{\cdot}63$ Cals. L. T. Reicher obtained 59·5 Cals. from the heat of combustion, but by correcting this for the external work the observed value becomes 50·7 Cals. Observations on the speed of decomposition show that the decomposition of nickel carbonyl is a reaction of the first order, which is explained by assuming the reaction occurs only on the walls of the containing vessel, while the formation of nickel carbonyl is a reaction of the second order, and this is explained by assuming that the reaction occurs in stages: $Ni+2CO \rightleftharpoons Ni(CO)_2$, and $Ni(CO)_2+2CO \rightleftharpoons Ni(CO)_4$. Traces of air, or of hydrogen sulphide, retard the reaction to a very marked degree; and small quantities of water vapour exert a slight disturbing action. The temp. coeff. of the decomposition is greater than that of the formation of nickel carbonyl. J. Dewar and H. O. Jones gave 6·4 Cals. for the mol. heat of vaporization.

L. Mond and R. Nasini found the at. refraction of the nickel in nickel carbonyl to be about three times as great as nickel in the metallic state or in its salts; A. J. F. de Silva showed that the mol. refraction of nickel carbonyl is higher than the sum of the at. refractions of nickel oxide and carbon monoxide. J. H. Gladstone found the mol. refraction for the H_α-line is 57·7°; and the mol. dispersion between the H_γ- and the H_α-lines is 5·93. L. Mond gave 58·63 for the mol. refraction μ/D; and 1·1236 for the dispersion coeff. He added that the compound is opaque to rays of wave-length exceeding 3·820. He also found that the gas burns with a faintly luminous flame in which metallic nickel is liberated, and which gives a continuous spectrum. When sparked in a vacuum tube at 5 mm. press., the spectrum of carbon monoxide alone is obtained. When the gas is diluted with hydrogen, it burns with a yellowish-green flame which furnishes the line spectrum characteristic of nickel. L. Mond found nickel carbonyl to be a bad conductor of electricity. G. Jaffé said that the ionization is 5·1 times as great as that of air. A. Mittasch gave 10^{-9} rec. ohms for the sp. conductivity of the liquid. L. Mond gave 38·21 for the magnetic rotatory power, a value greater than that of all other substances with the exception of phosphorus. The diamagnetic constant is $-3{\cdot}131\times10^{10}$. Unlike the general paramagnetic properties of the nickel salts, nickel carbonyl is thus strongly diamagnetic.

Attempts by L. Mond, H. Hirtz, and M. D. Cowap to prepare nickel tricarbonyl analogous with cobalt tricarbonyl were not successful. L. Mond suggested the first of the following formulæ to explain the physical properties of nickel carbonyl. Here nickel is represented as an octovalent element. H. E. Armstrong, J. H. Gladstone, H. O. Jones, and A. J. F. de Silva preferred the ring formula with nickel divalent.

$$\begin{matrix}CO\\CO\end{matrix}\!\!>\!\!\!>Ni<\!\!\!<\!\!\begin{matrix}CO\\CO\end{matrix}$$

$$Ni<\begin{matrix}CO-CO\\CO-CO\end{matrix}$$

The main argument in favour of the cycloid or ring formula is that it affords an explanation of the complete masking of the metal, comparable, for example, with that which sulphur suffers in thiophene. L. Mond added that it is doubtful if all the carbonyl radicles are directly associated with nickel since it would then be necessary to assume an excessive valency for the element. On the other hand; the ring formula does not explain why in the case of the analogous cobalt compound one carbonyl group is more easily eliminated than the others; and why the cobalt compound has double the formula weight in benzene soln. Consequently, said L. Mond and co-workers, these compounds probably have a molecular rather than an atomic constitution, similar to the hydrates of salts or of acids, the carbonyl group taking the place of the water of crystallization or hydration. Here again, however, the difficulty arises that we have to assume that these compounds, although they can be obtained in a gaseous form, have a normal gas density, and so far as they could be investigated therein, exist in the gaseous state also in this molecular condition.

According to M. Berthelot, at ordinary temp. nickel carbonyl is stable in the gaseous or liquid state when it is sealed up in glass tubes; if exposed to the air, oxidation occurs, and there separates, according to L. Mond, nickelous carbonate, and, according to M. Berthelot, green nickelous hydroxide; at the same time, a part of the vap. oxidizes, forming a white deposit having the composition $C_2O_3NiO.H_2O$. A mixture of the vap. with air or oxygen burns or explodes on contact with a red-hot substance, according to the relative proportions of oxygen and vap. present. The explosion of a mixture of dry nickel carbonyl and oxygen can be produced by shaking energetically with mercury. Nickel carbonyl is insoluble in water. The gaseous mixture in presence of a little water oxidizes slowly, with formation of a greenish, gelatinous precipitate. This compound contains nickel, oxygen, water, and some combined carbon; it blackens on heating from separation of carbon. Simultaneously with the production of this complex oxide in the cold, carbonic oxide is regenerated. The dry mixture undergoes a similar decomposition, but the oxide formed is yellowish-brown; in time it blackens by further decomposition. Liquid nickel carbonyl kept under water without exclusion of air decomposes in a similar manner, but more slowly. Nickel carbonyl thus behaves in a manner analogous to the organo-metallic radicles and the metallic derivatives of acetylene. Nickel carbonyl is insoluble in dil. acids or alkalies, and in acid soln. of cuprous chloride. The most suitable solvents are the hydrocarbons—*e.g.* turpentine. L. Mond and C. Langer found it to be soluble in alcohol, benzene, and chloroform; and V. Lenher and H. A. Loos, in toluene, acetone, and methyl or ethyl alcohol. When soln. in chloroform, acetone, benzene, toluene, and methyl or ethyl alcohol are allowed to stand for some time, there separates a green gelatinous precipitate which is possibly a mixture of nickel hydroxide and carbonyl. E. Hatschek and P. C. L. Thorne found that the soln. in benzene begins to dissociate below the b.p. turning greenish-brown and then black. Colloidal nickel is formed.

Oxidizing agents were found by L. Mond and co-workers to decompose nickel carbonyl; chlorine furnishes nickel chloride and carbonyl chloride; bromine behaves in an analogous manner; F. E. E. Lamplough studied the reaction with iodine. A. Mittasch found that iodine gives a nickel salt and carbon dioxide. According to J. Dewar and H. O. Jones, a soln. of chlorine, bromine, or iodine in an organic solvent decomposes the carbonyl with the evolution of carbon monoxide; liquid chlorine or bromine decomposes the solid carbonyl; iodine has no action on the liquid carbonyl; a soln. of iodine mono- or tri-chloride or cyanogen iodide in carbon tetrachloride is decomposed by the carbonyl, iodine is first set free, and this decomposes more carbonyl. Hydrogen chloride reacts readily with the carbonyl; hydrogen bromide or iodide has no action.

L. Mond and co-workers, and A. Mittasch found that sulphur decomposes nickel carbonyl; and J. Dewar and H. O. Jones found a soln. of sulphur in an organic solvent soon liberates carbon monoxide from the carbonyl. According to M. Berthelot, hydrogen sulphide in the cold rapidly precipitates a black sulphide from the vap. J. Dewar and H. O. Jones obtained nickel sulphide, hydrogen, and carbon monoxide by the action of hydrogen sulphide. The dry carbonyl in contact with conc. sulphuric acid detonates in a few moments; but if the carbonyl be diluted with nitrogen, the decomposition may proceed quietly—each atom of nickel furnishes a mol. of nickel sulphate and four mols of carbon monoxide—at the same time some of the sulphuric acid is reduced. J. Dewar and H. O. Jones found that with sulphuric acid, nickel sulphate, hydrogen, and carbon monoxide are slowly formed: $Ni(CO)_4+H_2SO_4=NiSO_4+H_2+4CO$.

M. Berthelot observed that ammonia gas does not act on nickel carbonyl immediately, but if oxygen be gradually added to the mixture, a white complex substance is formed which blackens when heated. According to H. O. Jones, nickel carbonyl in alcoholic soln. reacts with hydroxylamine, NH_2OH, forming a bluish-violet mass which solidifies in the desiccator, is insoluble in all solvents tried, and decomposes at 100°. The ratio of nickel to hydroxylamine in the compound is 1 : 4 or 1 : 5. Hydrazine, $N_2H_4.H_2O$, furnishes analogous compounds. M. Berthelot found that nitric oxide, passed into liquid nickel carbonyl, or mixed with its vap. volatilized in nitrogen, produces blue fumes, slowly deposited. The addition of a further quantity of nitric oxide, even when its initial vol. was four times that of the gaseous nickel carbonyl, reproduces these fumes. The inference is drawn that the vap. of another nickel compound is present as well as the nickel carbonyl, and forms a blue compound immediately with nitric oxide, which is present in excess. If a few bubbles of oxygen be introduced in place of the second quantity of nitric oxide, a blue compound, different from the one noticed above, is formed. According to R. L. Mond and A. E. Wallis, nitric oxide colours a one per cent. soln. of nickel carbonyl in chloroform an intense blue; and on evaporation in the absence of air, a blue powder is produced. It is assumed that a nickel nitrosocarbonyl is formed, but the analyses were unsatisfactory. L. Mond and co-workers found that nitric acid oxidizes nickel carbonyl and colours the alcoholic soln. blue. M. Berthelot found that phosphine reacts with nickel carbonyl, forming a black shining compound.

According to J. Dewar and H. O. Jones, aluminium chloride does not react with nickel carbonyl nor has the carbonyl any action on the aliphatic hydrocarbons, but with benzene or toluene, aluminium chloride, and nickel carbonyl, a rapid evolution of hydrogen chloride occurs and a dark viscid mass is formed; toluene, *m*-xylene, naphthalene, and mesitylene also react more or less slowly. Nickel carbonyl reacts with benzene in the presence of aluminium bromide. H. O. Jones found that nickel carbonyl reacts like the keto-compounds. Alkyl magnesium compounds, phenyl magnesium iodide, etc., also react with nickel carbonyl. J. Dewar and H. O. Jones found that nickel carbonyl and carbon disulphide do not react to an appreciable extent in the liquid state, unless the two liquids be exposed to light; but they readily interact in the vaporous state, and the reaction is favoured by a decrease of press. as is also the case with the oxidation of phosphorus and of aldehyde vap. The reaction is represented by $2Ni(CO)_4+CS_2=2NiS+8CO+C$ rather than by $Ni(CO)_4+CS_2=NiS+CS+4CO$. The reaction proceeds in darkness and in the absence of moisture. Carbonyl sulphide, allyl sulphide, thiophene, ethyl trithiocarbonate, ethyl dithiocarbonate, thiocarbonyl chloride, and thiocarbamide all react with nickel carbonyl to produce brown or black deposits. J. Dewar and H. O. Jones found that a soln. of cyanogen in an organic solvent decomposes nickel carbonyl with the evolution of carbon monoxide. The physiological action of nickel carbonyl has been studied by H. W. Armit, J. G. McKendrick and W. Snodgrass, L. Mond, E. Vahlen, A. Mittasch, etc. Small quantities of the vap. are very poisonous, being decomposed in the lungs into carbon monoxide and a nickel derivative.

L. Mond said that the metals and the metal salts do not react with nickel carbonyl. A. Mittasch found that sodium chloride, lithium chloride, mercuric chloride or cyanide, chromic chloride, potassium iodide, potassium nitrate, nickel sulphate, and silver nitrate are insoluble in liquid nickel carbonyl; traces of some salts do dissolve but the soln. are non-conducting. He also found that silver nitrate and platinum tetrachloride are decomposed by nickel carbonyl; L. Mond and co-workers also found that ammoniacal silver and cupric salt soln. are reduced. M. Berthelot said that a dil. or conc. soln. of potassium hydroxide has no action on the carbonyl. R. L. Mond and A. E. Wallis found that moist air, carbon monoxide, and nickel tetracarbonyl at 200° give a yellow deposit of colloidal basic nickel carbonate of variable composition.

Cobalt was found by I. L. Bell to react with carbon monoxide less readily than nickel, furnishing a little carbon. P. Sabatier and J. B. Senderens also found that the reaction $2CO=C+CO_2$ occurs at a higher temp. with cobalt than with nickel. L. Mond, C. Langer, and L. Quincke obtained no cobalt carbonyl under the conditions employed for the nickel compound; but later L. Mond, H. Hirtz, and M. D. Cowap found that **cobalt tetracarbonyl,** $Co(CO)_4$, can be made by heating cobalt over 150° in an atm. of carbon monoxide at a press. between 30–40 atm. The higher the press. up to at least 250 atm., the more rapid the formation of the carbonyl, likewise also when the temp. is raised to 220°. Cobalt tetracarbonyl furnishes orange-coloured transparent crystals which are best preserved by sealing them in an atm. of hydrogen or carbon monoxide in a glass tube. The sp. gr. of the crystals is 1·73 at 18°, if kept for a few hours the sp. gr. increases owing to decomposition. The vap. density could not be determined directly owing to the decomposition of the carbonyl. The crystals melt without decomposition at 51°; very slow decomposition sets in immediately after melting, and it is quite appreciable at 53°, and fairly rapid at 60°. Decomposition is complete at the last-named temp. in two days, and cobalt tricarbonyl is formed. The vap. press. at 15° is 0·072 mm. The mol. wt. by the cryoscopic method in benzene is 328, corresponding with the doubled formula $Co_2(CO)_8$. The crystals decompose when exposed to the atm., a deep violet substance, consisting of a basic cobalt carbonate, being left behind. Cobalt carbonyl is very slowly attacked by non-oxidizing acids, such as hydrochloric or sulphuric, whereas when nitric acid or bromine is present, the reaction is accelerated considerably, and the corresponding cobalt salt is formed with the elimination of carbon monoxide, according to the equation $Co(CO)_4+Br_2=CoBr_2+4CO$. Cobalt carbonyl is insoluble in water, but more or less soluble in organic solvents, such as carbon disulphide, ether, naphtha, alcohol, and also in nickel carbonyl. If these soln. are kept for some time, or if they are warmed, decomposition ensues. R. L. Mond and A. E. Wallis found that nitric oxide reacts with cobalt tetracarbonyl slowly at room temp., instantly at 40°, forming a cherry-red liquid with the composition **cobalt nitrosotricarbonyl,** $Co(CO)_3.NO$. The mol. wt. by the vapour density method is 171·7; theory requires 173. The mobile liquid is very volatile; its sp. gr. is 1·5126 at 14°; its b.p. 78·6° at 761 mm.; and its m.p. is −1·05°. The vap. press. at 14° is 77 mm., at 23°, 100 mm.; at 36°, 171 mm.; at 45°, 251 mm.; at 56°, 361 mm.; and at 66°, 517 mm. The compound slowly decomposes above 66°. It is stable under water in which it is insoluble; it is miscible in all proportions with alcohol, benzene, ether, chloroform, etc. It may be distilled in a current of inert gas at 50°–60°, with only a slight decomposition into cobalt tricarbonyl and nitric oxide. As indicated above, when cobalt tetracarbonyl is allowed to stand for a couple of days at 60°, it furnishes **cobalt tricarbonyl,** $Co(CO)_3$, which is purified by cooling the soln. in warm benzene. The crystals are jet-black. They are so slightly soluble in the various menstrua tried that their mol. wt. was not determined. The compound decomposes when heated above 60°. At temp. up to 60°, nitric oxide does not react with cobalt tricarbonyl, but at 75°–80° there is a slight reaction. J. H. Weibel observed that traces of cobalt carbonyl appear when an aq. soln. of a cobalt salt is treated with carbon monoxide at 100 atm. press. and at 150°.

K. Stammer said that iron at a dull red heat decomposes carbon monoxide with the separation of carbon; H. Buff and A. W. Hofmann, I. L. Bell, A. Guntz, P. Sabatier and J. B. Senderens, A. Gautier and P. Clausmann, G. Charpy, M. van Breukeleveen and A. ter Horst, etc., have made observations on the reactions: $Fe+CO=FeO+C+20·1$ Cals., and $FeO+CO=Fe+CO_2$; and on the cementation of iron by the carbon. L. Mond, C. Langer, and F. Quincke obtained no carbonyl under the conditions they employed for nickel tetracarbonyl. L. Mond and

F. Quincke volatilized reduced iron to a slight extent by heating it to 80° in a stream of carbon monoxide, and concluded by analogy with nickel tetracarbonyl, that an iron tetracarbonyl was formed. J. Garnier also inferred that from the luminosity of the flame of carbon monoxide a volatile compound of this gas with iron was formed in the manufacture of iron and steel. M. Berthelot also treated reduced iron at 45° with carbon monoxide and obtained evidence that a small quantity of a volatile iron carbonyl was formed. L. Mond and C. Langer isolated the compound and showed it to be **iron pentacarbonyl**, $Fe(CO)_5$, and not the tetracarbonyl. Finely divided iron was allowed to remain in contact with carbon monoxide at ordinary temp., and then heated to 120° to distil off the iron carbonyl. A better yield is obtained by distilling in a slow current of carbon monoxide. The iron carbonyl is condensed in a tube cooled to −20°. The remaining iron was allowed to cool, and again to stand in contact for 24 hrs. with carbon monoxide. The daily yield is about a gram of carbonyl per 100 grms. of iron. No increase in the yield was obtained by working with carbon monoxide under a press. of 10 atm. R. L. Mond and A. E. Wallis studied the best conditions for making this compound. A. Stoffel investigated the conditions governing the formation of iron pentacarbonyl. Up to 60°, the influence of temp. on the reaction is slight, but just below 80°, adsorption of the reaction product by the iron at first retards the formation of the carbonyl, and finally inhibits it. Above 80°, dissociation stops the action, so that large quantities in the state of vap. cannot be formed. The presence of ammonia accelerates the combination of carbon monoxide and iron; that of hydrogen sulphide exerts no influence. R. L. Mond and A. E. Wallis measured the yields at different temp. and press., and found that the formation of the carbonyl rapidly diminishes when the temp. exceeds 200°, but up to that temp. the yield is greater the higher the temp. and at a press. of 300 atm. is 4 to 5 times as great as at 100 atm. press. J. H. Weibel observed no formation of an iron carbonyl when an aq. soln. of an iron salt is treated with carbon monoxide at 100 atm. press. at 150°.

L. Mond and C. Langer found that iron pentacarbonyl is a pale yellow, viscid liquid. J. Dewar and H. O. Jones found the sp. gr. of the liquid referred to water at 4°:

	−20°	0°	21·1°	40°	60°	80°	120·5°
Sp. gr.	1·53	1·4937	1·4565	1·4330	1·3825	1·3510	1·310

The coeff. of expansion between 0° and 21° is accordingly 0·00121; between 20° and 40°, 0·00128; and between 40° and 60°, 0·00142—the mean coeff. of expansion over the whole range is 0·00138. According to L. Mond and C. Langer, the pentacarbonyl distils without decomposition at 102·8° and 749 mm. It solidifies below −21° to a mass of yellow, needle-shaped crystals. When heated to 180°, it is completely decomposed into iron and carbon monoxide. The dissociation at 130° amounts to about one per cent.; at 140°, it is quite marked, and is attended by the separation of iron; at 216° the dissociation is complete. The reaction is reversible. The dissociation increases with a diminution of press., and is smaller in an atm. of carbon monoxide than in an inert gas. Iron pentacarbonyl is more stable, and dissociates more slowly than nickel tetracarbonyl. J. Dewar and H. O. Jones found the b.p. to be 102·7° at 764 mm.; or 102·5° at 760 mm.; the m.p. is between −19·5° and −20°. The critical temp. is 255°–288°; the critical press., 29·6 atm.; and the critical density, 0·49. The vap. press., *p* mm., is:

	−7°	0°	16·1°	18·4°	35·0°	57°	78°
p	14·0	16·0	25·9	28·2	52·0	133 0	311·2

The heat of vaporization is 39·45 cals. per gram.

The vap. density 6·5 corresponds with the value 6·7 calculated for the pentacarbonyl. Analyses also agree with the pentacarbonyl. The formula $Fe(CO)_5$ agrees with the f.p. of a soln. of the carbonyl in benzene. The formation of ferrous salts when the pentacarbonyl is decomposed by non-oxidizing and non-reducing agents agrees with the assumption that the iron is bivalent; and the masking of the optical properties of the iron by the carbonyl groups is in agreement with the ring formula:

$$Fe\begin{matrix}\diagup CO—CO \diagdown \\ \diagdown CO—CO \diagup\end{matrix}CO$$

advocated by L. Mond, J. H. Gladstone, A. J. F. de Silva, etc. J. Dewar and H. O. Jones gave 1·519 for the index of refraction for Na-light at 22°, and 1·528 with Tl-light. L. Mond, and J. H. Gladstone found for the mol. refraction $\mu/D=69\cdot30$; and for the H-line, 68·5. The mol. dispersion between H_γ and $H_\alpha=6\cdot6$. The atomic dispersion of iron in this compound is much greater than that of iron in the salts of that element.

According to J. Dewar and H. O. Jones, iron pentacarbonyl is not altered when confined in a sealed tube in darkness, but it is decomposed in sunlight whether it be alone or in soln., and yellow crystals of the enneacarbonyl appear. When iron pentacarbonyl is exposed to air, L. Mond and C. Langer state that it is slowly decomposed with the formation of a brown precipitate, mainly hydrated ferric oxide. The pentacarbonyl is soluble in many organic liquids such as alcohol, ether, benzene, mineral oils, etc. According to L. Mond and co-workers, and J. Dewar and H. O. Jones, the halogens chlorine, bromine, and iodine react with decreasing velocity, forming the iron halide and carbon monoxide. Chlorine or bromine water acts quickly on the carbonyl. H. Freundlich and E. J. Cuy also noted that iodine and the pentacarbonyl react in sunlight or when warmed in alcoholic soln., forming ferrous iodide. L. Mond, J. Dewar, etc., showed that gaseous hydrogen iodide reacts with the evolution of hydrogen and carbon monoxide; gaseous hydrogen bromide or chloride does not act, but a soln. of these compounds in chloroform acts on the carbonyl. Dil. hydrochloric acid does not act at ordinary temp. Chloroform soln. of the mono- and trichlorides of iodine furnish ferrous chloride and carbon monoxide; and a soln. of cyanogen iodide in chloroform forms ferrous cyanide, and a little ferrous iodide. Cyanogen has no action on iron pentacarbonyl, but in alcoholic soln. there is a slow reaction. These reactions resemble those with nickel carbonyl, but they take place more slowly. Iron carbonyl, however, does not react with sulphur dissolved in xylene or carbon disulphide. Gaseous hydrogen sulphide is without action, but when dissolved in alcohol, it forms ferrous sulphide, hydrogen and carbon monoxide. Dil. sulphuric acid or dil. nitric acid has no action at ordinary temp., but when the acid is dissolved in ether or carbon tetrachloride there is a turbulent evolution of hydrogen and carbon monoxide—*e.g.* $H_2SO_4+Fe(CO)_5=FeSO_4+H_2+5CO$. Conc. nitric acid forms ferric nitrate quite readily. Iron carbonyl has no action on nitric acid dissolved in carbon disulphide or xylene. When heated with benzene and aluminium chloride in a sealed tube at 100°, benzaldehyde and anthracene are formed; no anthracene is produced in the cold. H. Freundlich and E. J. Cuy found a red compound with alcohol can be formed which is soluble in ether, and soon forms a green tetracarbonyl; it is a very strong reducing agent. According to L. Mond and C. Langer, alcoholic soln. of sodium and potassium hydroxides absorb the vap. rapidly, and also dissolve the liquid without the evolution of gas. After a while, a greenish precipitate is formed, which contains chiefly hydrated ferrous oxide, and the soln. becomes brown. On exposing it to the air, it takes up oxygen, and the colour changes to a dark red, whilst hydrated ferric oxide separates out. When an acid is added to an alkaline soln. of the pentacarbonyl, H. Freundlich and E. J. Cuy found that a white milky precipitate is produced which soon decomposes with the evolution of carbon monoxide and dioxide, and hydrogen, and the last-named gas is in the proportion to be expected if the iron in the carbonyl is dissolved as metal, so that in alkaline soln., the iron is present in the same state of oxidation as it is in the pentacarbonyl. According to J. Dewar and H. O. Jones, on mixing alcoholic soln. of ferropentacarbonyl and mercury chloride, a slight evolution of carbon monoxide is observed, and a yellowish, crystalline precipitate is formed containing iron, mercury, chlorine, and carbon monoxide. The analyses, however, did not give figures from which a definite formula could be deduced.

When iron pentacarbonyl in a sealed tube, below 60°, is exposed to sunlight either in the gaseous state or in soln.—in ether, amylene, alcohol, or ligroïn which gives better results as solvents than benzene—golden-yellow, tabular crystals are formed and the press. in the tube becomes very great. The dry crystals have a metallic lustre and resemble flakes of gold. L. Mond and C. Langer regarded this product as iron heptacarbonyl, $Fe_2(CO)_7$, but J. Dewar and H. O. Jones showed that the product is orange-red, and is **iron enneacarbonyl**, $Fe_2(CO)_9$, or $Fe(CO)_5.Fe(CO)_4$. The reaction is symbolized; $2Fe(CO)_5=Fe_2(CO)_9+CO$. The reaction induced by light is slowly reversed in darkness. The graphic formula is:

$$\begin{array}{l}Fe—CO.CO.CO.CO.\\Fe—CO.CO.CO.CO.\end{array}>CO$$

The light from the electric arc induces the change slowly, while the light from an acetylene flame has very little influence. Blue light is most active, and the activity diminishes towards the red end of the spectrum. Variations of press. up to 125 atm. have no appreciable influence on the reaction; and the change is inhibited at 60° to 100°: but at the temp. of liquid air, there is a slow decomposition. R. L. Mond and A. E. Wallis observed no reaction between nitric oxide and iron enneacarbonyl below 60°; at 63°, there is a slight reaction and beads of a red liquid appear. At 100°, the reaction is complex, some liquid pentacarbonyl and some tetracarbonyl are formed, and after a time the whole decomposes with violence. The reaction at 70°–85° is regular, and is represented $2Fe_2(CO)_9+NO=FeNO.3Fe(CO)_5+3CO$. The red liquid, **iron nitrosopentadecacarbonyl**, $Fe_4(CO)_{15}NO$, is decomposed by repeated distillation, forming iron pentacarbonyl, and a brown powder containing iron and nitric oxide. The properties of the red liquid resemble those of the nickel nitrosotricarbonyl. When iron pentacarbonyl is dissolved in nickel carbonyl, the decomposition by light is very slow, and a 10 per cent. soln. does not deposit solid or evolve gas, even after several weeks' exposure to bright sunlight. To account for this, it is suggested that combination takes place, resulting in the formation of **ferronickel enneacarbonyl**, $FeNi(CO)_9$, which is not acted on by light. This view is in harmony with the fact that these soln. are much paler in colour than corresponding soln. of the pentacarbonyl in other solvents. The crystals are dried over sulphuric acid and solid paraffin. The orange-red hexagonal plates are stable in dry air. The sp. gr. is 2·085 at 18°/18°; and when warmed to 100°, the enneacarbonyl decomposes, forming the pentacarbonyl, etc., $2Fe_2(CO)_9=3Fe(CO)_5+Fe+3CO$. The enneacarbonyl is almost insoluble in ether, benzene, or ligroïn; rather more soluble in ethyl alcohol, methylal, or acetone; and still more soluble in pyridine. Alumina adsorbs about 2·5 per cent. of its weight of iron pentacarbonyl; on exposure to light the powder becomes deeply coloured, and carbon monoxide is evolved.

When the crystals of the enneacarbonyl are heated between 50° and 90° in the presence of ether, ligroïn, or toluene, in an atm. of carbon dioxide, the liquid becomes intensely green. J. Dewar and H. O. Jones cooled the green toluene soln. and obtained green prismatic crystals of **iron tetracarbonyl**, $Fe(CO)_4$, the analogue of nickel tetracarbonyl. The crystals have a sp. gr. 1·994 at 18°/18°. From the effect of the tetracarbonyl on the f.p. of benzene soln., the mol. wt. is higher than is represented by the normal formula. Iron tetracarbonyl is stable under ordinary conditions, but at 140°–150°, it dissociates into metallic iron and carbon monoxide. The tetracarbonyl is soluble in toluene, ligroïn, ether, etc. The dark green soln. slowly lose their colour at 100°, rapidly at 140°, and iron is deposited. The soln. in pyridine and alcohol are green at first, but they turn red on standing.

H. Buff and A. W. Hofmann, and I. L. Bell found that carbon monoxide has no action on heated platinum; nor, according to P. Sabatier and J. B. Senderens, has finely divided platinum any action at 450°. L. Mond, C. Langer, and F. Quincke could not prepare a platinum-carbonyl by the method employed for nickel carbonyl. According to E. Harbeck and G. Lunge, the presence of 2·6 per cent. of carbon monoxide is sufficient to prevent the action of platinum black on a mixture of ethylene and hydrogen. Moreover, if platinum black is sat. with carbon monoxide and the excess driven out with hydrogen, its action on a mixture of ethylene and hydrogen is destroyed. Platinum black absorbs about 60 times its vol. of carbon monoxide, and palladium black about 36 times its vol. The compound formed is probably a true chemical compound, since the carbon monoxide is not eliminated by the subsequent action of other gases, such as hydrogen; it is very stable, but suddenly decomposes at 250° into its constituents. Attempts to isolate the compound were not successful since it is not volatile, and cannot be extracted by the ordinary solvents. L. Mond, H. Hirtz, and M. D. Cowap showed that if ruthenium-black is subjected to the action of carbon monoxide, a very small quantity of a yellow-orange deposit is formed in a cooled glass tube, and a comparatively strong mirror is formed in a heated glass tube. The reaction does not start below a press. of about 350–450 atm., and a temp. of 300°. The deposit is insoluble in hydrochloric acid, but soluble in nitric acid or bromine, gas being evolved. It contains ruthenium, and forms a ruthenium mirror when heated. The mirror obtained in the heated glass tube is soluble to a slight extent in hydrochloric acid (soln. contains iron). The insoluble part is not dissolved by aqua regia, and consists of ruthenium. The orange-yellow deposit obtained by heating finely divided ruthenium at 300° in carbon monoxide at 400 atm. press. is extracted by alcohol. The non-volatile product, **ruthenium dicarbonyl**, $Ru(CO)_2$, is insoluble in benzene, and in hydrochloric acid, but is soluble in ethyl alcohol, water, nitric acid, and in bromine with the evolution of gas. R. L. Mond and A. E. Wallis obtained another volatile ruthenium carbonyl which is crystalline and soluble in benzene.

§ 28. The Carbonyl Halides

In 1811, J. L. Gay Lussac and L. J. Thénard,[1] and J. Murray said that chlorine does not unite with carbon monoxide. J. Murray's statement was based on an attempt to refute the elementary nature of chlorine in favour of the hypothesis that chlorine is oxymuriatic acid. He showed that when carbon monoxide and chlorine are exposed to sunlight, and then treated with ammonia, the soln. gives off carbon dioxide when treated with nitric acid. He therefore concluded that the soln. contained ammonium chloride and carbonate, and that the carbonate was formed by the alleged oxymuriatic acid (chlorine) oxidizing the carbon monoxide. In opposition, J. Davy showed that no combination occurs when equal vols. of the dried gases are mixed in the dark, but combination does occur in light, and more particularly in sunlight. The gases contract to half their former vol. during the combination, and the product contains neither hydrochloric acid nor carbon dioxide. It is absolutely necessary that the constituents should be dried, otherwise a mixture of carbon dioxide and hydrogen chloride will be formed "in proportion to the quantity of water present." He named the product *phosgene*—from φῶς, light; and γεννάω, I give rise to—it is now called **carbonyl chloride,** $COCl_2$, or *carbon oxychloride*. T. Wilm and G. Wischin consider a modification of this process to be the best method of preparing the gas. The constituent gases are introduced at about the same rate into a ten-litre gas balloon, and thence into a second smaller balloon. Both balloons are exposed to sunlight. It is best to employ a slight excess of chlorine, and then to get rid of the excess, as recommended by A. Klepl, by passing the product through a tube packed with pieces of antimony; or, as recommended by M. Berthelot, by treating the gas with mercury. The gas thus purified can be liquefied by passing it into a tube surrounded by ice or a freezing mixture. T. Wilm and G. Wischin used this method of preparation; and J. Cathala devised a special apparatus for the synthesis.

M. von Recklinghausen observed that at the moment of illumination the mixture expands slightly; there is then a period of induction. G. Dyson and A. Harden observed that there is a well-marked period of induction with the gases dried by sulphuric acid. The effect of the insolation slowly disappears when the insolated gas is placed in darkness. The period of induction is greatly diminished by admixture with air; but does not appear to be specifically affected by the presence of carbonyl chloride, hydrogen chloride, excess of carbon monoxide, carbon tetrachloride vap., or small amounts of water vap. M. Wildermann showed that after the period of induction, the rate of combination is in accord with the mass law, being proportional to the conc. of the uncombined gases present. G. Dyson and A. Harden stated that the phenomenon with a mixture of carbon monoxide and chlorine has probably the same explanation as in the case of a mixture of hydrogen and chlorine (**2.** 18, 5); and that the light exerts a specific action on the chlorine in the presence of a gas with which it can combine. D. L. Chapman and F. H. Gee found that the period of induction is extended by small quantities of nitric oxide, ozone, and nitrogen chloride. They therefore explained the photochemical action to the use which the chlorine can make of the absorbed light-energy to effect the union of the two gases before that energy is degraded to ineffective heat. The inhibitory gases hasten the process of energy degradation, and in consequence the chlorine becomes less efficient. A. Coehn and H. Tramm found that the speed of the reaction is reduced by drying the gases, but the process invariably proceeds at an appreciable rate. J. Cathala found the presence of air and carbon dioxide also retarded the speed of reaction. K. F. Bonhöffer studied the photosensitive reaction $CO+Cl_2=COCl_2$: and M. Bodenstein, the dynamics of the photochemical reaction.

J. Davy did not succeed in making carbonyl chloride in quantity by passing a mixture of the component gases through a red-hot earthenware tube, but some of the compound is formed under these conditions. M. Bodenstein and G. Dunant showed that the reaction $CO+Cl_2\rightleftharpoons COCl_2$ is reversible, and that above 800° the decomposition of the compound is complete. They found :

	503°	553°	603°	800°
Amount decomposed . .	67	80	91	100 per cent.

The effect of time at 503° is illustrated by Fig. 39. S. Dushman, and J. A. Christiansen discussed the thermal decomposition of carbonyl chloride ; the latter found that the velocity of the reaction $ds/dt=k\sqrt{C_{Cl_2}}(C_{COCl_2}{}^{-x})$, where the constant k at different temp. is represented by $\log k=-11420T^{-2}+15{\cdot}154$. The thermal dissociation of carbonyl chloride was also studied by R. H. Atkinson and co-workers. P. Schützenberger found that carbonyl chloride is formed when the constituent gases are passed over spongy platinum at 300°–400° ; and E. Paterno, when these gases are passed over animal charcoal. E. Paterno made the gas by passing a rapid current of the mixed carbon monoxide and chlorine at ordinary temp. over animal charcoal; there is a rapid production of carbonyl chloride with the evolution of heat. R. H. Atkinson, C. T. Heycock, and W. J. Pope found that for good yields special precautions must be taken in the preparation of the charcoal and that highly activated wood charcoal is even more efficient than bone charcoal, so that the catalytic reaction is effected 50° lower than is the case with a mixture of hydrogen and chlorine. E. Schering also favoured activated charcoal. V. A. Plotnikoff showed that carbonyl chloride is formed when carbon monoxide and chlorine are passed through a tube containing pieces of aluminium chloride at 30°–35° ; or, better, if the gaseous mixture is passed through a sat. soln. of aluminium chloride in chloroform. He also draws attention to the connection of this mode of preparing the gas with E. Baud's complexes of aluminium and carbonyl chlorides.

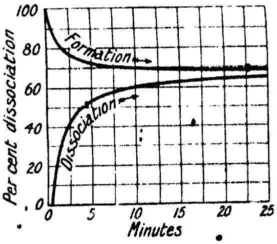

FIG. 39.—Reversibility of the Reaction $CO+Cl_2=COCl_2$ at 503°.

The union of carbon monoxide and chlorine has been discussed by J. Schiel, R. H. Atkinson and co-workers, and by A. S. Lavroff. F. Weigert found that although visible light accelerates both the decomposition and formation of carbonyl chloride, it is incapable of altering the percentage composition of the mixture in thermal equilibrium at temp. between 450° and 510°. Hence he argued that the effect of light is catalytic. A. Cöhn and H. Becker claim that this inference is not necessarily applicable to waves of smaller wave-length in the ultra-violet, because these very refrangible rays can decompose carbonyl chloride confined in quartz tubes. G. Kornfeld studied the radiations from the reacting system—*vide* carbon dioxide.

Carbonyl chloride is prepared by the action of carbon monoxide on chlorinating agents. Thus, F. Göbel made it by passing carbon monoxide over red-hot silver or lead chloride; and A. W. Hofmann, by passing carbon monoxide into boiling antimony pentachloride. Carbonyl chloride is also made by oxidizing carbon tetrachloride. Thus, P. Schützenberger made it by passing a mixture of carbon tetrachloride and carbon monoxide or dioxide over pumice-stone at 350°; and by passing carbon tetrachloride over zinc oxide at 200°. H. Goldschmidt made it by heating carbon tetrachloride with water in a sealed tube at 250°; H. E. Armstrong, V. Grignard and E. Urbain, E. Paterno and A. Mazzucchelli, J. Prud'homme, and P. Schützenberger, by the action of sulphuric anhydride at 100° on carbon tetrachloride. According to E. Paterno and A. Mazzucchelli, the main reaction between fuming sulphuric acid and carbon tetrachloride is represented by the equation: $CCl_4+2SO_3=COCl_2+S_2O_5Cl_2$; but there is a side reaction with the hot fuming acid: $CCl_4+4SO_3=2S_2O_5Cl_2+CO_2$. V. Grignard and E. Urbain represent the reaction with pyrosulphuric acid: $CCl_4+SO_3+H_2SO_4=COCl_2+2HClSO_3$; and with ordinary sulphuric acid, and kieselguhr as catalyst, $2H_2SO_4+3CCl_4=3COCl_2+4HCl+S_2O_5Cl_2$, together with a slight secondary reaction: $S_2O_5Cl_2+CCl_4=COCl_2+2SO_2Cl_2$. The presence of hydrogen chloride may be objectionable. G. Gustavson made carbonyl chloride by the action of phosphoric anhydride at 200°–210° on carbon tetrachloride: $P_2O_5+2CCl_4=CO_2+2POCl_3+COCl_2$. H. Erdmann thus describes the preparation of carbonyl chloride by the sulphuric anhydride process:

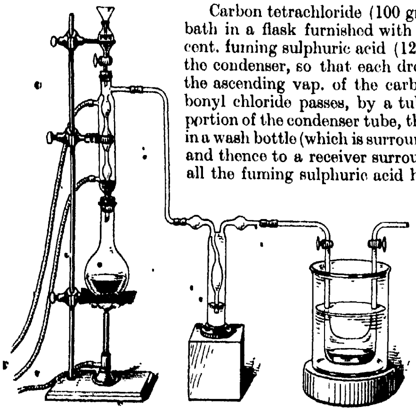

FIG. 40.—H. Erdmann's Process for Preparing Phosgene.

> Carbon tetrachloride (100 grms.) is heated to boiling on a water-bath in a flask furnished with a vertical reflux condenser; 80 per cent. fuming sulphuric acid (120 c.c.) is run in drop by drop down the condenser, so that each drop comes into intimate contact with the ascending vap. of the carbon tetrachloride. The evolved carbonyl chloride passes, by a tube fused at right angles to the upper portion of the condenser tube, through conc. sulphuric acid contained in a wash bottle (which is surrounded by water during the experiment), and thence to a receiver surrounded by a freezing mixture. When all the fuming sulphuric acid has been run in, the globular flask is boiled over a free flame for five minutes. The yield of crude carbonyl chloride is 90 per cent. of the theoretical. It is rectified, the boiling flask being heated by the hand. The accompanying product is a mixture of pyrosulphuryl chloride, $S_2O_5Cl_2$, and chlorosulphonic acid, SO_3HCl.

Carbonyl chloride is formed during the oxidation of chloroform, $CHCl_3$. Thus, M. Adrian found that a little carbonyl chloride and hydrogen chloride is formed when chloroform in the presence of air is exposed to sunlight; the reaction is retarded if ethyl alcohol be present. N. Schoorl and L. M. van den Berg have shown that when chloroform is decomposed by the action of light in the presence of an excess of oxygen, carbon dioxide, water, and chlorine are formed, but that when insufficient oxygen is present, carbon oxychloride and hydrogen chloride are produced in mol. proportions. G. Mossler observed the formation of carbonyl chloride when air and chloroform vap. are passed over a layer of potassium hydroxide. M. Schumburg, and R. Kobert observed the formation of carbonyl chloride when chloroform is burnt in a gas flame; and H. Erdmann, and C. D. Harries, when ozone acts on well-cooled chloroform; A. Emmerling and B. von Lengyel, by oxidizing chloroform with a mixture of sulphuric acid and potassium dichromate, a reaction which they represented by the equation: $2CHCl_3+K_2Cr_2O_7+5H_2SO_4=2COCl_2+2KHSO_4+Cr_2(SO_4)_3+Cl_2+5H_2O$; but H. Erdmann said that free chlorine is not formed, and prefers: $2CHCl_3+CrO_3+O_2=2COCl_2+CrO_2Cl_2+H_2O$. J. Dewar and G. Cranston found that carbonyl chloride is formed when equimolar proportions of chloroform and chlorosulphonic acid are heated to 120°.

J. Schiel noted that carbonyl chloride is formed when a mixture of chlorine and carbon dioxide is passed over red-hot carbon. G. Gustavson observed that some carbonyl chloride is formed when anhydrous sodium carbonate is heated in a sealed tube with phosphorous pentachloride; A. Emmerling and B. von Lengyel, when carbonyl sulphide is treated with chlorine at a red heat, or passed over molten copper chloride, or through boiling antimony pentachloride; and P. Schützenberger, by the action of chlorine monoxide on carbon disulphide. H. Gautier found that chlorine gas does not act on chloral, but in diffused daylight or in direct sunlight a reaction occurs in a few hours which he symbolized: $CCl_3.COH+2Cl_2=CCl_4+COCl_2+HCl$. According to W. Hentschel when trichloromethyl chloroformate, $COCl.OCCl_3$, is heated to 300° it decomposes into twice its vol. of carbonyl chloride, but at a dull red heat it yields carbon dioxide and carbon tetrachloride. H. Staudinger showed that oxalyl chloride decomposes, forming carbonyl chloride and carbon monoxide when distilled through a glass tube heated to 600°, or when boiled with aluminium chloride in carbon disulphide soln. A. Cahours found that bis-trichloromethyloxalate, $CCl_3.O.CO.CO.O.CCl_3$, decomposes at 350°–400° into carbonyl chloride and carbon monoxide. L. Michalski found that some carbonyl chloride is formed when a mixture of carbon, calcium oxide and chloride is heated in the electric furnace: $CaO+CaCl_2+5C=2CaC_2+COCl_2$. S. Peacock made it by passing air and chlorine over heated carbonaceous materials.

Carbonyl chloride, said J. Davy, is a colourless gas with a smell "more suffocating than that of chlorine, and it occasions a very painful sensation in the eyes." It does not fume in air. W. Wahl found that carbonyl chloride crystallizes homogeneously. On cooling, the liquid becomes supercooled, and, as a rule, an unstable modification crystallizes out of the supercooled melt. If cooled rapidly, the growth of this modification may be entirely arrested and the remainder of the melt becomes quite viscous. If the preparation is allowed to become warm after the unstable modification has been formed, a transition into the stable form very soon takes place. When this again is partially melted, it crystallizes readily on cooling. The stable modification possesses a high double-refraction, but isotropic sections also occur. It belongs, therefore, either to the tetragonal or hexagonal system, but it has not been possible to determine to which of the two, as the cleavage is not very distinct. The optical character of the stable modification is positive. The unstable modification possesses an extremely high double-refraction and shows parallel extinction. It is probably orthorhombic. J. Davy gave for the **vapour density** of the gas, 3·6808; T. Thomson, 3·4249; and A. Emmerling and B. von Lengyel, 3·505 at 0° and 760 mm. A. F. O. Germann and V. Jersey gave 4·4708 to 4·5263, A. Emmerling and B. von Lengyel found the gas readily condenses to a colourless liquid of **specific gravity** 1·432 at 0°/4°, or 1·392 at 18·6°/4°; W. H. Perkin gave 1·4204 at 0°/4°, and 1·4115 at 4°/4°; and E. Beckmann and F. Junker, 1·42 at 8·2°—*vide infra*. E. Paterno and A. Mazzucchelli made observations of the sp. gr. between −15·4° and 59·9°; and they represented the sp. gr., S, at $\theta°$, by $S=1·4264-0·002326\theta$. R. H. Atkinson and co-workers gave for the mean coeff. of **cubical expansion** of the liquid between −79° and +49·9°, 0·00177. A. F. O. Germann and V. Jersey found the **vapour pressure** at 0°=552 mm. N. I. Nikitin found the vap. press. of carbonyl chloride to be 889·2 mm. at 12·6°; 540·4 mm. at −0·41°; 232·2 mm. at −19·43°; and at −94·2°, a few tenths of a mm. R. H. Atkinson, C. T. Heycock, and W. J. Pope found for the vap. press. p mm., and density D:

	−110°	−80°	−50°	−20°	0°	+20°	+40°	+50°
p . . .	—	4	47·5	226	568	1212	—	388360
D . . .	1·685	1·617	1·549	1·481	1·435	1·388	1·338	1·314

E. Paterno and A. Mazzucchelli represented their measurements between −23° and 25°, by $\log p=\bar{7}·5995-1326T^{-1}$, where p represents the press. in mm. of mercury, and T denotes the absolute temp. N. I. Nikitin also measured the vap. press. between −99° and 12·6°. The central constants were discussed by S. F. Pickering. L. Hackspill and M. Mathieu gave 183° ± 0·5° for the **critical temperature,** and E. Paterno and A. Mazzucchelli, 187°; the last-named found for the **critical density,** 0·5135; and the **critical pressure,** 51·5 atm. The law of rectilinear diameters applies to this compound, and the equation of the line below 111°, is $1{\cdot}4277-0{\cdot}00214\theta$, and above 111°, $1{\cdot}4380-0{\cdot}0022\theta$. H. Erdmann gave −118° for the **melting point;** R. H. Atkinson and co-workers gave −104°; S. von Wroblewsky and K. Olszewsky, −103·5°; and R. H. Atkinson and co-workers gave −126° to −128°; A. Emmerling and B. von Lengyel, 8·2° at 756·4 mm. for the **boiling point;** E. Beckmann and F. Junker, 8·2° at 756 mm.; and E. Paterno and A. Mazzucchelli, 8·02° at 760 mm. M. Berthelot gave for the **heat of formation** from amorphous carbon, $(C, O, Cl_2)=44{\cdot}1$ Cals., at constant press. J. Thomson gave 55·14 Cals.; and for the heat of formation, (CO, Cl_2), M. Berthelot gave 18·8 Cals.; J. Thomson, 26·14 Cals.; and M. Bodenstein and G. Dunant, 23·0 Cals. E. Beckmann and F. Junker gave 29° for the mol. rise of the b.p. F. Weigert examined the **absorption spectrum.** A. Emmerling and B. von Lengyel gave 3·936 for the **index of refraction;** and W. H. Perkin, 1·0295 for the **specific magnetic rotation,** and 4·003 for the **molecular magnetic rotation** at 2·8°. V. Henri studied the **absorption spectrum** of the vapour.

R. H. Atkinson, C. T. Heycock, and W. J. Pope gave the following data for the solubility of carbonyl chloride expressed in grams per 100 grms. of solvent: *toluene,* at 17·0°, 23·5°, 30·5°, and 31·5°: 244·7, 124·2, 79·38, and 74·48 respectively; *coal-tar xylene,* at 12·3°, 16·4°, 16·9°, 23·8°, and 29·8°: 457·3, 225·6, 217·9, 103·4, and 71·24 respectively; *creosote oil,* at 16·2°: 77·42; *petroleum boiling at* 180°–280°, at 12·3°, 15·8°, 16·7°, 22·4°, 23·7°, 29·9°, and 30°: 263·8, 163·1, 143·4, 79·5, 71·2, 49·2, and 48·6 respectively; *heavy lubricating oil,* at 15·6°, 23·5°, and 31·0°: 79·7, 39·3, and 24·5 respectively; *nitrobenzene,* 106·4 at 16·8°; *a-chloronaphthalene,* 104·5 at 17·0°; *chlorobenzene,* at 12·3°, 16·6°, 16·7°, 24·2°, and 29·7°: 422·1, 204·3, 221·6, 99·9, and 81·9 respectively; *acetylene tetrachloride,* at 16·8°, 25·1°, and 29·9°: 149·7, 89·4, and 74·9 respectively. Toluene, coal-tar, xylene, and chlorobenzene are by far the best solvents of those examined, and in view of their elevated b.p. would appear to offer most advantages as scrubbing agents for effluent gases containing carbonyl chloride. Ordinary burning petroleum boiling at 180° to 280° is the next best solvent, but heavy mineral lubricating oil and acetylene tetrachloride are not quite so good. N. W. Taylor and J. H. Hildebrand made some observations on this subject. C. Baskerville and P. W. Cohen gave the results indicated in Table XIX. M. Berthelot found carbonyl chloride to be very sparingly soluble in cold water; and readily soluble in benzene, toluene, and other hydrocarbons, as well as in glacial acetic acid.

TABLE XIX.—SOLVENTS FOR CARBONYL CHLORIDE.

Solvent.	Wt. of solvent grms.	Wt. $COCl_2$ absorbed grms.	Wt. ratio of $COCl_2$: solvent.	Reaction.
Carbon tetrachloride	79·5	22	1 : 3·6	None
Chloroform	49·4	29	1 : 1·7	Change
Gasoline	37·0	30	1 : 1·2	Change
Paraffin oil	34·6	0	0	None
Russian mineral oil	30·1	10·8	1 : 2·8	None
Benzene	43·9	43·6	1 : 1	None
Toluene	50·3	33·5	1 : 1·5	Change
Glacial acetic acid	31·4	19·5	1 : 1·6	Change
Ethyl acetate	20·5	20·2	1 : 1	None
Chlorocosane	25·2	7·8	1 : 3·2	None

J. Davy said that carbonyl chloride is not decomposed by **hydrogen;** neither hydrogen nor **oxygen** singly produces any effect when the mixture is sparked, but when a mixture of 2 vols. of hydrogen, one of oxygen, and two of carbonyl chloride is sparked, hydrogen chloride and carbon dioxide are formed. B. Humiston found that **fluorine** furnishes some carbonyl fluoride when it reacts with phosgene. Carbonyl chloride dissolves **ozone,** forming a blue liquid. E. Paterno and A. Mazzucchelli found that below 0°, carbonyl chloride dissolves large proportions of **chlorine,** forming at $-15°$, a golden-yellow liquid with 28·3 per cent. of free chlorine. A. F. O. Germann and V. Jersey measured the m.p. curve of soln. of chlorine and carbonyl chloride, and found a eutectic with 25 molar per cent. of chlorine, and angular points with 6, 11, 50, 63, 75, and 91 molar per cent. of chlorine. These are taken to indicate the existence of a series of **chlorocarbonyl chlorides**:—$COCl_2 : Cl_2$ as 16 : 1, 8 : 1, 1 : 1, 3 : 5, 1 : 3, and 1 : 10—which dissociate at the m.p. The second corresponds with octohydrated chlorine. J. A. Besson found that **hydrogen iodide** readily dissolves in liquid carbonyl chloride, but even when cooled with ice and salt, there is a violent reaction with the liberation of iodine. M. Delépine and L. Ville found that carbonyl chloride slowly liberates iodine from an aq. soln. of **potassium iodide.** J. Davy found that carbonyl chloride reddens litmus; and J. Davy, and M. Berthelot found that it is slowly decomposed by cold **water** and rapidly by hot water: $COCl_2+2H_2O=2HCl+H_2CO_3$; and the carbonic acid then decomposes into carbon dioxide and water. Hence carbonyl chloride, $COCl_2$, can be regarded as a chloride of carbonic acid, $CO(OH)_2$. M. Berthelot considered that carbonyl chloride dissolves unaltered to the extent of 2 to 3 vols. in water, and that it reacts with the water only slowly; but V. Grignard and E. Urbain, and E. Paterno and A. Mazzucchelli found that the chloride cannot exist for an appreciable time in contact with water without forming carbonic and hydrochloric acids. In the case of gaseous carbonyl chloride, carbon dioxide forms an inert separating layer at the surface of the liquid; and in the case of liquid carbonyl chloride, the water in immediate contact with the carbonyl chloride is sat. with hydrochloric acid and this retards the reaction. The action is therefore immediately dependent on diffusion. Acids retard the reaction between carbonyl chloride and water. Attempts were made to measure the speed of the reaction. W. D. Bancroft has discussed the reaction $COCl_2+H_2O=CO_2+2HCl$ which is irreversible, and with an excess of water goes to completion, but in hydrochloric acid, the rate of hydrolysis is negligibly small. With **alcohol,** carbonyl chloride yields ethyl chlorocarbonate, $COCl(OC_2H_5)$, and ethyl carbonate, $CO(OC_2H_5)_2$.

E. Beckmann and F. Junker found that at a low temp. liquid carbonyl chloride acts as a solvent. It dissolves iodine; iodine trichloride; arsenic trichloride; antimony tri- and pentachlorides; sulphur chloride; and many organic substances; but it does not dissolve red phosphorus; arsenic; arsenious oxide; boric oxide; antimony; bismuth; stannous chloride; sulphur; selenium and its chlorides; potassium; sodium; calcium; the thiocyanates; sulphides, and sulphates of the alkalies; zinc chloride; ferric chloride and sulphate; chromic chloride, mercuric chloride and iodide; cuprous and cupric chloride; lead chloride and chromate; or silver chloride.

H. V. Regnault found that the aq. soln. with conc. **hydrochloric acid** gives carbon dioxide. According to E. Baud, **aluminium chloride** dissolves in liquid carbonyl chloride, and on evaporation of the soln. at the ordinary temp., there remains a colourless liquid which solidifies at $-2°$ and has the composition $2AlCl_3.5COCl_2$. Its dissociation tension is equal to 760 mm. at 30°. By removal of carbonyl chloride, the compound $2AlCl_3.3COCl_2$ is formed; this has a dissociation tension of 760 mm. at 55°. On further removal of carbonyl chloride, the compound $4AlCl_3,COCl_2$ is obtained in the form of silky needles which do not decompose to an appreciable extent below 750°. The last two compounds are formed when aluminium chloride is distilled in a current of dry carbonyl chloride, and also when the vap. of aluminium chloride is led by means of a current of carbonic oxide through a red-hot tube. These two compounds are present in commercial aluminium chloride. J. A. Besson found that when a soln. of **aluminium bromide** in carbonyl chloride is exposed to light, or heated at 100°–150°, bromine and carbon monoxide are liberated. A. von Bartal found that aluminium chlorobromide is a product of the action of carbonyl chloride and molten aluminium bromide at 100° : $AlBr_3+COCl_2=CO+Br_2+AlCl_2Br$, while the action of an excess of liquid carbonyl chloride furnishes carbonyl chlorobromide, COClBr. He also obtained a complex product of the composition, $Al_3C_2O_2Cl_2I$, by the action of carbonyl chloride on molten **aluminium iodide.** J. A. Besson, and A. von Bartal studied the action of **boron bromide.** The former said that if boron bromide is heated in sealed tubes at 150° for about 10 hrs. with half its weight of carbonyl chloride, almost the whole of the carbonyl chloride is decomposed, and the liquid remains colourless provided the temp. has not materially exceeded 150°. The product yields two fractions, 30°–40° and 60°–70°, the latter or both containing a liquid which is only slowly attacked by water. If these fractions are added slowly to a soln. of sodium thiosulphate cooled to 0°, and the oily liquids that separate are again distilled, they yield respectively carbonyl chlorobromide and carbonyl bromide.

J. Davy sublimed **sulphur** in carbonyl chloride without change. J. A. Besson found that under press. and at 200°, **hydrogen sulphide** furnishes carbonyl sulphide : $COCl_2+H_2S=COS+2HCl$. Some sulphur and carbon dioxides are also formed, and **hydrogen selenide** at 200° gives selenium, hydrogen chloride, and carbon monoxide ; and at 230°, the selenium acts on the excess of carbonyl chloride producing selenium chloride. J. Nuricsan found that carbonyl chloride reacts with **cadmium sulphide** at ordinary temp., or better at 260°–280°, forming carbonyl sulphide. H. V. Regnault found that the aq. soln. with conc. **sulphuric acid** gives carbon dioxide. E. Paterno and A. Mazzucchelli found the reactivity of aq. soln. of sulphuric acid with carbonyl chloride decreases continuously with increasing conc. of the acid, and with fall of temp. According to E. Chauvenet, carbonyl chloride attacks metallic sulphides between 300° and 450° in accordance with the equation $MS+COCl_2=MCl_2+COS$. The ease with which sulphides are thus converted into anhydrous chlorides furnishes a useful method for the treatment of minerals in analysis. The process is also suitable for preparing carbonyl sulphide.

J. Davy noted that carbonyl chloride unites with **ammonia,** " forming a salt perfectly neutral and dry, but deliquescent by attracting moisture from the air. It is remarkable that in the formation of this ammoniacal salt, the gas combines with as much as four times its bulk of ammoniacal gas." The product of the action is carbamide or urea : $COCl_2+4NH_3=CO(NH_2)_2+2NH_4Cl$. There are numerous products of side reactions studied by A. Hantzsch and B. C. Stuer, S. Natanson, H. V. Regnault, and G. Bouchardt. According to L. Gattermann and G. Schmidt, when dry carbonyl chloride is passed into **ammonium chloride** heated to 400°, chloroformamide distils over. A. Hantzsch and B. C. Stuer showed that if the liquid obtained by the action of aq. **hydroxylamine** on carbonyl chloride, be treated with **nitrous acid,** carbon dioxide, nitrous oxide, and water are produced ; but if the operation be conducted in methyl alcohol, there is evidence of the formation of hyponitrous **acid.** H. V. Regnault found that the aq. soln. with conc. **nitric acid** gives carbon dioxide. J. Davy said **phosphorus** can be sublimed unchanged in carbonyl chloride. J. A. Besson found that carbonyl chloride has virtually no action on phosphine ; in the cold, there is a slow reaction with **phosphonium bromide,** but a rapid one at 50°, and in sealed tubes the action is complete in a few hours. The products are hydrogen chloride, hydrogen bromide, hydrogen phosphide, carbon monoxide, and solid yellow hydrogen phosphide ; **phosphonium iodide** reacts slowly with the chloride at 0°, and in sealed tubes between 0° and 10°, the action proceeds somewhat rapidly with production of hydrogen chloride, carbon monoxide, phosphorous iodide, P_2I_4, and red phosphorus, which retains about 10 per cent. of iodine, seemingly in the form of a subiodide. H. M. Bunbury measured the adsorption of carbonyl chloride by birchwood charcoal and observed at the final press. p mm., grams of carbonyl chloride adsorbed by 2·1922 grms. of charcoal:

	18°					100°		
	730	217	147	56	2·7	1596	825	292 mm.
$COCl_2$ . . .	1·385	0·985	0·962	0·715	0·428	0·945	0·693	0·420

The results can be represented by the usual formula $x/m=0·255p^{0·231}$ at 18°, and $x/m=0·038p^{0·488}$ at 100°. The rate of adsorption at 14° in the presence of 0·7434 grm. of carbonyl chloride is:

Time	6	8	10	12	18 min.
Press.	160	115	100	94	91 „

J. Davy found that when **zinc, tin, arsenic, antimony, or potassium** is heated in carbonyl chloride, the chloride of the metal and carbon monoxide are formed. The decomposition is effected in a few minutes, without explosion or ignition; in the case of potassium, some carbon monoxide is decomposed and carbon deposited. O. W Richardson measured the ionization which occurs during the action of carbonyl chloride on potassium-sodium alloys. R. H. Atkinson and co-workers suggest that the action on **mercury** may be symbolized: $2Hg+COCl_2=CO+2HgCl$. M. Delépine and L. Ville showed that if a little free chlorine is present, carbonyl chloride slowly attacks iron, and this is the source of the yellow colour of the commercial liquid. The liquid, free from chlorine, dissolves iron-rust. When **zinc oxide** is similarly treated, zinc chloride and carbon dioxide are formed. According to E. Chauvenet, when the **oxides** of the metals are heated in a slow current of carbonyl chloride at a temp. varying from about 350° in the case of vanadium oxide, to 650° in the case of thoria, the chlorides are formed. Chlorides of the following elements have been prepared in this way: vanadium, tungsten, tantalum, titanium, zirconium, thorium, tin, barium, magnesium, zinc, beryllium, aluminium, iron, chromium, manganese, nickel, uranium, cerium, yttrium, and lanthanum. An excellent yield of the anhydrous higher chloride was obtained in each instance, except with tungstic oxide, when the oxychloride was formed, and in the case of titanium, when a mixture of chloride and oxychloride was produced. The method is specially suitable for preparing the chlorides of the rare-earth metals. **Silica** is not attacked by carbonyl chloride. The reactions were also studied by F. P. Venable and D. H. Jackson. It was used by C. Baskerville for decomposing zircon, and thorianite, and in preparing chlorides from alumina, ceria, zirconia, and thoria. C. Baskerville mentioned that heated silica bricks were bleached in contact with heated phosgene owing to the removal of iron; and sand could be likewise freed from ferruginous pigments. E. W. Washburn and E. E. Libman recommended the reaction for removing iron from zirconia.

J. Barlot and E. Chauvenet also showed that carbonyl chloride will attack numerous natural **phosphates**, such as vivianite, pyromorphite, uranite, and monazite, and natural silicates, such as thorite, gadolinite, cerite, and zircon, yielding in each case the anhydrous metallic chloride. The phosphates are attacked at temp. between 300° and 500°, whilst the **silicates** require temp. above 1000°, emerald not being decomposed at 1400°. This reaction forms a ready method of analysis of such minerals, and also of preparing anhydrous metallic chlorides from these minerals. W. Gintl found that carbonyl chloride reacts with **silver cyanide,** forming silver chloride, and cyanogen chloride. Numerous reactions between carbonyl chloride and **organic compounds** have been studied; and this reagent is employed in the manufacture of organic dye-stuffs, and some pharmaceutical products. D. lo Monaco studied the adsorption by straw, hay, grass, leaves, sawdust, cotton, charcoal, etc. E. Paterno and A. Mazzucchelli found that carbonyl chloride is absorbed with avidity by heavy lubricating oils, and expelled rapidly and almost completely by a current of air. Its physiological action has been described by R. Kobert, and by R. Müller.

J. Schiel[2] found that some **carbonyl bromide**, $COBr_2$, is probably formed when a mixture of the vap. of bromine and carbon monoxide is exposed to sunlight. The rate of combination of the gases was found by A. Piva to depend on the proportion of moisture present, and when special care is taken to dry the bromine and carbon monoxide, the velocity of the change is extremely low. Were complete absence of moisture attainable, it appears probable, but is not certain, that no reaction would occur. The reaction yields carbon dioxide and hydrogen bromide as final products, and takes place in two stages, $CO+Br_2=COBr_2$ and $COBr_2+H_2O=CO_2+2HBr$. In the first stage, equilibrium is reached with a small conc. of the carbonyl bromide which must be removed as it is formed in order that the reaction may continue. K. F. Bonhöffer studied the photosensitiveness of the reaction $COBr_2=CO+Br_2$. A. von Bartal obtained a small quantity of carbonyl bromide by the action of bromine on carbon monoxide in the presence of aluminium bromide, or by the action of the silent discharge. A. Brochet possibly obtained it by the action of bromine on trioxymethylene, $CH_2:(O.CH_2)_2:O$. A. J. Besson found that impure carbonyl bromide is produced by heating at 150° a mixture of boron tribromide or phosphorous tribromide and carbonyl chloride for 10 hrs.—*vide supra.* A. Emmerling, and A. von Bartal prepared it by oxidizing bromoform with potassium chromate and conc. sulphuric acid in a flask with a reflux condenser. The liquid bromide was rectified by slow distillation over antimony. The latter considers that the best method of preparation is to allow sulphuric acid of sp. gr. 1·84 to drop slowly into carbon tetrabromide at 160°–170°. The red distillate is then shaken with mercury, distilled, shaken with powdered antimony, and again distilled. The yield is 50–60 per cent.

At ordinary temp., according to A. von Bartal, carbonyl bromide is a heavy, mobile, colourless liquid, which fumes in air, and smells like carbonyl chloride. A. J. Besson gave 6·60 for the vap. density; and 2·48 for the sp. gr. of the liquid at 0°; A. von Bartal gave 2·45 for the sp. gr. at 15°. A. Emmerling gave the b.p. between 12° and 30°; A. J. Besson, 63°–66°; and A. von Bartal, 64°–65° with slight decomposition. The last-named also said that the compound is decomposed by light or heat. It is decomposed by water, but rather more slowly than is the case with carbonyl chloride. It is very sensitive towards oxidizing agents. The vap. attacks caoutchouc very quickly. It also reacts readily with many organic compounds, and has been used in the preparation of dye-stuffs.

As indicated above, A. J. Besson made **carbonyl chlorobromide**, COBrCl, by the action of boron bromide on carbonyl chloride; and A. von Bartal made it by heating equal weights of carbonyl chloride and aluminium bromide in a sealed tube at 140°–145°. The colourless or slightly yellowish liquid has a smell like that of carbonyl chloride. A. J. Besson gave 4·85 for the vap. density; and 1·98 for the sp. gr. at 0°. A. von Bartal gave 1·82 for the sp. gr. at 15°, and 25° for the b.p., whereas A. J. Besson gave 35°–37° for the b.p. According to A. von Bartal, the chlorobromide attracts moisture from the air, and the liquid thereby becomes turbid; it is coloured yellow by exposure to sunlight. *Carbonyl iodide*, COI_2, has not been prepared. As previously indicated, H. Moissan found that fluorine does not react in the cold with carbon monoxide; and S. B. Cowardins showed that iodine and carbon monoxide do not react when heated or when exposed to sunlight; nor does carbon monoxide react with lead iodide or arsenic pentaiodide. When carbonyl chloride is gradually added to cooled arsenic trifluoride, W. Steinkopf and J. Herold found that **carbonyl fluoride**, COF_2, was formed. It solidified in liquid air, and boiled at −150° to −160°. B. Humiston also prepared some carbonyl fluoride by the action of fluorine on carbonyl chloride.

§ 29. Carbonyl Sulphide

In 1841, J. P. Couerbe[1] studied the products obtained when the xanthates are subjected to dry distillation, and he reported that a gas which he called *xanthin*, $COSH_2$, was given off. A. Fleischer and W. Hanke found that the alkali xanthates furnish the mercaptan, the two ethyl sulphides, carbon disulphide, and carbonyl sulphide, when the anhydrous salts are used; and mercaptan, the two ethyl sulphides, carbon disulphide, carbon dioxide, and hydrogen sulphide when the hydrated salts are employed. They therefore suggest that the xanthin gas obtained by J. P. Couerbe was really carbonyl sulphide contaminated with hydrogen sulphide and mercaptan vapour. J. P. Couerbe did not isolate the pure gas. Up to the time of C. Than's discovery, 1867, carbonyl sulphide was regarded as a mixture of carbon dioxide and hydrogen sulphide. In that year, C. Than showed that when a mixture of sulphur vap. and carbon monoxide is passed through a moderately heated tube, a compound is formed corresponding with *carbon oxysulphide*, or **carbonyl sulphide**, COS. C. Than showed that carbonyl sulphide probably occurs in some hepatic waters; and A. W. Hofmann, H. Kolbe, and F. Salomon showed that this compound is also present in volcanic gases, and in the sulphuretted waters of volcanic districts. It is possibly formed by the reaction $8CO_2+9H_2S=3COS+5CO+H_2+8H_2O+6S$, a reaction which can be imitated by passing a mixture of carbon dioxide and hydrogen sulphide through a red-hot tube. Carbonyl sulphide also occurs in the products of the decomposition of some organic substances.

G. Chevrier said that when a mixture of sulphur vapour and carbon monoxide is sparked, carbonyl sulphide is formed, but F. González and E. Moles obtained none at 110°–260° under atm. press. or under reduced press. They explain that the statement is based on the result obtained when moisture is present. C. Than, P. Klason, C. Bender, and L. Ilosvay de N. Ilosva, made carbonyl sulphide by the action of potassium thiocyanate on dil. sulphuric acid. The thiocyanate is first resolved into thiocyanic acid, and the acid is then hydrolyzed to carbonyl sulphide and ammonia: $HCNS+H_2O=COS+NH_3$; the ammonia then unites with the excess of acid present: $KCNS+H_2O+2H_2SO_4=COS+KHSO_4+(NH_4)HSO_4$. P. Klason recommended the following procedure:

> Fifty c.c. of a conc. aq. soln. of potassium or ammonium thiocyanate are added to a cold mixture of 290 c.c. or 520 grms. of conc. sulphuric acid, and 400 c.c. of water. The gas contaminated with about 2·5 per cent. of carbon dioxide and 0·05 per cent. of carbon disulphide is given off at 25°. A. W. Hofmann recommended passing the gas through an ethereal soln. of triethylphosphine to free it from carbon bisulphide. P. Klason found that the absorption of this latter is much more rapid and complete if a small quantity of pure triethylphosphine is used instead of a soln., the gas being then passed through pure sulphuric acid to free it from traces of the phosphine. Carbon oxysulphide is only absorbed very slowly by a 33 per cent. aq. soln. of potash. If the gas obtained as above is passed slowly through about 20 cms. of such a soln., the whole of the carbonic anhydride is absorbed with a loss of only about 7 per cent. of the oxysulphide.

Carbonyl sulphide was made by F. G. Reichel by passing carbon monoxide over heated magnesium sulphate; A. Cossa, G. Chevrier, and M. Berthelot, by the action of carbon dioxide on boiling sulphur: $2CO_2+3S=2COS+SO_2$; A. Gautier, by passing a mixture of hydrogen sulphide and carbon dioxide through a red-hot tube; A. J. Besson, by heating carbonyl chloride and hydrogen sulphide at 200° under press.; J. Nuricsan, and F. Weigert, by passing carbonyl chloride over cadmium sulphate at ordinary temp. or better, at 260°–280°; and A. Gautier, by passing hydrogen sulphide and carbon monoxide over china clay contained in a porcelain tube at a bright red heat. The issuing gas contains 60–64 per cent. of carbonyl sulphide, 35–39 per cent. of carbon monoxide, about one per cent. of carbon dioxide, traces of hydrogen sulphide, and the excess of carbon disulphide. The proportion of carbon monoxide is lower, and the proportion of carbonyl sulphide higher, the higher the temp. The products are passed into a flask half filled with ice-cold water, which condenses the greater part of the disulphide; then through potassium hydroxide, which absorbs hydrogen sulphide and carbon dioxide; then through acidified cuprous chloride, which absorbs carbon monoxide, and finally through a 12-per-cent. soln. of aniline in alcohol. and over pumice and sulphuric acid. Alcoholic aniline has no action on carbonyl sulphide, but readily absorbs carbon disulphide. The tube contains crystals of silicon sulphide, etc. Alumina can be used in place of china clay, but it becomes finely divided and difficult to manage; zinc oxide also furnishes carbonyl sulphide, but copper, iron, and lead oxides do not. C. Böttinger used a mixture of ultramarine and carbon in place of china clay.

F. G. Reichel made carbonyl sulphide by passing a mixture of carbon dioxide and disulphide over heated magnesia. J. Dewar and G. Cranston found carbonyl sulphide is formed by heating carbon disulphide and chlorosulphonic acid in a sealed tube at 100°; H. E. Armstrong, by heating sulphur trioxide and carbon disulphide in a sealed tube at 100°: $3SO_3+CS_2=COS+4SO_2$; or chromic anhydride and carbon disulphide at 180°; T. Carnelley, by passing a mixture of alcohol vap. and carbon disulphide over red-hot copper when ethylene and acetylene are formed along with the carbonyl sulphide; C. Winkler, by passing a mixture of carbon dioxide and disulphide over red-hot platinized asbestos; A. Ladenburg, by heating in a sealed tube, carbon disulphide and carbamide at 110°, or with oxamide at 200°, or with acetamide at 210°; A. R. Hantzsch, by heating a mixture of triethylphosphine and carbon disulphide, $(C_2H_5)_3P.CS_2$, with acetic, propionic, or butyric acid; A. Ladenburg, by heating thioacetic acid to 300°, and by passing carbon disulphide over ethyl isocyanate; A. W. Hofmann, by shaking allyl thiocyanate with conc. sulphuric acid; and F. Salomon, by treating Bender's salt, $C_2H_5O.CO.SK$, with hydrochloric acid, $SK.CO.OC_2H_5+HCl=COS+KCl+C_2H_5OH$. L. Ilosvay de N. Ilosva used potassium ethyl thiocarbonate and sulphuric acid. N. D. Costeanu found carbonyl sulphide is formed when dry carbon dioxide acts on the alkali sulphides at 220°. According to A. Stock and E. Kuss, carbonyl sulphide in a highly purified condition can be most conveniently made by the decomposition of ammonium thiocarbonate, $NH_4.CO.SNH_2$, by means of an acid: $NH_4.CO.SNH_2+2HCl=COS+2NH_4Cl$. There is a simultaneous hydrolysis of a little carbonyl sulphide into carbon dioxide and hydrogen sulphide: $COS+H_2O\rightleftharpoons CO_2+H_2S$, but these impurities can be removed by alkali which does not appreciably affect the carbonyl sulphide. The gas is free from carbon disulphide which contaminates the gas prepared from a thiocyanate and acid.

A short-necked, 750 c.c. flask with 500 c.c. of a 10 per cent. soln. of hydrochloric acid is fitted with a wide tube *A*, Fig. 41, 12 mm. bore, connected by a rubber connector with a small flask *B* containing 20 grms. of ammonium thiocarbonate. A stream of dry hydrogen is led through the apparatus by the inlet tube *C*, and exit tube *D*. The tube *D* is connected with an ordinary wash bottle with 50 c.c. and two 10 bulb tubes with 40 c.c. of a 33 per cent. soln. of soda-lye. If the lye is more dilute, more gas is decomposed. Following on in the train after the soda-lye is a calcium chloride tube, a U-tube packed with glass wool and phosphorus pentoxide, and finally a U-tube dipping in liquid air for condensing the carbonyl sulphide. The flask *B* is turned so that the salt enters the apparatus at the rate of about a gram per minute, and the gas comes off rapidly, uniformly, and without any particular rise of temperature. The stream of hydrogen prevents any marked decomposition of the moist gas by the soda-lye, and also keeps the tube *A* clear. The liquid carbonyl sulphide is then fractionally distilled in vacuo. The first fraction at −66° contains so small a quantity of carbon dioxide that if all were distributed in the resulting gas, the impurity would be only 0·03 per cent. by volume. Hydrogen sulphide was not present. All the subsequent fractions have the tension of pure carbonyl sulphide. The yield is 62·5 per cent. of the theoretical.

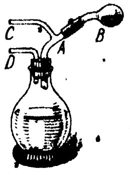

FIG. 41.—Preparation of Carbonyl Sulphide.

L. Ilosvay de N. Ilosva emphasized that the physical and chemical properties of carbonyl sulphide come midway between those of carbon dioxide and carbon disulphide. P. Klason said that the purified gas is colourless and has no smell. W. Wahl found that carbonyl sulphide crystallizes in extremely fine needles, which grow with great rapidity. The double-refraction of these needles is very high, and they always extinguish the polarized light when parallel to the principal sections of the nicols. The needles are thus either tetragonal, hexagonal, or orthorhombic, but it has not been possible to find any experimental evidence from which conclusions might be drawn as to which of these crystal systems carbonyl sulphide belongs. No polymorphic change has been observed above −200°. C. Than said that the vap. density is 2·1046 (air unity). L. Ilosvay de N. Ilosva found the mean coeff. of expansion of the gas between 0° and 100° to be 0·0037317 at constant vol., and 0·0037908 at constant press. The gas condenses to a colourless, mobile, highly refractive liquid, which, according to A. Stock and E. Kuss, has a sp. gr. of 1·24 at −87°. C. J. Smith found the viscosity of the vap. in C.G.S. units to be 0·0001135 at 0°, 0·0001200 at 15°, and 0·0001554 at 100°; the viscosity constant in W. Sutherland's formula, 330; and the mean collision area of the mols. of the vap. is $1·06\times10^{-15}$ sq. cm.; A. O. Rankine estimates this to be $1·06\times10^{-15}$ sq. cm. with a possible error of 2 to 3 per cent. The press., p atm., necessary to liquefy the gas at different temp. is:

	0°	3·8°	10·7°	12·0°	17·0°	39·8°	41·2°	63·0°	69·0°	74·6°	85·3°
p . .	12·5	15·0	17·5	19·6	21·5	44·0	45·0	59·0	65·0	74·0	80·0

A. Stock and E. Kuss represent the vap. press. of the liquid:

	−133°	−111°	−98·5°	−86°	−75°	−54°	−50·2°
Vap. press. . .	1	12	37	100	210	635	760 mm.

According to W. Hempel, the critical temp. is 105°, and the critical press., 60 atm.; the b.p. of the liquid is −47·5° at atm. press.; A. Stock and E. Kuss say −50·2° at 760 mm. Carbon dioxide boils at −78°, and carbon disulphide at 46°. According to L. Ilosvay de N. Ilosva, the liquid solidifies when poured from one vessel to another; A. Stock and E. Kuss gave −138·2° for the m.p. Carbon dioxide melts at −56·4°; carbon disulphide at −112·1°. The higher m.p. of carbon dioxide is thought to be an effect of polymerization. M. Berthelot found the heat of combustion to be 131·01 Cals. at constant press., and the heat of formation from amorphous carbon and rhombic sulphur: (C,S,O)=19·6 Cals.; J. Thomsen's value is about twice as great: (C,S,O)=37·32 Cals., (CO,S)=8·03 Cals.; and G. N. Lewis and W. N. Lacey found for the free energy of formation of $(S_{\text{liquid}},CO)=-6070$ cals. at 302°. V. Henri studied the absorption spectrum of the vapour.

W. Hempel found that 100 c.c. of water at 13·5° dissolve 80 c.c. of carbonyl sulphide; A. Stock and E. Kuss, that 54 c.c. are dissolved at 20°; and L. W. Winkler, found the absorption coeff., β, and the weight, w, of gas dissolved by 100 grms. of solvent at 760 mm. press. to be:

	0°	5°	10°	15°	20°	25°	30°
β	1·333	1·056	0·836	0·677	0·561	0·468	0·403
w	0·356	0·281	0·221	0·179	0·147	0·122	0·104

A. W. Hofmann said that 100 vols. of triethylphosphine dissolve about 100 vols. of the gas, and, unlike carbon disulphide, does not form a compound. W. Hempel found 100 c.c. of a hydrochloric acid soln. of cuprous chloride dissolved 20 c.c. of carbonyl sulphide at 13·5°; 100 c.c. of an alcoholic soln. (2 c.c. water and 2 c.c. alcohol) of potassium hydroxide (1 grm.) dissolve 7200 c.c. of the gas (13·5 c.c.); 100 c.c. of pyridine dissolve 4·4 c.c. of gas (13·5°); and 100 c.c. of nitrobenzene dissolve 12·0 c.c. of gas (13·5°). M. Berthelot noted the ready solubility of the gas in absolute alcohol. A. Stock and E. Kuss found that 100 c.c. of alcohol dissolve 800 c.c. of gas (22°) and 100 c.c. of toluene, 1500 c.c. of gas (22°). It is slowly and regularly absorbed by 33 per cent. sodium hydroxide (about 2 per cent. per minute), much more readily by an 8 per cent. soln. (33 per cent. per minute), or by a 23 per cent. soln. of potassium hydroxide (8 per cent. per minute). It is therefore quite possible to estimate readily absorbable gases in the carbonyl sulphide by using 33 per cent. sodium hydroxide, and allowing for the loss of the latter gas during the time of the absorption. Liquid carbonyl sulphide was found by L. Ilosvay de N. Ilosva to dissolve sulphur, and to mix readily with alcohol or ether, but not with water or glycerol. For the absorption coeff. in various salt soln., *vide* Table XX.

R. Witzeck, and A. Stock and E. Kuss found the dry gas is permanent even in sunlight, but if moisture be present, the gas forms carbon dioxide and hydrogen sulphide. The decomposition is very slow in diffuse daylight. C. Than found that at a red heat, carbonyl sulphide decomposes into sulphur and carbon monoxide, and R. Witzeck said that it is slowly decomposed when heated in a sealed tube at 200°–300°. According to W. Hempel, a platinum wire heated to whiteness by an electric current decomposes the gas completely without change of vol., forming sulphur and carbon monoxide. G. N. Lewis and W. N. Lacey studied the equilibrium conditions of the reaction $CO+S=COS$, and found $K=[COS]/[CO]=201$ at 302°; and 435 at 260°. A. Stock and P. Seelig showed that two equilibria are probably involved, (i) $COS\rightleftharpoons CO+S$, and (ii) $2COS\rightleftharpoons CO_2+CS_2$; the second may be due to $2CO+S_2\rightleftharpoons CO_2+CS_2$. There was no evidence of the formation of carbon monosulphide mentioned by G. N. Lewis and W. N. Lacey, or of sulphur dioxide mentioned by P. Winternitz. The reaction $2COS\rightleftharpoons CO_2+CS_2$ in either direction is rather slow, and $2COS\rightleftharpoons 2CO+S_2$, rather fast. The dissociation of carbonyl sulphide was independent of the amounts of carbon dioxide or disulphide present, thus showing that carbon monoxide and sulphur are formed directly from carbonyl sulphide and not primarily from carbon dioxide or disulphide. At 800°, 64 per cent. of carbonyl sulphide was dissociated, and at 950°, 76 per cent. A. Stock, W. Siecke, and E. Pohland found that near 400°, the equilibrium in reaction (i) is disturbed by the separation of sulphur. When this reaction is suppressed by the addition of carbon monoxide, reaction (ii) can be studied below 500°. The decomposition (i) is not evident below 400°, and attains a maximum of 64 per cent. at 900°. Reaction (ii) reaches a maximum of 43 per cent. at 600°, and 16 per cent. by (i). The equilibrium (i) depends on the press., while (ii) does not. Quartz is a marked catalyst for (ii), but has little influence on (i). Hence, carbonyl sulphide at room temp. can be kept for years in glass vessels, but is rapidly decomposed in quartz vessels.

C. Than showed that the gas is very inflammable, taking fire even when brought in contact with a red-hot splinter of wood, and burning with a blue, slightly luminous flame. A mixture of one vol. of the gas with 1½ vols. of oxygen inflames with a slight explosion, burning with a blue flame; but, said W. Hempel, if the gas be mixed with 7½ vols. of air, the mixture burns without explosion. E. J. Russell found that a thoroughly dried mixture of carbonyl sulphide and oxygen does not explode with the passage of an electric spark. C. Than showed that carbonyl sulphide is slowly decomposed by water: $COS+H_2O=CO_2+H_2S$. The pure gas, said A. Stock and E. Kuss, does not at once give a precipitate with a soln. of barium hydroxide or of cupric sulphate. P. Klason said that with baryta-water, a turbidity occurs in half a minute. P. Klason found that an aq. soln. of starch iodide is soon decolorized, and a soln. of lead acetate rendered turbid. M. Berthelot found that cuprous sulphate separates very slowly from a soln. of carbonyl sulphide in a hydrochloric acid soln. of cuprous chloride. In the reacting system, $COS+H_2O\rightleftharpoons CO_2+H_2S$, when the water is in large excess, if C denotes the conc. of the carbonyl sulphide, the rate of decomposition will be $-dC/dt=k'C$. G. Buchböck's results show that the velocity constant k' is very nearly 0·0005267; and this shows that the reverse action is negligible, and that the products of the reaction have no influence on the velocity. He suggests that the decomposition is the resultant of two reactions: $COS+H_2O\rightleftharpoons HS.CO.OH$, and $HS.CO.OH\rightarrow H_2S+CO_2$, in which the quantity of thiocarbonic acid, $HS.COOH$, is always proportional to the carbonyl sulphide. The effect of temp. is represented by $\log k=-11736{\cdot}73T^{-1}+45{\cdot}66354$. R. Witzeck found that the decomposition is very rapid at a high temp., and he measured the effect of various acids and salts in isohydric soln., and found that if S denotes the absorption coeff. of the carbonyl sulphide, $-dC=kC/S$, where $k=k'S$. The results are indicated in Table XX, and they agree well with theory only when referred to particular groups of salts. In general, the rate of decomposition decreases with the addition of acids, and the decrease is greater the more ionized the acid; and increases with the conc. Monochloroacetic acid caused a slight increase in the velocity of decomposition, and the effect of many of the metal salts also is to cause slight increase. P. Klason found that carbonyl sulphide can be preserved for a time over 50 per cent.

TABLE XX.—EFFECT OF ACIDS AND SALTS ON THE DECOMPOSITION OF CARBONYL SULPHIDE

Added substance.	Isohydric soln. contains grm. eq. per litre.	$k \times 10^6$.	Absorption coeff. S.	Velocity in sat. soln. $k \times S \times 10^6$.

sulphuric acid, and, unlike hydrogen sulphide, it is not decomposed by a sulphuric acid soln. of cupric sulphate. G. Buchböck found that the presence of carbamide and of glycerol accelerated the speed of decomposition. G. Buchböck claimed that the velocity of decomposition is almost inversely proportional to the viscosity, η, of the solvent, or $dC=kC/S\eta$. P. Klason found that soln. of alkalies and alkaline earths decompose carbonyl sulphide more rapidly than does water; as previously indicated by P. Klason, and M. Berthelot, carbonyl sulphide is absorbed but slowly by a 33 per cent. soln. of sodium hydroxide; but R. Witzeck found the contrary. The reaction probably occurs in two stages, say: $COS+2KOH=KS.CO.OK+H_2O$; and $KS.CO.OK+KOH=KSH+KO.CO.OK$. Conc. alkali-lye absorbs the gas more slowly than more dil. soln., and potash-lye more quickly than soda-lye. P. Klason found the gas to be completely and rapidly absorbed by a 33 per cent. aq. soln. of potassium hydroxide mixed with its own vol. of alcohol; with an alcoholic soln. of potassium hydroxide, C. Bender obtained potassium ethyl thiocarbonate, $C_2H_5O.CS.OH$. C. Than found that chlorine, and fuming nitric acid, at ordinary temp. have no action on carbonyl sulphide; but at a red heat, A. Emmerling and B. von Lengyel found carbon monoxide, sulphur chloride, and carbonyl chloride are formed: $COS+2Cl_2=COCl_2+SCl_2$. The last-named also found that with boiling or cold antimony pentachloride, carbonyl chloride is formed. C. Than said that mixtures of nitric oxide and carbonyl sulphide are not explosive. According to M. Berthelot, gaseous ammonia, and, according to P. Kretzschmar, an alcoholic soln. of ammonia rapidly absorb carbonyl sulphide, forming ammonium thiocarbamate. When the soln. in aq. ammonia is evaporated, E. Schmidt, and M. Berthelot obtained carbamide and thiocarbamide. The action of carbonyl sulphide on a number of organic products has been studied by B. Holmberg, F. Weigert, M. Freund and E. Asbrand, etc. Heated mercury, copper, iron, and silver were found by M. Berthelot to remove sulphur from carbonyl sulphide; and cuprous chloride reacts: $COS+2CuCl+H_2O\rightleftharpoons CO_2+2HCl+Cu_2S$. P. Klason, and W. Hempel found carbonyl sulphide to be a narcotic poison. The analytical determination of carbonyl sulphide has been discussed by P. Klason, W. Hempel, E. J. Russell, and other workers.
